SMALL ANIMAL CRITICAL CARE MEDICINEISBN:978-1-4160-2591-7

Notice

> Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Authors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

ISBN: 978-1-4160-2591-7

Front Matter

Dedication

“One looks back with appreciation to the brilliant teachers, but with gratitude to those who touched our human feeling. Curriculum is necessary raw material, but warmth is the vital element for the growing plant and for the soul of the child.”

–Carl Jung

With special thanks to: –My husband, Stefan, and sons, Maxwell and Henry, for their infinite warmth, love, and support,–My grandma Leona, mom (Judy), dad (Paul and wife Amalia), brothers (Steve and Bruce), and sister (Andrea) for always believing in me,–Dr. Lesley King for her guidance,–And my extended family and friends who helped me smile despite it all!

–Deborah Silverstein

To my parents Max and Joyce, my sister Jane, and my brother Bill for their endless love and support, and to my friends who have made it all worthwhile.

–Kate Hopper

Contributors

Jonathan A. Abbott, DVM, DACVIM

Associate Professor, Department of Small Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University, Blacksburg, Virginia

Feline Cardiomyopathy

Sophie Adamantos, BVSc, CertVA, DACVECC, MRCVS

Staff Clinician, Emergency and Critical Care Medicine, Queen Mother Hospital for Animals, Royal Veterinary College, Hatfield, Herfordshire, United Kingdom

Pulmonary Edema

Janet Aldrich, DVM, DACVECC

Staff Veterinarian, Veterinary Medical Teaching Hospital, School of Veterinary Medicine, University of California, Davis, Davis, California

Atelectasis, Phosphate Disorders, Shock Fluids and Fluid Challenge

Amy J. Alwood, DVM, DACVECC

Allegheny Veterinary Emergency Trauma & Specialty, Monroeville, Pennsylvania

Acetaminophen, Salicylates

Lillian R. Aronson, VMD, DACVS

Assistant Professor, Surgery, Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Urosepsis, Kidney Transplantation

Rodney S. Bagley, DVM, DACVIM (Neurology)

Professor, Neurology and Neurosurgery, Department of Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, Washington

Postcraniotomy Management

Linda Barton, DVM, DACVECC

Head, Emergency/Critical Care ServiceVCA Veterinary Specialty Center of Seattle, Lynnwood, Washington

Respiratory Failure, Daily Assessment of the Critically Ill Patient

Shane W. Bateman, DVM, DVSc, DACVECC

Clinical Associate Professor, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio

Hypercoagulable States

Matthew W. Beal, DVM, DACVECC

Assistant Professor, Emergency and Critical Care Medicine, Chief, Section of Medicine, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Peritoneal Drainage Techniques

Allyson C. Berent, DVM, DACVIM

Lecturer, Small Animal Internal Medicine, Fellow, Interventional Radiology and Interventional Endoscopy, Waltham Lecturer in Minimally Invasive Diagnostics and Therapeutics, Department of Small Animal Internal Medicine–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Acute Biliary Diseases of the Dog and Cat, Hepatic Failure

Philip J. Bergman, DVM, MS, PhD, DACVIM (Oncology)

Chief Medical Officer, BrightHeart Veterinary Centers, Greenwich, Connecticut

Adjunct Faculty Member, Memorial Sloan-Kettering Cancer Center, New York, New York

Tumor Lysis Syndrome

Amanda K. Boag, MA, VetMB, DACVIM, DACVECC, MRCVS

Department of Veterinary Clinical Science, Royal Veterinary College, North Mymms, Hertfordshire, United Kingdom

Aspiration Pneumonitis and Pneumonia Pulmonary Contusions and Hemorrhage

Elise Mittleman Boller, DVM, DACVECC

Staff Veterinarian Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary HospitalSchool of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania,

Sepsis, Septic Shock

Manuel Boller, Dr.Med.Vet., DACVECC

Lecturer, Emergency and Critical Care, Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania Philadelphia, Pennsylvania*Sedatives, Muscle Relaxants, and Opioids Toxicity*

Pyrethrins, Anticonvulsants

Betsy R. Bond, DVM, DACVIM (Cardiology)

Staff Cardiologist Department of Medicine, The Animal Medical CenterNew York, New York

Nitroglycerin, β-Blockers

Dawn M. Boothe, DVM, PhD, DACVIM, DACVCP

Professor, Physiology and Pharmacology, Director, Clinical Pharmacology Laboratory, Department of Anatomy, Physiology, and Pharmacology, College of Veterinary Medicine, Auburn University, Auburn, Alabama

Antimicrobial Use in the Critical Care Patient

Søren R. Boysen, DVM, DACVECC

Assistant Professor, Emergency and Critical Care, Faculty of Veterinary Medicine, University of Montreal, St-Hyacinthe, Québec, Canada

Gastrointestinal Hemorrhage

Benjamin M. Brainard, VMD, DACVA, DACVECC

Instructor, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, The University of Georgia, Athens, Georgia

Pulmonary Artery Catheterization, Pheochromocytoma

Andrew J. Brown, MA, VetMB, MRCVS, DACVECC

Assistant Professor, Emergency and Critical Care Medicine, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Cardiogenic Shock, Illicit Drugs, Rodenticides Hemodynamic Monitoring

Scott Brown, VMD, PhD, DACVIM

Josiah Meigs Distinguished Professor and Head, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, University of Georgia, Athens, Georgia

Hypertensive Crisis

Dennis E. Burkett, VMD, PhD, DACVECC, DACVIM (Cardiology)

Staff Cardiologist, Veterinary Referral Center + Emergency Service, Malvern, Pennsylvania

Left Ventricular Failure, Bradyarrhythmias and Conduction Abnormalities

Jamie M. Burkitt, DVM, DACVECC

Assistant Professor, Clinical Small Animal Emergency and Critical Care, Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California, Davis, Davis, California

Sodium Disorders, Relative Adrenal Insufficiency, Hypoadrenocorticism Anticholinesterase Intoxication

Daniel L. Chan, DVM, DACVECC, DACVN, MRCVS

Lecturer, Emergency and Critical Care, Department of Veterinary Clinical Sciences, The Royal Veterinary College, University of London, North Mymms, Hertfordshire, United Kingdom

Acute Lung Injury and Acute Respiratory Distress Syndrome, Anticoagulants

Peter S. Chapman, BVetMed, DECVIM-CA, MRCVS

Assistant Professor, Medicine, Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Vomiting and Regurgitation

C.B. Chastain, DVM, MS, DACVIM

Professor, Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri–Columbia, Columbia, Missouri

Syndrome of Inappropriate Antidiuretic Hormone

Dennis J. Chew, DVM, DACVIM

Professor, Department of Veterinary Clinical Sciences, The Ohio State University, Columbus, Ohio

Calcium Disorders

Monica C. Clare, VMD, DACVECC

Department of Emergency and Critical Care, Animal Surgical & Emergency Center, Los Angeles, California

Care of the Ventilator Patient

Leah A. Cohn, DVM, PhD, DACVIM

Associate Professor, Small Animal Medicine, Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri–Columbia, Columbia, Missouri

Acute Hemolytic Disorders

Steven G. Cole, DVM, DACVECC, DACVIM (Cardiology)

Staff Cardiologist, Veterinary Referral Center + Emergency Service, Malvern, Pennsylvania

Cardiopulmonary Resuscitation, Cardioversion and Defibrillation

Merilee F. Costello, DVM, DACVECC

Allegheny Veterinary Emergency Trauma & Specialty, Monroeville, Pennsylvania

Upper Airway Disease, Endocarditis

Etienne Côté, DVM, DACVIM (Cardiology)

Assistant Professor and Staff Cardiologist, Department of Companion Animals, Atlantic Veterinary College and Veterinary Teaching Hospital, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Pneumonia

M. Bronwyn Crane, DVM, DACT

Theriogenology Resident, College of Veterinary Medicine, Oregon State University, Corvallis, Oregon

Pyometra

Dennis T. (Tim) Crowe, DVM, DACVS, DACVECC, FCCM

President, Veterinary Surgery, Emergency and Critical Care Services and Consulting, Chief of Staff Pet Emergency Clinic, Inc. Thousand Oaks and Ventura, California, Bogart, Georgia

Patient Triage

William T.N. Culp, VMD

Department of Clinical Studies (Small Animal Surgery)–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Abdominal Trauma

Meredith L. Daly, VMD, DACVECC

Resident, Emergency and Critical Care, Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Digoxin Overdose, Fluoroquinolones

Harold Davis, BA, RVT, VTS (Emergency/Critical Care and Anesthesia)

Manager, Emergency & Critical Care Service, Veterinary Medical Teaching Hospital, School of Veterinary Medicine, University of California, Davis, Davis, California

Peripheral Venous Catheterization, Central Venous Catheterization

Teresa DeFrancesco, DVM, DACVIM (Cardiology), DACVECC

Associate Professor of Cardiology and Critical Care, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

Temporary Transvenous Pacing, Transcutaneous Pacing

Armelle M. de Laforcade, DVM, DACVECC

Assistant Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University, North Grafton, Massachusetts

Shock, Systemic Inflammatory Response Syndrome

Suzanne Donahue, VMD, DACVECC

Veterinary Referral Center + Emergency Service, Malvern, Pennsylvania

Chest Wall Disease

Kristi L. Dosher, DVM

Emergency Veterinary Hospital of Springfield, Springfield, Oregon

Mastitis

Patricia M. Dowling, DVM, MS, DACVIM, DACVCP

Professor, Department of Veterinary Biomedical Sciences, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Motility Disorders, Anaphylaxis

Sharon Drellich, DVM, DACVECC

Internship Director, Emergency and Critical Care Medicine, Angell Memorial Animal Hospital, Boston, Massachusetts

Thrombocytopenia, Intraabdominal Pressure

Kenneth J. Drobatz, DVM, MSCE, DACVIM, DACVECC

Professor and Section Chief, Section of Critical Care, Director, Emergency Service, Department of Clinical Studies–Philadelphia, The Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Cyanide Serotonin Syndrome Acute Abdominal Pain, Heat Stroke

N. Joel Edwards, DVM, DACVIM (Cardiology)

Upstate Veterinary Specialties, Latham, New York

Preface

Veterinary practitioners are often faced with the need to care for critically ill and traumatized patients on a moment's notice. After-hours emergency and critical care facilities are in increasing demand as pet owners are ever-more likely and willing to take their pets to such facilities when life-threatening conditions arise. As a consequence of this demand and client expectations, veterinarians are increasingly aware that they must provide state-of-the-art critical care therapy and monitoring for their patients and that their preparedness for such situations is imperative.

WHY IS THIS BOOK IMPORTANT?

Veterinary critical care medicine is still a relatively new but rapidly emerging specialty that is focused on providing life-sustaining therapy and support systems for desperately ill and traumatized patients who would not survive without them. Critical care medicine encompasses not only the period immediately following hospital presentation but the entire course of acute medical crisis and high risk. It incorporates advanced technology, intensive patient monitoring, and cutting-edge medical concepts. It requires a strong fundamental knowledge of all body systems and a basic understanding of the pathophysiology of disease states—an amount of information that is often daunting and difficult to master.

As anyone teaching or practicing in the field of veterinary critical care knows, there is a deficit of comprehensive texts that provide a practical and action-oriented review of all relevant topics in critical care. Although there are several available texts labeled as “emergency and critical care” resources, they are all heavily weighted toward emergency medicine and fail to adequately address many topics vital to the management of critical care patients. This textbook is the first of its kind devoted to the practice and challenges of critical care medicine as a specialty in its own right. We intend for it to be an essential, state-of-the-art resource for anyone working with critical patients in general practice clinics, specialty veterinary practices, and university teaching hospitals. It emphasizes interventional therapy in the critically ill or traumatized patient, while addressing important considerations regarding underlying clinical findings, pathophysiology, clinical course and prognosis. The scope of topics is broad and clinically oriented, helping the practitioner provide the highest standard of care for their critically ill and injured patients.

ORGANIZATION

This book is the compilation of work from many veterinary specialists, all of whom have written on critical care topics in their areas of expertise. It brings many facets of critical care together into a single text source, with topics ranging from the most frequently encountered problems in the intensive care unit to a detailed pharmacology section and advanced critical care procedural and monitoring techniques. The remarkable team of over 150 international experts who have contributed to this text offers in-depth, authoritative guidance on clinical problems from a multitude of perspectives. They provide the most up-to-date information on common problems facing the practitioner and the more challenging aspects of critical care medicine. The focus has been on creating the best organized and most rapidly accessible reference tool for the entire critical care team under some of the most demanding and emotional clinical circumstances.

With 20 major sections and 217 *chapters and appendixes, Small Animal Critical Care Medicine* provides an in-depth resource for the diagnostic, therapeutic, procedural, and management issues pertinent to the critically ill patient. Its user-friendly design makes it an approachable resource while its in-depth content provides essential and often difficult to find information. The book is composed of short, concise chapters and is organized into logical sections, beginning with assessment and triage and covering management approaches for frequently encountered problems seen in patients presenting with critical care issues. The largest part of the book contains sections grouped by organ system, covering common and uncommon diseases, syndromes, and disturbances of homeostasis seen in small animal critical patients. Acute derangements of the respiratory, circulatory, nervous, gastrointestinal, endocrine, renal, and reproductive systems, as well as metabolic and hematologic disorders, are covered. Other sections cover traumatic injuries, perioperative complications, intoxications, inflammatory and infectious diseases, and other miscellaneous disorders not readily classified by organ system or discipline. Special sections featuring clinical procedures, monitoring, anesthesia and pain management, and critical care pharmacology are also included.

DISTINCTIVE FEATURES

This book provides key, in-depth information that covers all aspects of veterinary critical care medicine. It is not only organized with an easy-to-use format for referencing all aspects of critical care medicine, but also contains numerous figures, color plates, and tables for rapidly visualizing the concepts and information presented within the chapters. Chapters provide concise information regarding etiology, differential diagnoses, clinical manifestations, laboratory findings, diagnostic methods, and therapeutic approaches. The key points boxes at the beginning of each chapter enable the reader to rapidly see an overview of the topic, and extensive cross referencing within the chapters allows for further reading of specific topics mentioned within. For further reference or an in-depth review of specific aspects of a particular topic, annotated suggested readings are included at the end of each chapter. Readers wishing more details on pathophysiologic mechanisms or pharmacokinetics and clinical studies are referred to a more extensive list of references in the Companion CD. The inside cover and the appendixes at the end of the text provide valuable information regarding frequently used conversions, key calculations, diagnostic test reference ranges, and one of the most comprehensive lists of constant rate infusion drug doses available.

Critical care medicine poses a unique set of challenges and rewards, and we hope that this book will fill the gap that exists between basic medical and surgical references and the available emergency-oriented manuals. We also hope that this book will enable veterinarians, who have committed themselves to the knowledgeable and skillful care of their patients, to better deliver on that solemn promise and enhance both quality of life for pets and the ongoing relationship with those who love them.

Acknowledgments

The editors are most appreciative to all of the Elsevier staff, especially Tony Winkel, Maureen Slaten, and Beth Hayes. Without the support and dedication of this talented group of individuals, this text would not have been possible.

1 Chapter 1 Physical Examination

Timothy B. Hackett, DVM, MS, DACVECC

1.1 KEY POINTS

- Hands-on assessment of critically ill patients is essential to detect life-threatening changes in their condition.
- Clinicians should use their eyes, ears, hands, and nose to evaluate the critically ill patient before jumping to blood tests, electrodiagnostic techniques, or imaging.
- Physiologic variables related to oxygen delivery take precedence in evaluating the critically ill patient.
- Clinicians and other personnel should note and record both subjective and objective physical examination parameters as often as necessary, taking into consideration the patient's current problems and anticipated complications.

1.2 INTRODUCTION

Physical examination, or more correctly, serial physical examination, is the core of critical care medicine. Sometimes it seems that all intensivists do is monitor, record, and interpret readily available physiologic variables. Although this may be true, it is important to remember why. The goal is to detect problems with organ function before organ dysfunction becomes organ failure.

Technology helps to identify life-threatening problems. Arterial blood gas machines, oscillometric blood pressure monitors, pulse oximeters, ultrasound machines, and portable coagulation analyzers are just a few of the technologic advances that have found their way into 24-hour emergency and critical care veterinary practices. Their appropriate use has improved our ability to provide the best care to our patients. However, with reliance on technology, clinicians may have forgotten some of the “art” of the physical examination. To date there is no readily available technology that can measure adequacy of perfusion or degree of hydration. Although measurement of parameters such as blood pressure provides vital information, it can be interpreted only in light of the physical examination. When a clinician reaches for an ultrasonography probe or electrocardiograph (ECG) before touching the patient with hands and stethoscope, something has been lost.

The physical examination of the critically ill patient is approached much in the same way as for the emergency patient. With focus on the efficacy of oxygen delivery, the first priority is assessing the respiratory and cardiac systems. The ABCs (airway, breathing, and circulation) of resuscitation provide a simple systematic approach to the primary survey.

1.3 AIRWAY AND BREATHING

Patients adapt respirations to minimize the work of breathing. Animals with upper airway obstruction, dynamic airway collapse, bronchitis, or other obstructions to airflow will breathe slowly and deeply. With upper airway and extrathoracic obstructions, the effort will be on inspiration. With obstruction or collapse of the intrathoracic small airways, the effort will be on expiration. By decreasing the force of respiration, this so-called *obstructive breathing pattern* will favor maximal flow through narrowed airways with minimal energy expenditure. The effect of respiratory rate and depth on obstructive breathing can be experienced by trying to breathe through a straw.

Animals with pleural space disease, atelectasis, or pulmonary fibrosis will adopt what is known as a *restrictive breathing pattern*. By minimizing the change in volume while increasing the respiratory rate, they can maintain alveolar minute ventilation despite decreased pulmonary compliance (see Chapter 9, Tachypnea and Hypoxemia).

1.4 CIRCULATION

Alveolar oxygenation is the first essential step in providing adequate oxygen delivery to the tissues. A normal cardiovascular system is then necessary to carry the blood to the lungs for oxygen loading and back to the body. Physical assessment of the circulatory system relies on palpation and observation of venous distention, palpation of the arterial pulse (for synchrony, quality, and heart rate), evaluation of mucous membrane color and capillary refill, and auscultation of the heart and lungs. Inadequate global perfusion is considered an indicator of circulatory shock and is a clinical diagnosis made from physical examination alone.

1.4.1 Heart Rate

A normal heart rate indicates that at least one component of cardiac output is normal. We expect a heart rate of 70 to 120 beats/min in small dogs, 60 to 120 beats/min in large dogs, and 120 to 200 beats/min in cats.

Bradycardia results in decreased cardiac output and subsequent poor perfusion; cats often develop bradycardia (<120 beats/min) in shock, and this can be associated with imminent cardiac arrest. Bradycardia is an unusual finding in a critically ill patient and can result from electrolyte imbalances (hyperkalemia), neurologic disease (increased intracranial pressure), conduction disturbances (atrioventricular block, sick sinus syndrome), or overdose of analgesic or anesthetic drugs. An ECG is indicated for full assessment of bradycardia.

Tachycardia (dogs >180 beats/min, cats >220 beats/min) is the body's response to decreased blood volume, pain,
anxiety, and hypoxemia. Increasing heart rate will temporarily increase cardiac output and oxygen delivery. 2
However, there is some limitation to this response. When the heart rate becomes too fast, diastolic filling is 3
compromised and stroke volume suffers. Sinus tachycardia often results from circulatory shock or pain;
tachycardia that is irregular or associated with pulse deficits usually indicates an arrhythmia, and an ECG is
indicated.

1.4.2 Mucous Membrane Color

Evaluation of mucous membrane color is subjective but can give an experienced clinician a great deal of important information. Pale or white mucous membranes are indicative of anemia or vasoconstrictive shock. Red mucous membranes suggest vasodilation as seen in systemic inflammatory states and hyperthermia. Cyanotic gums indicate a normal packed cell volume (cyanosis will not be clinically evident without adequate hemoglobin) but severe hypoxemia. A yellow hue indicates increased serum bilirubin (from hepatic disease or hemolysis), and a brown color of the gums can be seen with methemoglobinemia. During examination of the gums, petechiation or bleeding should be noted. Thrombocytopenia is an early finding in disseminated intravascular coagulation. Petechiae and bruising are clinical signs of platelet deficiency or dysfunction.

1.4.3 Capillary Refill Time

Evaluation of capillary refill time (CRT) is also subject to interpretation. You may even notice a normal CRT in a recently deceased patient. However, used in conjunction with pulse quality, respiratory effort, heart rate, and gum color, the CRT can help assess a patient's blood volume and peripheral perfusion, and give an insight into causes of a patient's shock. Normal CRT is 1 to 2 seconds. This is consistent with a normal blood volume and perfusion. A CRT longer than 2 seconds is a subjective sign of poor perfusion or peripheral vasoconstriction. Peripheral vasoconstriction is an appropriate response to low circulating blood volume and reduced oxygen delivery to vital tissues. Patients with hypovolemic and cardiogenic shock should be expected to have peripheral vasoconstriction. Peripheral vasoconstriction is also commonly associated with cool extremities, assessed by feeling the distal limbs. A CRT less than 1 second is indicative of a hyperdynamic state and vasodilation (as are bright red mucous membranes). Hyperdynamic states can be associated with systemic inflammation, heat stroke, distributive shock, and hyperthermia.

Venous distention can be a sign of volume overload or right-sided congestive heart failure. Palpation of the jugular vein may demonstrate distention, although it may be easier to appreciate by clipping a small patch of hair over the lateral saphenous vein. With the patient in lateral recumbency, if the lateral saphenous vein in the upper limb appears distended (as if the vessel is being held off), slowly raise the rear leg above the level of the heart. If the vein remains distended, the patient likely has an elevated central venous pressure, and volume overload or diseases causing right-sided congestive heart failure (dilated cardiomyopathy, tricuspid insufficiency, pericardial effusion) should be considered. A patient with pale mucous membranes from vasoconstriction in response to hypovolemia would not be expected to have venous distention. In comparison, cardiogenic shock is more likely to cause pale mucous membranes and increased venous distention.

1.4.4 Pulse Quality

The pulse should be palpated while listening to the heart or palpating the apex. A strong pulse that is synchronous with each heartbeat is normal and consistent with adequate blood volume and cardiac output. Digital palpation of pulse quality as assessed by digital palpation is largely a reflection of pulse pressure. Pulse pressure equals the difference between the systolic and diastolic arterial blood pressures. Hence a normal pulse pressure may be present despite abnormal systolic and diastolic pressures. For this reason digital palpation of pulse quality is a very poor indicator of arterial blood pressure. Both the femoral and dorsal pedal pulses should be palpated. It is said that a palpable dorsal pedal arterial pulse indicates a systolic blood pressure of at least 80 mm Hg, although experienced clinicians will find they are able to feel these pulses in hypotensive patients. An irregular pulse or one that is asynchronous with cardiac auscultation is a sign of a significant cardiac arrhythmia. An ECG can confirm the arrhythmia and help determine the best treatment.

Bounding pulses indicate either a hyperdynamic state (as discussed with rapid CRTs) or some form of diastolic run-off (such as a patent ductus arteriosus or aortic insufficiency). Close attention to cardiac auscultation for holosystolic or diastolic murmurs can help refine the list of possible causes. Remember, a pulse indicates only the difference in systolic and diastolic arterial blood pressure and does not give accurate information on systemic mean arterial blood pressure.

Weak pulses are a common finding in the critically ill and can be due to decreased cardiac output (either low stroke volume or decreased contractility), peripheral vasoconstriction, or decreased pulse pressure. The response to intravenous fluid therapy will help distinguish among the causes of shock.

1.5 AUSCULTATION

Cardiac and pulmonary auscultation is an essential part of the physical examination. Clinicians and critical care nurses should perform serial auscultation throughout a patient's hospital stay. Nursing staff and clinicians should auscultate the heart and pulmonary sounds at least twice during a shift, once at the beginning and once before they leave. Subtle changes in respiratory noise can signal early problems with fluid overload or aspiration pneumonia.

The respiratory system should be evaluated from the nasal sinuses, the larynx and trachea, down to all the lung fields. Stertor and wheezes in the upper airways and quiet crackles in the lungs may be an early sign of fluid overload. Inspiratory stridor can be heard with laryngeal paralysis, and expiratory wheezes indicate small airway collapse and bronchitis. Crackles across the lung fields can be heard with pneumonia or pulmonary edema. Aspiration pneumonia often affects the cranioventral lungs, and pulmonary edema may begin in the perihilar fields near the base of the heart. Decreased lung sounds may be heard with consolidation of the lungs, pneumothorax, and pleural effusion. With pleural effusion, a fluid line may be detected by ausculting the standing patient's chest. Changes in lung sounds may be an indication for thoracic radiography. Critically ill patients should have their oxygenating ability assessed frequently with pulse oximetry or arterial blood gas measurement, or both. Any change in respiratory character or sounds should prompt immediate reevaluation of oxygenation status. 3

4

Cardiac auscultation should be repeated at least once daily. As mentioned with pulse quality, the pulse should be palpated while listening to the heart. New murmurs or asynchronous pulses should be noted and investigated. Cardiac arrhythmias in the critically ill are an early sign of cardiac dysfunction. As with failure of any organ system, these abnormalities should be investigated and underlying metabolic or oxygen delivery problems corrected.

1.6 LEVEL OF CONSCIOUSNESS

The patient's level of consciousness and response to surroundings should be assessed frequently. If the patient appears normal, alert, and responsive we can be happy with overall neurologic and metabolic status. Patients that are obtunded (“depressed” indicates a feeling and is not applicable to our patients) or less responsive to visual and tactile stimuli may be suffering from a variety of complications and illnesses. Stupor (can be aroused only with painful stimuli) is a sign of severe neurologic or metabolic derangements. Coma (cannot be aroused with any stimuli) and seizures are signs of abnormal cerebral electrical activity from primary neurologic disease or secondary to metabolic derangements such as hepatic encephalopathy. One of the most concerning issues in the critically ill patient is any decrease in the gag reflex. This may be a result of a general decrease in the level of consciousness or primary neurologic deficit. A decrease in the gag reflex places the animal at high risk of aspiration, a potentially fatal complication. Oral intake should be withheld in animals with a compromised gag reflex, and if the gag reflex is absent, immediate endotracheal intubation to protect the airway is indicated.

1.7 TEMPERATURE

Body temperature should be monitored frequently, if not continuously, in the critically ill patient. Hyperthermia should be differentiated from true fever. Hospitalized animals may develop hyperthermia from cage heat or heating pads. True fever should be investigated quickly, because systemic inflammation and infectious complications are common problems in the critically ill.

Many critically ill animals have difficulty maintaining their body temperature and require external heat supplementation. Heat may be supplied by placing warm water-filled gloves or bottles in towels next to the animal. Heating pads should be used with caution; use a low temperature setting and insulate the animal with a blanket or fleece pad. Heat lamps should be used from a distance of more than 30 inches to prevent burns. Circulating hot water blankets can be used to increase body temperature. Circulating hot air systems (Bair Hugger) are another excellent source for active rewarming. Electric cage dryers or hand-held blow dryers are useful if the animal is already wet. A warming waterbed can be made by placing a thick plastic bag over an appropriate-size container filled with warm water. A towel is placed under the animal to prevent its nails from perforating the plastic and burning the patient, and blankets are placed on top of the animal to prevent heat from escaping. Intravenous fluids warmed to body temperature usually help increase body temperature. To prevent overwarming, body temperature should be monitored at regular intervals and warming measures discontinued when the body temperature reaches 100° F. Animals should be monitored carefully to prevent iatrogenic hyperthermia and burns.

1.8 HYDRATION

Although many issues related to assessing blood volume and the adequate circulation have been addressed, it is important to gauge fluid balance of critically ill patients. Hydration status is a measure of interstitial fluid content; in comparison, perfusion parameters (mucous membrane color, CRT, heart rate) are a measure of intravascular volume. It is important to assess both of these parameters separately and alter the fluid plan accordingly. Daily body weight is the most objective way to monitor hydration. Day-to-day changes in body weight reflect fluid balance. A dehydrated patient should gain weight as fluid spaces are rehydrated, and overhydration will be associated with progressive increases in weight. Hydration is assessed clinically by evaluation of skin turgor (skin elasticity). With dehydration skin turgor decreases and skin tenting becomes prolonged. With overhydration skin turgor increases and the subcutaneous tissues gain a “jelly-like” consistency. A serous nasal discharge, peripheral edema, and chemosis are also signs of overhydration. Peripheral edema can occur with overhydration; it can also indicate vasculitis or decreased oncotic pressure (hypoproteinemia). Skin turgor in cachectic and obese animals can be very difficult to assess.

Clinicians should also be wary of third space fluid accumulation. Third-space fluid loss is fluid collection within tissues or a body cavity that does not contribute to circulation. Pleural and abdominal effusions could lead to increases in body weight or maintenance of body weight while the patient becomes clinically hypovolemic. Daily (more often when appropriate) calculation of fluid balance is essential in critically ill animals. This requires accurate measurement of all fluid intake and output including food and water intake, urine, vomit, and feces. Significant discrepancies in the volume of intake versus output require complete reevaluation of the patient and alteration of the fluid plan accordingly.

1.9 GASTROINTESTINAL SYSTEM

The gastrointestinal (GI) tract may be difficult to evaluate but not impossible. It must be remembered that GI problems are seen often with circulatory shock and critical illness. The frequency, character, and volume of GI losses should be monitored. If fresh or digested blood is observed, GI protectants and antibiotics may be indicated. A rectal examination and close inspection of rectal thermometers are good ways to evaluate stool quality. Vomiting should be distinguished from regurgitation, and any retching or vomiting dog should be monitored for gastric dilatation-volvulus.

1.10 NURSING CARE

Recumbent patients require attentive nursing care to prevent complications. Pressure points over bony protuberances should be massaged regularly and padded heavily to prevent decubitus ulcers. The best treatment for decubitus ulcers is prevention. Once formed, they should be debrided and kept as clean, dry, and pressure-free as possible. These 4
ulcers may be a significant source of infectionand may warrant antimicrobial therapy. Patients should be turned 5
frequently (every 2 to 4 hours) to help prevent lung consolidation and pneumonia. The cage should be set up so that urine and diarrhea drain away from the animal. Urine and fecal scald can cause significant problems and should be prevented. Water-based ointment may be applied to the skin around clean genital and perineal areas for protection from scald. Bladder size should be monitored frequently, especially in animals with spinal disease, and the bladder

expressed regularly if necessary. Animals should be observed for fecal impaction, and enemas or manual evacuation performed as necessary.

Patients should be kept clean, dry, warm, and as comfortable and pain free as possible. Bandages, dressings, and drains should be monitored closely for local swelling or other complications and changed when soiled. Eye ointment should be applied regularly to prevent corneal ulcers in patients that fail to blink adequately. Appropriate pain control should always be provided. Any large breed painful, anxious dog that is in pain should be monitored for gastric dilatation-volvulus. Nutritional needs should be aggressively addressed. Postoperative patients should receive at least 30 kcal/kg q24h. Frequent, hands-on contact with the patient is invaluable in high-quality clinical assessment and monitoring. Owner visits often improve the attitude of the patient and provide insights on their behavior. Compassionate care cannot be overemphasized as one of the important factors for recovery.

2 Chapter 2 Patient Triage*

D. Tim Crowe, DVM, DACVS, DACVECC, FCCM, NREMT-I, PI, CFF

2.1 KEY POINTS

- Triage means *to sort* and describes the process of prioritizing patient care when there is more than one patient requiring attention.
- In critical care medicine, patients requiring triage will include those arriving at the hospital on an emergency basis, hospitalized patients being transferred to the intensive care unit (ICU) from other areas of the hospital, and current ICU patients that deteriorate suddenly.
- Care of the seriously injured or critically ill patient requires a state of around-the-clock readiness of the facility, supplies, equipment, and staff.
- A “ready area” prepared with appropriate supplies and equipment that can be accessed readily is essential to stabilization of the critical patient.
- Triage is achieved by a primary survey based on the ABC approach, followed by a secondary survey.

* The author would like to dedicate this chapter in memory of Dr. John Anderson who died May 16, 2006. John and I taught some of the very first K-9 Emergency Care for Police Officers, and he continued teaching these throughout the country. Triage was one of John's favorite areas to teach.

2.2 INTRODUCTION

Care of the seriously injured or critically ill patient requires a state of around-the-clock readiness of the appropriate facility, supplies, equipment, and staff. Triage means *to sort* and describes the process of prioritizing patient care when there is more than one patient requiring attention. In critical care medicine patients requiring triage will include those arriving at the hospital on an emergency basis, hospitalized patients being transferred to the ICU from other areas of the hospital, and current ICU patients that deteriorate suddenly. Priority of need is based on the level of urgency required to ameliorate the global, tissue, and cellular consequences of their conditions. Optimal management 6 involves horizontal resuscitative care, a collective effort done by several individuals working together. This is in contrast to vertical resuscitative care, during which diagnostic and therapeutic tasks are completed in a step-by-step fashion. The latter is an effective way to deliver care but is slower and more burdensome to the practitioner.[1]

2.3 READINESS

There is good evidence that critically and multiply injured patients benefit from preplanned preparedness of facility and staff and a team approach with preplanned objectives (Box 2-1).[2,3] The ideal number of staff to have on a veterinary triage-resuscitation team has not been fully investigated. However, in the author's experience three to four is considered the minimum and is supported by research in human trauma centers[4]; these would include a veterinarian and at least two technical support staff. In the case of emergency patient assessment and stabilization, it is important that emergency team members be familiar with both their own roles and those of their colleagues.[2]

Resuscitation and stabilization of critical patients require rapid reestablishment of adequate oxygen delivery to the tissues. Research has shown that if cellular hypoxia of the gastrointestinal tract in dogs that are in hemorrhagic shock continues beyond *1 hour,* death from organ dysfunction and sepsis from gastrointestinal bacterial translocation and endotoxin absorption across the gut wall may occur a day to several days later.[5] Speed of resuscitation is also pivotal in saving the life of a pet with multiple injuries.[4] Therefore shock and tissue hypoxia must be reversed rapidly in the critically ill patient. To accomplish this, preplanning is imperative.

A "ready area" that is set up for immediate resuscitation is required.[1] The area should have excellent lighting and be organized in an "open system," where most items that may be needed are in the open and can be accessed readily. Suggested items for the "ready area" are listed in Box 2-1. It is highly recommended that the bag-valve and reservoir and the masks (small and large) be assembled for immediate use. A crash cart that is fully stocked and prepared for cardiopulmonary arrest should also be kept in the "ready area." Around-the-clock radiographic and ultrasonographic capabilities, laboratory capabilities, and continuous ICU care are required for most critically ill or injured patients. Laboratory assessment is mandatory and may include arterial and venous blood gas analysis, clinical chemistry levels (especially glucose), red and white blood cell counts, and urinalysis. Assessment of coagulation, serial hematocrits, and total plasma solids must be possible and readily available.

2.4 INITIAL ASSESSMENT AND CARE ON ARRIVAL

Appropriate treatment of the seriously ill or injured patient can be instituted only if the patient continues to be evaluated appropriately. A primary survey is performed initially; this is followed by a secondary survey once the patient is considered relatively stable. Pain control is also achieved early and effectively. Analgesic and sedative drugs with significant hemodynamic effects (such are acepromazine and medetomidine) should not be used in the critical patient. In addition, nonsteroidal antiinflammatory agents should be avoided until hemodynamic stability, 6
7 gastrointestinal function, and renal function have been evaluated. Opioids and benzodiazepines are the most frequently used sedative and analgesic drugs for the critically ill or injured patient. See Chapter 164, Analgesia and Constant Rate Infusions, for further discussion of analgesia of the critical patient.

2.4.1 Box 2-1 Guideline of Items Required for the Resuscitation (Ready) Area

2.4.1.1 General

Surgical gurney: a stretcher that has height adjustments with wheels that can be locked

Small, medium, and large plastic (preferred) backboards

Surgical grade lighting (dual beam and 50,000 lumens)

2.4.1.2 CPR

Crash cart with ready-to-use clear endotracheal tubes, laryngoscope, and assorted blades

Drugs for resuscitation (e.g., epinephrine, calcium, atropine, lidocaine, dopamine)

2.4.1.3 Oxygen Administration

Oxygen source (with a regulator or flow meter attached to an E cylinder and caddy, or anesthesia machine with Y connector or in-line wall-mounted oxygen)

Resuscitators (Ambu bag or breathing circuit that allows manual ventilation): infant, pediatric, and adult sizes, all with reservoirs

Small, medium, and large preassembled Crowe oxygen collars

Infant, pediatric, and adult nasal cannulas

Large and small cone masks

Positive end-expiratory pressure valves that can be attached to resuscitation device

Mechanical ventilator set up and ready to be connected

2.4.1.4 Fluid Resuscitation

Blood draw and IV catheter placement cart

Infusion pumps and syringe pumps

Fluid and towel warmer

Lactated Ringer's solution, normal saline, Plasmalyte, or Normosol R

Whole blood and plasma and synthetic substitutes (Oxyglobin, hetastarch, dextran)

2.4.1.5 Miscellaneous

Doppler blood flow detector and blood pressure cuffs

Suction units (two ideally) with reservoirs, with one connected to a sterile suction trap

Duct tape to immobilize patients

Warming device (blanket, water-circulating heating pad, warm air flowing device)

Clippers and clipper blades

Pleur-evac (for pleural space continuous evacuation)

Portable ultrasonography unit

2.4.1.6 Wound Management

Sterile towels to pack wounds and wrap patients that have multiple wounds

Wet saline dressings and surgical scrub for all preparations

Other dressing materials and bubble wrap and newspaper for splints

2.4.1.7 Emergency Surgical Procedures

Chest-crack surgical pack; infant, medium, and adult Balfour retractors

Tracheostomy tray

Vascular cutdown tray

Chest tube tray

Peritoneal lavage tray with several lavage catheters

Wound (laceration) tray

2.4.2 Primary Survey

The primary survey of a critical patient should follow the ABC approach.[1]

2.4.2.1 A = Airway

The primary survey begins with assessment of the patient's airway. This includes early, aggressive, nonconfining oxygen supplementation. This may be achieved by directing an oxygen source at the animal's nose or mouth (flow-by oxygen), via a face mask or with a clear plastic hood.[6] If respiratory function is compromised or absent, bag-valve-mask ventilation should be instituted immediately while preparations are made to intubate. Preoxygenation of patients with the bag-valve-mask before attempting intubation may reduce the incidence of cardiopulmonary arrest. Orotracheal intubation (with or without anesthesia) is indicated if the airway is obstructed or if the patient has an absent gag reflex. If an orotracheal tube cannot be placed because of obstruction, emergency tracheotomy or cricothyroidotomy is indicated.

2.4.2.2 B = Breathing

Once a patent airway is established, the animal's breathing efforts are observed. If there are none visible or only weak breathing efforts evident, the animal should be intubated (if this has not already been done) and manual positive pressure ventilation initiated immediately. If the animal is completely unconscious the head of the animal should not be elevated and intubation should be attempted with the animal in lateral or dorsal recumbency. Following intubation manual positive-pressure ventilation is initiated immediately.

If the animal is breathing spontaneously, the adequacy of oxygenation and ventilation is best assessed by careful visualization and auscultation. In some cases such emergency measures as an emergency tracheotomy and pleural space decompression must be completed rapidly. If the animal is breathing spontaneously, the adequacy of oxygenation should be ascertained by pulse oximetry and arterial blood gas measurement. These assessments generally are performed as part of the secondary survey.

2.4.2.3 C = Circulation

Major visible hemorrhage is stopped by applying pressure manually and with compression dressings. Occasionally direct exposure and temporary vascular occlusion must be done to stop severe hemorrhage that does not respond to manual pressure and dressings. In these cases, subsequent ligation or repair of the bleeding vessels will be required.

Tissue perfusion is assessed by observing the level of consciousness, pulse strength, mucous membrane color, capillary refill time, jugular vein distention, and heart rate. When palpable pulses and audible heart beat are absent, cardiac arrest should be assumed and cardiopulmonary resuscitation (CPR) started. If intubation and manual ventilation was not begun previously, it should be initiated immediately in addition to chest compressions and appropriate resuscitative drug administration (see Chapter 4, Cardiopulmonary Resuscitation). Obtundation, pale mucous membranes, slow capillary refill times, and poor jugular vein distention are all indicative of poor perfusion or shock. Arterial blood pressure and assessment of jugular vein distention and speed of filling and emptying is also used to help determine global perfusion, and rapidly determined point-of-care serial lactate, PvO_2, and base excess values will aid in further assessment of tissue perfusion. Venous partial pressure of oxygen (PO_2) has been found by the author to be an effective means of assessing perfusion effectiveness. PvO_2 measurements below 35 mm Hg are considered an indication of hyperperfusion. The use of Doppler blood flow monitoring, with the probe placed on the palmar arterial arch (or even the surface of the eye in the arrested or near arrested unconscious patient) has been shown to be a very effective is assessing circulatory function.

The three main causes of shock are hypovolemia, vasodilation, and cardiac failure, and patients may suffer from more than one of these problems. Most shock states in the trauma patient result from blood loss, with secondary causes associated with plasma-fluid loss, third space loss within edema associated tissues and pain over time. In contrast, critically ill patients may be hypovolemic due to severe dehydration or third space fluid losses (especially losses into the gastrointestinal tract). Vasodilation is most commonly a consequence of a severe systemic inflammatory response, with or without sepsis. Anaphylaxis and ischemic-reperfusion injury can also cause generalized vasodilation. Vasodilatory shock may cause hyperemic mucous membranes and bounding pulses, but most patients with vasodilatory shock have concurrent hypovolemia and will demonstrate signs more consistent with hypovolemic shock before adequate fluid resuscitation. Primary cardiac disease is the most common cause of cardiogenic shock.

Intravenous access ideally is secured while assessment of the ABCs is being performed. Catheters will be more easily placed when a small opening in the skin is made to provide easier access to the vein. If the vein is collapsed then a mini-cutdown procedure is recommended. This is commonly done with an 18- to 20-gauge needle; the bevel of the needle is used as a small blade and a ¼-inch incision is made over the vein and a curved small-tipped hemostat is used to isolate and stabilize the vein for catheter introduction. Immediate fluid resuscitation is indicated in all shock patients other than those suspected to have cardiac failure. In most cases fluid resuscitation aims to restore normal cardiovascular parameters. In cases of active internal hemorrhage, a less aggressive fluid resuscitation approach such as “hypotensive resuscitation” may be considered[7] (see Chapter 65, Shock Fluids and Fluid Challenge).

2.4.2.4 D = Disability

The ABCs of triage have been extended to ABCDE. The *D* stands for disability. The animal's level of consciousness and ability to move and feel pain in all four limbs are assessed. The letters AVPU can be used for quick categorization: *A* = alert, *V* = responsive to verbal stimulation, *P* = responsive to painful stimulation, and *U* = unresponsive to painful stimulation. Seizure activity requires immediate anticonvulsant therapy and should be controlled before starting the primary survey. Research again has shown that the most important emergency triage drug to use in virtually all head or spinal cord emergent or critical conditions is supplemental oxygen. 7

8

2.4.2.5 E = External Assessment

External assessment is particularly relevant to the acute trauma victim. The entire animal is evaluated for bleeding (including from orifices), lacerations, punctures, abrasions, contusions, significant swelling, crepitus, pain on palpation, obvious hernias, open fractures, angulations, or deformities. The umbilical region is examined for periumbilical ecchymosis (Cullen sign), which may indicate hemorrhage in the peritoneum or retroperitoneum.

2.4.3 Secondary Survey

Once the primary survey is complete and appropriate emergency therapy has been instituted, a secondary survey is performed. This includes a full physical examination, measurement of arterial blood pressure, assessment of jugular vein distention and relaxation time, and evaluation of emergency blood work results. Ideally emergency blood work should include hemoglobin levels, or packed red blood cell volume, total protein, blood glucose, electrolytes, arterial and venous blood gas, and lactate measurements. Abnormalities should be managed as indicated.

Oxygenation is assessed with pulse oximetry or arterial blood gas analysis. Arterial partial pressure of oxygen (PaO_2) of less than 80 mm Hg (pulse oximeter saturation [SpO_2] <95%) is indicative of hypoxemia, and a PaO_2 of less than 60 mm Hg (SpO_2 <90%) indicates severe hypoxemia. If severe hypoxemia persists despite oxygen therapy and management of primary disease processes (evacuation of pleural space disease, for example), mechanical ventilation is indicated. Ventilatory ability is evaluated best by measurement of the partial pressure of carbon dioxide in arterial or venous blood (PCO_2). PCO_2 levels of greater than 45 mm Hg indicate hypoventilation, and PCO_2 levels greater than 60 to 70 mm Hg despite treatment of the primary disease process is an indication for mechanical ventilation.

2.5 TRIAGE

2.5.1 Hospital Arrival

When patients present to the hospital on an emergency basis, a quick history is obtained from the owner or agent of the pet. The team must be ready to move the animal from the transporting vehicle into the hospital. A backboard made of Plexiglas or plastic or a commercially available stretcher can be very useful, as can a cart or gurney. Initial questions include “What happened?” “When?” “What was done?” and “Does the animal have any current health problems?” A more detailed history can be obtained later, once the animal has been assessed and stabilized. Rapid assessment and triage should be completed within the first few minutes of arrival in all critically ill or injured animals.[1] It is recommended when possible to have the owners accompany the pet to the ready resuscitation area in the treatment part of the hospital and, in some cases, to have them sit in a chair while early interventions are being accomplished (jet flow-by oxygen, auscultation and palpation, clipping for IV catheter placement). As these are done the owner can be asked further questions such as “Did you see the accident?” “Is he allergic to any medications? When was the last time he ate? Are there any other medical conditions that he has?” This also allows the owner to see where the pet has been taken and that there are others working to help in the pets care. Seeing positive things being done for the pet will help relieve stress for the owner. In some cases, when help is very scarce, the owner may have to assist the veterinarian (recognized as not ideal but sometimes this is necessary although it does carry additional risks).

When multiple patients require attention simultaneously, those that are not ambulatory are considered of the highest priority. Those able to walk under their own power but have obvious problems with breathing, circulation, or other significant problems would receive the second highest priority. Patients that are ambulatory with no obvious problems would be left as the lowest priority.

2.5.2 Safety

Ideally gloves are worn when contacting the patient; this is to protect both the patient and the caregiver. Trauma patients commonly are covered in blood, and this may be the patient's own blood or that of an injured person who has handled the animal. To prevent transmission of hepatitis, human immunodeficiency virus, or nosocomial infections, two pairs of latex gloves or one pair of plastic nitrile gloves should be worn. Other precautions such as wearing protective eyewear should also be considered.

Other safety risks should also be assessed and action taken accordingly. Muzzles should be placed on conscious dogs, and distressed cats should be wrapped in a towel. Cats can also be left in the transport carrier or the box they came in. Oxygen therapy is of particular importance in patients with obvious respiratory distress. Jet flow-by oxygen is most commonly used initially; the stream of oxygen can be directed down the mouth of open-mouth–breathing patients. If cats are too distressed to be handled, high rates of flow-by oxygen can be directed into the carrier. Within a minute or two the concentration of oxygen will be close to 100%. If high-percentage supplemental oxygen alone does not ameliorate the signs of severe respiratory distress, positive-pressure ventilation is indicated.

If cases are oxygen responsive, a Crowe oxygen collar can be placed on them or a nasal or bilateral nasal catheter or cannula can be inserted and oxygen provided at a rate of 100 to 200 ml/kg/min (which provides from 40% to 80% oxygen in most cases).

2.6 SPECIAL CONSIDERATIONS FOR THE HOSPITALIZED PATIENT

When the hospitalized patient is brought to the ICU or the ICU patient suddenly deteriorates and requires evaluation, some unique considerations arise that are not relevant to emergency patient triage. A review of the fluid and drug therapy for that patient is important. Overall fluid balance (fluid intake versus fluid output) should be assessed during the entire hospitalization in case substantial fluid deficits or excesses exist. Drug therapies should be scrutinized for possible interactions, incorrect dosages, and incorrect route of administration. Incorrect administration of drugs such as potassium chloride and insulin can be a cause of unexpected collapse and cardiac arrest. Lastly, it is important to perform a full primary and secondary survey on these patients, including a review of the emergency blood work. 8
There can be a temptation to skip much of this procedure because the animal has already undergone recent physical 9
examinations and diagnostic tests. Critically ill patients can change rapidly; patient deterioration or failure to improve despite therapy warrants complete reassessment every time.

2.7 SUMMARY

The ultimate objective of the triage process is to identify those patients that require the most urgent medical attention. Adequate patient care requires the appropriate facilities, equipment, and staff, with 24-hour availability. A predesignated, appropriately prepared "ready area" will allow provision of urgent, possibly lifesaving care to the unstable patient. A standard approach to a primary and secondary survey will provide an efficient method of patient assessment, with minimal risk of missing important clinical abnormalities. In addition to these objectives, clear client communication is vital to ensure that owners fully understand the nature and prognosis of all disease processes identified in their pets.

3 Chapter 3 Survival Prediction Index

Lesley G. King, MVB, DACVECC, DACVIM

3.1 KEY POINTS

- Scoring systems such as the SPI are used to categorize patients into groups with similar severity of disease, which allows risk stratification of groups of patients for clinical research studies.
- Ideally, scoring systems should be independent of the diagnosis and therefore applicable to any patient and any disease, and they should use readily available information that can be collected early during hospitalization,
- The Survival Prediction Indices (SPI 1 and 2) were developed and validated for use in dogs admitted to the intensive care unit.

3.2 INTRODUCTION

A variety of systems that place a numeric score on the severity of disease are used in human critical care,[1-4] and similar systems are being developed for use in the small animal intensive care unit (ICU).[5-12] Equations have also been developed for large animals but are beyond the scope of this chapter.[13-16] Some systems globally classify the degree of physiologic derangement regardless of the diagnosis, and some are designed to be applied to specific situations, for example peritonitis or trauma. These systems have the common goal of attempting to objectively classify the severity of disease; in other words, to predict the outcome within a given patient population.

3.3 APPLICATIONS AND INDICATIONS FOR SCORING SYSTEMS

All scoring systems are developed for the same purpose: to categorize patients into groups with similar severity of disease. This is particularly important for risk stratification of groups of patients for clinical research studies. Clinical research trials are necessary to advance our understanding of the pathophysiology and management of disease. However, small animal patients with naturally occurring disease are usually a mixture of ages and breeds, may be brought for treatment at different stages of the problem, may have received a variety of treatments, and may have multiple concurrent diseases in addition to the problem being studied.

Although research animals with experimentally induced disorders are important models of naturally occurring disease in both humans and animals and provide a much more homogeneous population, the use of these animal models has certain disadvantages. In particular, experimentally induced models of disease may be expensive and time consuming to produce, and the disorders may not be identical to those that occur in clinical patients. Thus, results from experimental studies may not apply directly to clinical cases.

Our ability to draw conclusions from clinical trials of management techniques or new therapies is therefore often hampered by our inability to define homogeneous patient populations that can be compared. For example, if we were testing a new drug for treatment of dogs with autoimmune hemolytic anemia, the results might be difficult to interpret unless the test group has been proven to have the same type and severity of hemolysis, the same degree of systemic illness, and therefore the same risk of mortality as the standard treatment group. This problem can be addressed partially by developing an index for scoring the severity of disease, which attempts to place a numeric value on the degree of illness in the patients included in the clinical trial. Patients can then be categorized into groups with a similar severity of disease, which then allows comparison of groups for clinical trials.

Similarly, these scoring systems can also be used if a specific test result is being studied to determine its relationship to the severity of disease. They may also have some utility for triage of patients to objectively and prospectively allocate resources of staffing and equipment. Objective characterization of the severity of disease also allows quality control and comparison of actual outcomes between institutions and within institutions over time.

Ideally, such indices should be independent of the diagnosis and therefore applicable to any patient and any disease. In addition, the ideal prediction index should use readily available information that can be collected early during hospitalization, before beginning the clinical trial. If it can be shown that the severity of illness is initially statistically similar in two groups that are then treated differently, the results of the clinical trial carry more weight.

3.4

EVALUATING THE PREDICTIVE ACCURACY OF SEVERITY-OF-DISEASE SCORING SYSTEMS

The statistical accuracy of severity-of-disease scoring systems can be assessed by evaluation of the area under the receiver operating characteristic curve, sensitivity and specificity, odds ratios, or positive and negative predictive indices. The predictive accuracy of logistic regression equations is usually estimated using receiver operating characteristic (ROC) curves, which demonstrate the tradeoff between the true-positive rate (sensitivity) and the false-positive rate (1 minus specificity) at varying predictive cut-points. The area under the ROC curve (AUC) represents the probability that a randomly selected “survivor” has a larger predicted probability of survival than a randomly selected “nonsurvivor,” and is therefore a measure of the predictive value of the equation. The higher the AUC value (closer to 1), the more accurate is the equation. In human outcome prediction equations, AUC values commonly are obtained as high as 0.85 to 0.90.

3.5

SURVIVAL PREDICTION INDEX: THE PILOT STUDY

The survival prediction index (SPI) was developed as a method of scoring the severity of disease of critically ill dogs in the ICU.[5-7] The system comprises parameters that are independent of the diagnosis, and are part of the routine monitoring and evaluation of ICU patients. Data for this calculation can therefore be collected early during hospitalization and before interventions being tested in clinical trials.

A pilot study was conducted initially to develop an SPI using data from 200 dogs admitted to the ICU at the Veterinary Hospital of the University of Pennsylvania.[5] The SPI was calculated by logistic regression analysis, using clinical parameters collected within the first 24 hours after admission to the ICU. For the pilot study, all of the data were collected by one person. The parameters were chosen to reflect the function of vital organ systems, the severity of underlying physiologic derangement, and the extent of physiologic reserve (Box 3-1).

Some parameters were measured serially as part of routine intensive monitoring, for example rectal temperature, heart rate (HR), respiration rate (RR), mean arterial pressure (MAP), oxygen saturation (SaO_2), packed cell volume (PCV), total solids (TS), and glucose. Other parameters such as age, body weight, white blood cell count (WBC), creatinine, albumin, bilirubin, and bicarbonate were usually measured only once within the 24-hour study period. If serial measurements of a parameter were available, the most abnormal value (most deviated above or below the normal range) was used. In postoperative patients, the initial body temperature was usually low, and then increased to a plateau over the first few hours. In these cases, the plateau rather than the admission temperature was recorded. Based on clinical observation, animals were assigned a score of 1 or 2 if they had clinical evidence of central

nervous system disease, and 0 if they were thought to be neurologically normal. Similarly, animals were assigned a score of 1 if they had medical illness, and 0 if they had surgical disease. Finally, animals were given a score of 5 if they had chronic illness, and 0 if their disease was acute. Chronic illness was diagnosed if there was evidence of failure of a major organ persisting for longer than 1 month, for example, chronic renal failure, chronic hepatic insufficiency, or chronic congestive heart failure; systemic neoplasia such as lymphosarcoma or hemangiosarcoma; any form of immunosuppression including chemotherapy, immunosuppressive drugs, hyperadrenocorticism, or diabetes mellitus; or congenital disease that may lead to compromised organ function, such as brachycephalic airway conformation, immune deficiency, portosystemic shunt, or cardiovascular anomalies. Outcome was defined 10
as alive or dead after 30 days, with day 1 defined as the day of admission to the ICU. Outcome was determined by 11
reexamination or by a telephone conversation with the owner.

3.5.1

Box 3-1 Parameters Recorded Within 24 Hours of Admission to the Intensive Care Unit

SPI	SPI 2
Age (years)	Age (years)
Body weight (kg)	Respiration rate (breaths/min)
Rectal temperature (°F)	Mean arterial pressure (mm Hg)
Heart rate (beats/min)	Service of entry (surgical or medical)
Respiration rate (breaths/min)	Packed cell volume (%)
Mean arterial pressure (mm Hg)	Creatinine (mg/dl)
Oxygen saturation SaO_2 (%)	Albumin (g/dl)
Neurologic disease (Y/N)	
Service of entry (surgical or medical)	
Chronic disease (Y/N)	
Packed cell volume (%)	
Total solids (g/dl)	
Glucose (mg/dl)	
White blood cell count (cells/mm^3)	
Creatinine (mg/dl)	
Albumin (g/dl)	
Bilirubin (mg/dl)	
Bicarbonate (mmol/L)	

Logistic regression analysis resulted in the following linear equation:

$$
\begin{aligned}
\text{logit}(\text{P}) = {} & -19.9676 + 0.1537(\text{rectal temperature}) \\
& +0.00742(\text{MAP}) - 0.0144(\text{BW}) - 0.00164(\text{HR}) \\
& +0.00423(\text{RR}) + 0.0668(\text{SaO}_2) + 0.0123 \\
(\text{bicarbonate}) & - 1.2567(\text{neurologic disease}) \\
& - 0.8375(\text{creatinine}) + 0.0350(\text{PCV}) - 0.0403 \\
(\text{WBC}) & - 0.2732(\text{albumin}) + 0.5082(\text{TS}) \\
& - 0.1163(\text{age}) + 0.00280(\text{glucose}) - 0.2114 \\
(\text{bilirubin}) & - 0.9294(\text{medical / surgical}) \\
& - 0.0796(\text{acute / chronic})
\end{aligned}
$$

The numeric values are entered into the linear equation to give a value for logit P, which is the log odds of survival. An exponential equation is used to solve for P, the predicted probability of survival.

$$
\text{P}(\text{SPI}) = \frac{e^{\text{logit}(p)}}{\left[1 + e^{\text{logit}(p)}\right]}
$$

The predicted probability (SPI) value thereby obtained is within the range of 0 to 1, with 0 indicating the most severe disease, and 1 indicating no mortality risk. The AUC for this equation, calculated using data from the 200 dogs used to develop the equation, was 0.89, suggesting reasonable predictive accuracy for this particular patient population.

3.6 SURVIVAL PREDICTION INDEX 2: THE MULTICENTER TRIAL

The first objective of the multicenter study was to test prospectively the accuracy of the SPI in a larger cohort of dogs admitted to various ICUs.[6] The investigators wished to include critically ill dogs in a variety of locations, and to use data collected by a variety of personnel. A second objective, using the multicenter data, was to generate an improved SPI, the SPI 2. Lastly, using estimation and validation samples, the predictive accuracy of SPI 2 was to be tested for future use.

Data were collected from dogs admitted to small animal ICUs at four locations: University of Pennsylvania, Tufts University, University of Minnesota, and VCA Veterinary Referral Associates in Gaithersburg, Maryland. Six hundred and twenty-four dogs were included, with the same parameters recorded as with the pilot study, within 24 hours of ICU admission. Data were collected by a variety of individuals including the investigators, veterinary nurses, and veterinary students. The overall survival rate was 61.1%, with 381 of 624 dogs alive after 30 days. There was no significant difference in survival rate among the sites. The dogs were divided randomly into an estimation group (n = 499) and a validation group (n = 125).

3.6.1 Prediction of Outcome in the New Sample, Using the Model From the Pilot Study

The AUC for the pilot SPI model, using the original group of dogs, was 0.89. When it was tested using data from the new (estimation) group of dogs (n = 499), the AUC decreased to 0.723. The high AUC value previously reported was positively biased because it was calculated using the same data that were used to generate SPI. Additionally, it is possible that there were differences between the original population of test dogs and those included in this multicenter study.

3.6.2 Using the New (Multicenter) Sample to Create a New Survival Prediction Index

The data from this new (multicenter) group of dogs were used to perform a new logistic regression analysis, thereby reestimating the parameters to create a new SPI, the SPI 2. In the full model, the AUC obtained for the estimation sample (n = 499) was 0.773, while that of the validation sample (n = 125) was 0.72. Then a backward elimination procedure was used to sequentially eliminate variables that had a minimal impact on the accuracy of prediction of survival, thereby obtaining a more manageable model with fewer variables, while retaining the same level of discrimination in predicting outcome. Variables that were eliminated included temperature, body weight, heart rate, neurologic status, SaO_2, bicarbonate, white blood cell count, total solids, glucose, bilirubin, and chronicity of disease. The AUC for the reduced model in the estimation sample was 0.76, and in the validation sample was 0.68, which showed minimal loss in predictive accuracy. Thus, the new SPI 2 equation is as follows:

$$\begin{aligned}\operatorname{logit}(P) = {} & 0.3273 + 0.0108(\mathrm{MAP}) - 0.0101(\mathrm{RR}) \\ & - 0.2183(\text{creatinine}) + 0.0164(\mathrm{PCV}) \\ & + 0.3553(\text{albumin}) - 0.1184(\text{age}) \\ & - 0.8069(\text{medical} / \text{surgical})\end{aligned}$$

where medical/surgical ratio is equal to 1 if the animal is from a medical service and 0 if it is from a surgical service. The numeric values are entered into the linear equation to give a value for logit P, which is the log odds of survival. The exponential equation is used to solve for P, the predicted probability of survival.

$$P(\text{SPI } 2) = \frac{e^{\operatorname{logit}(p)}}{1 + e^{\operatorname{logit}(p)}}$$

The predicted probability (SPI 2) value falls within the range from 0 to 1, with 0 indicating the most severe disease and 1 indicating no mortality risk.

The optimal cut-point was derived from the ROC curve using the ratio of the nonsurvival-to-survival rates, which in the sample from the University of Pennsylvania was 0.389/0.611, or 0.637. This tangent line corresponds to a prediction index cut-point of approximately 0.50. The estimated positive and negative predictive values (95% confidence interval) at this (optimal) cut-point are 73.4% (68.9% to 77.5%) and 66.2% (59.0% to 72.7%), respectively. The estimated sensitivity and specificity at this cut-point are 82.7% (78.4% to 86.3%) and 53.1% (46.6% to 59.5%), respectively.

3.7 SCORING SYSTEMS IN THE HUMAN ICU

Numerous similar studies have been published and the findings are in routine use in humans to classify patients into 11
groups for clinical trials.[1-14] The most commonly used system in human medicine is the acute physiology, age, 12
chronic health evaluation (APACHE) scoring system.[1,2] In studies of human patients using APACHE scoring, AUC values as high as 0.90 are commonly obtained. The numbers of human patients used to develop those equations were

much larger than can easily be collected by veterinary researchers. For example, data were accrued from more than 17,000 patients for development of the APACHE III scoring system.[2]

The APACHE III scoring system is similar to the SPI 2 because it includes MAP, RR, hematocrit, and creatinine and albumin concentrations. Some variables that were found not to be significant in the study dogs are still included in the APACHE system, specifically HR, temperature, partial pressure of oxygen, and alveolar-arterial oxygen gradient, WBC count, and bilirubin and glucose concentrations. Other variables that are included in the APACHE scoring system but that were not tested as part of the SPI 2 study include urine output, blood urea nitrogen level, and serum sodium concentration.

3.8 USING SPI And APACHE IN PATIENT SUBSETS

Preliminary studies of the SPI 2 suggest that it may be more accurate in dogs admitted to the ICU with a medical problem (AUC = 0.75) than with surgical admissions (AUC = 0.70).[6] However, there were approximately twice as many medical admissions in this study as surgical admissions, which may have contributed to this difference. Additional studies are needed to further explore this question in veterinary patients. Similarly, in human medicine the APACHE system is not as accurate in patients treated for trauma-induced illness, compared with those who have medical conditions.[17] The authors of that study hypothesized that the prediction for previously healthy humans who had acute trauma would have been more accurate if it had included an anatomic component similar to that suggested in the animal trauma triage scoring system.[9]

3.9 SERIAL USE OF THE SPI On Sequential Days Of ICU Hospitalization

In another study, the utility of serial estimations of the SPI on days 1 and 3 of ICU hospitalization was evaluated.[7] It was hypothesized that data obtained later during hospitalization, closer to the time of the actual outcome, might provide a more accurate prediction that would be more clinically useful for decision making in specific patients. In a group of 64 dogs, the AUC was higher using day 3 measurements (AUC = 0.70) than that obtained using day 1 measurements (AUC = 0.65), but the increase in the AUC value was not statistically significant.[7]

3.10 LIMITATIONS OF SCORING SYSTEMS

Much debate centers around the potential use of these scoring systems for prioritization of resources toward patients that have a greater predicted chance of survival. Although this approach may have debatable merit in human medicine from a moral perspective, the high AUC values in the scoring systems for humans suggest that there may be enough predictive accuracy to justify their use for this purpose. In contrast, the study of scoring systems in veterinary medicine is still in its infancy. The systems that have been developed were studied in relatively small numbers of animals. Many have not yet been adequately validated, or if they have been validated, they do not give a level of predictive accuracy that compares with the systems available for human medicine. In individual animal patients, therefore, it is arguable whether the veterinary systems provide additional information over that obtained by the thoughtful evaluation by an experienced clinician. Veterinary indices should be used to statistically predict percentages of survival in groups of patients, rather than in individual animals. The lower AUCs for the veterinary scoring systems show that they provide sufficient predictive accuracy to be a valid tool for statistical analysis, but are insufficiently accurate to justify their use for decision making for individual animals. If outcome prediction equations were used to determine treatment for individual patients, there is a significant risk that an individual patient might be predicted to die, and therefore be euthanized, but instead would have survived; alternatively, another patient might be treated based on a score that predicts survival, but might die. Much further study needs to be done to refine these systems, to include many more patients in both estimation and validation samples, and to generate more accurate equations and scoring systems.

4 Chapter 4 Cardiopulmonary Resuscitation

Steven G. Cole, DVM, DACVECC, DACVIM (Cardiology)

4.1 Key Points

- Successful cardiopulmonary resuscitation (CPR) requires a team that is well prepared and well equipped and communicates clearly during the course of the resuscitation.
- Causes of cardiopulmonary arrest fall into two categories, reversible and irreversible, with a vastly different prognosis for survival following CPR. It is appropriate to discuss “do-not-resuscitate” orders during hospital admission for patients with end-stage disease processes.
- Basic life support is the cornerstone of CPR and includes airway management, ventilation, and artificial circulation with external chest compression or internal cardiac compression.
- Advanced life support provides more specific interventions based on the circumstances of the arrest. Techniques include electroencephalogram monitoring, drug therapy, and defibrillation.
- Intensive care is often essential to minimize the impact of postresuscitation syndromes and improve chances for the long-term survival of a patient that has been resuscitated successfully.

4.2 INTRODUCTION

Proficiency in cardiopulmonary resuscitation (CPR) is essential for every veterinarian practicing in an emergency or critical care setting. Given the nature of the patient population in these environments, cardiopulmonary arrest is not uncommon. In many cases, this represents a situation in which intervention can be lifesaving. Proper technique and timing may result in the return of spontaneous circulation and can make the difference between life and death. Guidelines for CPR in humans exist, with recommendations determined from an evidence-based review of clinical and experimental studies by an international consensus committee.[1] Unfortunately, no large-scale clinical studies of CPR have been done in veterinary patients, and recommendations for performing CPR in animals have been extrapolated from human guidelines, as well as experimental studies with animal models.[2-4] In general, the prognosis for dogs and cats suffering cardiopulmonary arrest is poor, with less than 10% of patients surviving to hospital discharge; however, the possibility for a successful outcome does exist.[5,6] Despite prevailing conventional wisdom, a retrospective study indicates that most of the animals that do survive are neurologically intact at the time of hospital discharge.[7]

The likelihood of a successful outcome is increased when the resuscitation team is well prepared. Preparation begins with a well-defined and well-equipped resuscitation area. Ideally, this area should include a “crash cart” with supplies for venous access, airway management, and drug therapy, as well as monitoring equipment and a defibrillator (see Appendix 1). Oxygen should also be available, along with supplies necessary to perform manual ventilation, such as an Ambu bag, Bain circuit, or anesthesia machine. Essential to this preparation is the training of staff and their practice of specific roles and techniques in controlled situations. Each resuscitation team should have a defined leader to allow rapid decision making and clear communication during the resuscitation. Knowing the wishes of the owner before CPR is performed facilitates this process. This may be accomplished by establishing a resuscitation code at the time of hospital admission. In the author's hospital, a green code means all appropriate measures (including open-chest CPR) will be performed, a yellow code limits the team to closed-chest CPR only, and a red code means do not resuscitate. Finally, it is very useful to have a debriefing session following CPR to enhance the effectiveness of the team in future resuscitations.

4.3 CAUSES OF CARDIOPULMONARY ARREST

Cardiopulmonary arrest is defined as the complete cessation of effective circulation and ventilation. Common causes of cardiac arrest in veterinary patients include hypotension (secondary to hypovolemia, sepsis, or drug administration), hypoxemia (secondary to hypoventilation or lung disease), metabolic derangements (e.g., severe metabolic acidosis) and/or electrolyte abnormalities (e.g., hyperkalemia). Primary myocardial disease, which is a common cause of cardiac arrest in humans, is uncommon in veterinary patients. In some patients, full cardiopulmonary arrest is preceded by respiratory arrest, and chances for survival are markedly better if intervention is performed at this stage.[6] It is important to recognize that there are two subsets of patients that suffer cardiopulmonary arrest, those with reversible causes of arrest and those with disease processes that cannot be reversed. In the latter case, when the patient suffers cardiopulmonary arrest secondary to an end-stage disease, CPR offers little chance of a successful long-term outcome. In these cases, it is often appropriate to discuss the various resuscitation orders and the prognosis for recovery with the owner while obtaining a resuscitation code at the time of hospital admission.

4.4 BASIC LIFE SUPPORT

Basic life support encompasses the ABCs (airway, breathing, circulation) of CPR and is the foundation for all resuscitation efforts. Although many clinicians focus on drug therapy and defibrillation during resuscitation, establishing an airway, ensuring adequate ventilation, and generating blood flow via external chest compression or 14
internal cardiac compression must be performed quickly and properly to maximize the chance for recovery. 15
Traditionally, the ABC mnemonic has been followed for determining the order of intervention in basic life support. This often results in a delay in the initiation of chest compressions until the patient is intubated. Recent guidelines stress the importance of early initiation of chest compressions with minimal interruptions.[1] This concept may be extended to veterinary CPR, and although an airway should be established as soon as possible, chest compressions should not be delayed until after the patient is intubated.

4.4.1 Airway

An airway may be established rapidly by routine orotracheal intubation in most patients suffering respiratory or cardiopulmonary arrest (see Chapter 17, Endotracheal Intubation). This may be facilitated by the use of a laryngoscope and, if necessary, a stylet to stiffen the endotracheal tube. In some patients, the airway is obscured by saliva, gastric contents, blood, or edema fluid, and in these situations it is useful to have suction available to help clear the pharynx and aid in the visualization of the glottis. In other cases, the airway is obscured by pharyngeal swelling or a mass effect, and in many cases the patient may be intubated by directly palpating the larynx and then manually directing the tube into the glottis.

After the patient is intubated, the cuff should be inflated and the tube secured. Given the stress of an arrest situation, as well as the manipulation of the patient that occurs during CPR, it is not uncommon for the tube to be misplaced or to become displaced into the esophagus. Because of this, it is important to verify placement. This may be accomplished by direct visualization of the tube entering the larynx, palpation of the neck to ensure that the tube is not felt within the esophagus, auscultation of breath sounds, and proper chest wall movement during ventilation. End-tidal carbon dioxide ($ETCO_2$) monitoring is also useful to verify tube placement because tracheal gas should contain carbon dioxide (as long as blood flow to the lungs is present), but esophageal gas does not. If problems are encountered, the airway should be reevaluated and the patient should be reintubated if necessary. It is also important to verify that the cuff is inflated, because this is often a source of problems.

In rare instances, the patient cannot be intubated orotracheally. These situations include airway obstruction by foreign bodies that cannot be retrieved easily, massive pharyngeal swelling or mass effects, trauma with laryngeal or proximal tracheal disruption, and trismus or dental fixation devices that prevent normal jaw motion. When orotracheal intubation is not possible, an emergency tracheostomy is indicated (see Chapter 18, Tracheostomy). Should a tracheostomy tube not be available, a standard endotracheal tube may be used, with care taken not to place the tube distal to the carina, resulting in bronchial intubation. If necessary, the tube may be cut to a more appropriate length, with care taken not to cut the cuff balloon tubing.

4.4.2 Breathing

Once an airway is established, the patient should be ventilated manually with 100% oxygen. An Ambu bag is used most commonly, but a Bain circuit or anesthesia machine may also be used. The recommended respiratory rate during CPR is 10 to 24 breaths/min. Ventilation should be delivered to achieve normal chest wall excursions and, if possible, the airway pressure should be monitored and should not exceed 20 to 30 cm H_2O.

4.4.2.1 Box 4-1 Formulas for Myocardial and Cerebral Perfusion Pressure

- Myocardial perfusion pressure = Aortic diastolic pressure − Right atrial pressure
- Cerebral perfusion pressure = Mean arterial pressure − Intracranial pressure

If normal chest wall motion is not observed, problems with the endotracheal tube (esophageal intubation, uninflated cuff) should be investigated, because this is a common source of problems with ventilation during CPR. In the absence of airway-related problems, diminished chest excursions or decreased compliance suggests airway obstruction, severe parenchymal disease, or severe pleural space disease. Airway obstruction is not common, but it is possible for the endotracheal tube to become occluded by tracheal secretions, vomitus, or exudate. Severe parenchymal disease is often present in patients suffering respiratory or cardiopulmonary arrest, and possible manifestations include pulmonary edema, pneumonia, pulmonary contusions, inflammatory lung disease (acute lung injury [ALI] or acute respiratory distress syndrome [ARDS]), and neoplasia. Pleural space disease is also common, and ventilation may be limited by pleural effusion (hemothorax, chylothorax, hydrothorax, pyothorax), diaphragmatic hernia, or pneumothorax. Pneumothorax presents an especially challenging situation during CPR, because positive-pressure ventilation often exacerbates the condition and may result in tension pneumothorax. In this situation, air often is introduced faster than it can be removed by thoracocentesis, and cardiopulmonary arrest in an animal with pneumothorax is an indication for open-chest CPR.

Recommended rates for ventilation are commonly exceeded during CPR in humans.[8,9] The detrimental effects of relative hyperventilation during CPR have been documented in animal models of cardiac arrest, including elevated mean intrathoracic pressures compared with lower ventilation rates, and associated decreases in myocardial perfusion pressure and survival.[8,9] Although no studies exist in veterinary patients, it is almost certain that recommended ventilation rates are exceeded in this population as well, and this may have detrimental effects on the rate of successful resuscitation. Accordingly, it is important that the potential be recognized and hyperventilation avoided during CPR in veterinary hospitals.

4.4.3 Circulation

Blood flow during CPR is generated by external chest compression (closed-chest CPR) or by direct cardiac
compression (open-chest CPR). Regardless of the technique, the goal is to maximize blood flow to the coronary
and cerebral vascular beds. Coronary blood flow is driven by the myocardial perfusion pressure, which is
governed by the aortic diastolic pressure and right atrial pressure (Box 4-1). Myocardial perfusion pressure is an
extremely important variable in resuscitation, and it has been positively correlated to successful resuscitation in 15
both experimental models and in human patients.[10-11] Cerebral perfusion pressure is dictated by the mean aortic 16
pressure and intracranial pressure, and it is the major determinant of cerebral blood flow (see Box 4-1).

External chest compressions are performed more often than direct cardiac compressions in veterinary CPR, and the mechanism of blood flow varies depending on patient size. The cardiac pump model of blood flow is the most likely mechanism at work in small patients (<15 kg), with forward blood flow resulting from direct cardiac compression. The thoracic pump model of blood flow predominates in larger patients (<15 kg). In this model, forward blood flow occurs secondary to phasic changes in intrathoracic pressure generated by chest compressions.

External chest compressions are performed with the patient in lateral recumbency at a rate of 100 to 120 compressions per minute. The chest is compressed to a depth of 25% to 33% of the thoracic diameter with a 50:50 ratio of compression to relaxation. In small patients (<15 kg), the compressions are performed directly over the heart to maximize the effectiveness of the cardiac pump mechanism. In very small patients, such as puppies and cats, the entire thorax may be encircled, and the chest compressed with the operator's thumbs. For larger patients (>15 kg), compressions should be performed over the widest portion of the thorax. This results in the greatest change in intrathoracic pressure and maximizes flow via the thoracic pump mechanism. It should be noted that the cardiac output increases with higher compression rates, but it is difficult to maintain a rate of greater than 100 to 120 compressions per minute for an extended period. From a practical standpoint, the person performing compressions should stand so that the spine (as opposed to the sternum) of the patient is closest to the compressor. This position reduces the tendency of the patient to be pushed off the table while compressions are being performed. Additionally, having a small stepstool available allows for better leverage, resulting in better compressions with less fatigue.

Interposed abdominal compressions may be performed to increase the effectiveness of external chest compressions, resulting in increased venous return to the thorax in diastole and thus increasing forward flow.[12] Interposed abdominal compressions are an adjunct to standard CPR and may be considered in patients without known abdominal trauma, hemoperitoneum, or recent abdominal surgery when adequate personnel are available. With this technique, the abdomen is compressed during the relaxation phase of chest compressions, requiring coordination between the thoracic and abdominal compressors.

Although properly performed external chest compressions may generate approximately 20% of normal cardiac output, this may be diminished by factors that interfere with transmission of pressure or may result in collapse of the heart and great vessels. These conditions include pleural effusion, diaphragmatic hernia, pneumothorax, large-volume pericardial effusion and cardiac tamponade, and/or chest wall trauma resulting in rib fractures or disruption of the intercostal musculature. In addition, it can be difficult to achieve effective chest compressions in very large dogs (>50 kg). In these situations, direct internal cardiac compressions may result in significantly higher myocardial perfusion pressure than closed-chest CPR.[13] Open-chest CPR allows access to the descending aorta for aortic occlusion (cross-clamping), which directs blood flow to the coronary and cerebral circulation. Because of this, open-chest CPR should also be considered in cases of exsanguinating abdominal hemorrhage, when ongoing volume loss into the peritoneal cavity is likely to occur during CPR. Finally, because of its hemodynamic benefits, open-chest CPR should be considered in patients in whom closed-chest CPR has not resulted in return of spontaneous circulation within 2 to 5 minutes.

It should be noted that the decision to perform open-chest CPR should not be taken lightly, because the facilities and expertise to close the thoracotomy and treat the patient postarrest must be available. To perform open-chest CPR, the left lateral thorax is rapidly clipped and a brief aseptic preparation is applied. A lateral thoracotomy is performed at the fifth intercostal space extending from the dorsal fourth of the chest wall to a few centimeters from the sternum, avoiding laceration of the internal thoracic vasculature. The fifth intercostal space may be estimated by flexing the animal's elbow and drawing it caudally. Some veterinarians prefer to perform the entire thoracotomy with Mayo scissors, but a scalpel blade may also be used. Ventilation should be halted as the pleural space is entered, to avoid laceration of the lungs. Once the chest is open, a rib retractor may be used to increase exposure and facilitate manipulation of the heart. The heart is compressed manually at a rate of 100 to 120 compressions per minute, and this may be performed with either one or two hands depending on the size of the patient. An incision in the pericardium, below the level of the phrenic nerve, may also be performed to drain pericardial effusion, if present, and to facilitate manipulation and compression of the heart. As mentioned above, a lateral thoracotomy provides access to the descending aorta, which may be bluntly dissected and occluded with an aortic cross-clamp or with an encircling Penrose drain, red rubber drain, or Rumel tourniquet. Once spontaneous circulation resumes, the aortic occlusion may be removed gradually over 5 to 10 minutes. It is important to recognize that the chest may also be accessed via a transdiaphragmatic approach, and open-chest CPR should be performed immediately if an intraoperative arrest occurs during a celiotomy.

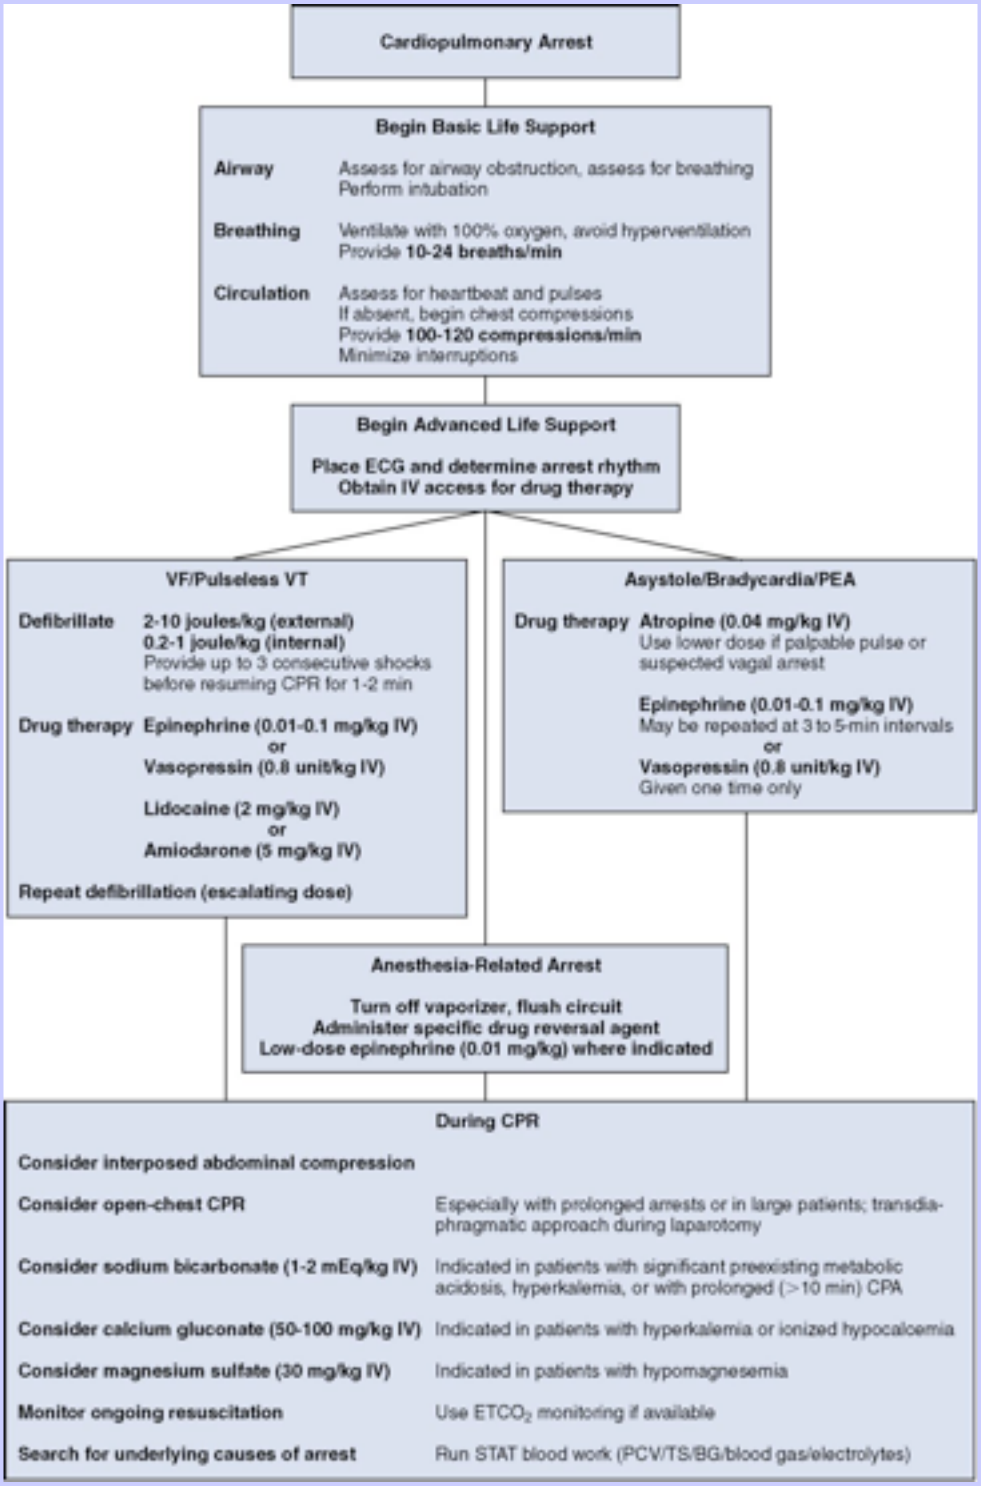
4.5 ADVANCED LIFE SUPPORT

Advanced life support extends the scope of CPR beyond ABC to include the Ds and Es of resuscitation: drug therapy, electrocardiographic (ECG) analysis, and electrical defibrillation. Drug therapy in CPR is aimed at improving the efficacy of basic life support techniques, as well as managing underlying problems associated with the arrest. ECG analysis allows for advanced life support interventions to be tailored to the underlying rhythm (Figure 4-1). Electrical defibrillation provides the only effective method of managing ventricular fibrillation and is also indicated in patients with pulseless ventricular tachycardia. Although advanced life support techniques are an essential component of CPR, properly performed basic life support is vital to the success of a resuscitation effort.

4.5.1 Establishing Access for Drug and Fluid Therapy

Obtaining access for drug and fluid therapy is vital during CPR. Either central or peripheral venous access
typically is established at the onset of resuscitation (see Chapters 61 and 63, Peripheral Venous Catheterization
and Central Venous Catheterization, respectively). Central venous access is ideal because circulation time of 16
drugs is better than with peripheral venous access.[14] Should peripheral veins be used, it is important to use large 17
flush volumes to deliver drugs more rapidly to the central venous circulation. Vessels are typically collapsed
during cardiopulmonary arrest, so rapid surgical cutdown is often necessary to secure venous access. When
performing a cutdown, it is important to make the incision large enough to easily dissect, puncture, and secure the 17
vessel of interest. Should venous access not be obtained, intraosseous catheterization may be performed using the 18
femur, proximal tibia, or humerus (see Chapter 62, Intraosseous Catheterization).

Figure 4-1 Algorithm for performing cardiopulmonary resuscitation in veterinary patients.



Cardiopulmonary Arrest
Begin Basic Life Support
Airway
Assess for airway obstruction, assess for breathing
Perform intubation
Breathing
Ventilate with 100% oxygen, avoid hyperventilation
Provide 10-24 breaths/min
Circulation
Assess for heartbeat and pulses
If absent, begin chest compressions
Provide 100-120 compressions/min
Minimize interruptions
Begin Advanced Life Support
Place ECG and determine arrest rhythm
Obtain IV access for drug therapy
VF/Pulseless VT
Defibrillate
2-10 joules/kg (external)
0.2-1 joule/kg (internal)
Provide up to 3 consecutive shocks before resuming CPR for 1-2 min
Drug therapy
Epinephrine (0.01-0.1 mg/kg IV)
or
Vasopressin (0.8 unit/kg IV)
Lidocaine (2 mg/kg IV)
or
Amiodarone (5 mg/kg IV)
Repeat defibrillation (escalating dose)
Asystole/Bradycardia/PEA
Drug therapy
Atropine (0.04 mg/kg IV)
Use lower dose if palpable pulse or suspected vagal arrest
Epinephrine (0.01-0.1 mg/kg IV)
May be repeated at 3 to 5-min intervals
or
Vasopressin (0.8 unit/kg IV)
Given one time only
Anesthesia-Related Arrest
Turn off vaporizer, flush circuit
Administer specific drug reversal agent
Low-dose epinephrine (0.01 mg/kg) where indicated
During CPR
Consider interposed abdominal compression
Consider open-chest CPR
Especially with prolonged arrests or in large patients; transdiaphragmatic approach during laparotomy
Consider sodium bicarbonate (1-2 mEq/kg IV)
Indicated in patients with significant preexisting metabolic acidosis, hyperkalemia, or with prolonged (>10 min) CPA
Consider calcium gluconate (50-100 mg/kg IV)
Indicated in patients with hyperkalemia or ionized hypocalcemia
Consider magnesium sulfate (30 mg/kg IV)
Indicated in patients with hypomagnesemia
Monitor ongoing resuscitation
Use ETCO2 monitoring if available
Search for underlying causes of arrest
Run STAT blood work (PCV/TS/BG/blood gas/electrolytes)

Another technique that is extremely useful is intratracheal drug administration. This can be performed immediately after intubation, minimizing the delay that often occurs while venous access is established. With this technique, the drug dosage is doubled, diluted to a volume of 2 to 5 cc, and is administered through a red rubber catheter that has been advanced past the tip of the endotracheal tube to the approximate level of the carina. This exposes the drug to the large surface area of the lung and pulmonary circulation, where it is absorbed and delivered to the central circulation. With the notable exceptions of sodium bicarbonate and calcium, most common CPR drugs may be administered by this route. It should be noted that intracardiac drug administration is not recommended because of risks of lacerating lung tissue, disrupting the coronary vasculature, or injecting drugs that may trigger arrhythmias or myocardial ischemia (e.g., epinephrine).

4.5.2 Electrocardiography

ECG analysis is a key component of advanced life support, serving both as a monitoring tool and as the basis for interventions such as drug therapy or defibrillation. Common initial arrest rhythms in veterinary patients include ventricular fibrillation, asystole, pulseless electrical activity, and sinus bradycardia.[15] The underlying rhythm often changes during the course of CPR, and this may dictate a change in therapy. Additionally, the cardiac rhythm often changes with the return of spontaneous circulation (ROSC), and this must be recognized and managed appropriately. Of intrest, and somewhat counterintuitive, ventricular fibrillation has the most specific therapy (defibrillation) and is considered the rhythm most responsive to treatment, but asystole was the most common initial arrest rhythm in a recent retrospective analysis of patients surviving CPR.[7]

Table 4-1 Guidelines for Drug Therapy and Initial Defibrillator Settings (Monophasic Waveform Defibrillators) During Cardiopulmonary Resuscitation

	Weight (lb)	**5**	**10**	**20**	**30**	**40**	**50**	**60**	**70**	**80**	**90**	**100**
	Weight (kg)	**2.5**	**5**	**10**	**15**	**20**	**25**	**30**	**35**	**40**	**45**	**50**
Drug (conc.)	**Dosage**	**ml or joules**										
Epi low (1:10,000)	0.01 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Epi high (1:1000)	0.1 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Atropine (0.54 mg/ml)	0.05 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Lidocaine (20 mg/ml)	2 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Sodium bicarbonate (1 mEq/ml)	1 mEq/kg	2.5	5	10	15	20	25	30	35	40	45	50
Calcium gluconate (100 mg/ml)	50 mg/kg	1	2.5	5	7.5	10	12.5	15	17.5	20	22.5	25
Magnesium sulfate (4 mEq/ml)	0.2 mEq/kg	0.1	0.25	0.5	0.75	1	1.25	1.5	1.75	2	2.25	2.5
Vasopressin (20 U/ml)	0.8 μ/kg	0.1	0.2	0.4	0.6	0.8	1	1.2	1.4	1.6	1.8	2
Amiodarone (50 mg/ml)	5 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Naloxone (0.4 mg/ml)	0.04 mg/kg	0.25	0.5	1	1.5	2	2.5	3	3.5	4	4.5	5
Flumazenil (0.1 mg/ml)	0.02 mg/kg	0.5	1	2	3	4	5	6	7	8	9	10
External defibrillation	2-10 J/kg	20	30	50	100	200	200	200	300	300	300	360
Internal defibrillation	0.2-1 J/kg	2	3	5	10	20	20	20	30	30	30	50

Modified from Cole SG, Otto CM, Hughes D: Cardiopulmonary cerebral resuscitation in small animals: a clinical practice review. Part II, *J Vet Emerg Crit Care* 13:13, 2003.

4.5.3 Drug Therapy

Drug therapy during CPR is designed to augment basic life support techniques, enhancing blood flow to the myocardial and cerebral circulation, as well as to address factors that may have precipitated or will perpetuate cardiopulmonary arrest. Commonly used CPR drugs with dosage recommendations are shown in Table 4-1. Most drugs used in CPR may be given by several routes, with intravenous administration preferred (central venous administration is ideal). Other routes, including intraosseous or intratracheal, may also be used, but some medications, including sodium bicarbonate and calcium, are not recommended for intratracheal administration.

4.5.3.1 Fluid Therapy

Routine use of bolus IV fluid therapy during CPR is controversial. Fluid boluses are indicated in hypovolemic animals to restore blood volume and to maximize the cardiac output generated by compressions (see Chapter 65, Shock Fluids and Fluid Challenge). Additionally, rapidly administered fluids may be used to flush drugs and reduce transit time from the peripheral to central circulation. However, when an animal is euvolemic or hypervolemic, as may be the case when a hospitalized patient suffers cardiopulmonary arrest, bolus fluid therapy may cause a significant rise in central venous and, therefore, right atrial pressure. By increasing right atrial pressure, myocardial perfusion pressure is diminished, with potentially detrimental results. Thus the use of intravenous fluids during CPR should be determined on a case-by-case basis. 18

19

4.5.3.2 Vagolytic Agents

Atropine is a vagolytic drug that abolishes parasympathetic tone and is indicated in patients that have cardiopulmonary arrest associated with slow pulseless electrical activity or asystole. Atropine is also indicated in patients with symptomatic bradycardia and in vagal arrests that may be experienced by debilitated patients with elevated vagal tone secondary to coughing, retching, vomiting, defecating, or to gastrointestinal, pulmonary, or neurologic disease. The dosage of atropine is 0.04 mg/kg IV, IT, or IO as necessary. Atropine is available in a 0.54 mg/ml concentration, and a shortcut dosage in an arrest situation is 1 ml/10 kg. It should be noted that the full-arrest dosage of atropine may produce a significant tachycardia in animals with perfusing rhythms. In this situation, it is recommended that the dosage be reduced to one fourth or half of the arrest dosage. Atropine may be repeated at 5-minute intervals as necessary during the course of CPR.

4.5.3.3 Vasopressors

Vasopressor drugs are used to increase vascular resistance and to increase aortic blood pressure during CPR (see Chapter 176, Vasoactive Catecholamines). This, in turn, maximizes myocardial and cerebral perfusion pressures and blood flow to the heart and brain. Vasopressors, such as epinephrine or vasopressin, are indicated in all types of cardiopulmonary arrest. Epinephrine is a catecholamine that has both strong α-adrenergic (vasopressor) and β-adrenergic (inotropic and chronotropic) effects. Studies have shown that the α-adrenergic effects are most important in CPR, and that the β-adrenergic effects may actually be detrimental to long-term outcome.[16,17] Epinephrine has both low-dosage and high-dosage recommendations, with the low dosage being 0.01 to 0.02 mg/kg and the high dosage being 0.1 to 0.2 mg/kg. Because the high dosage has been associated with worse neurologic outcomes in people (despite higher initial rates of ROSC), the low dosage is currently recommended in human CPR guidelines.[1] However, experimental evidence indicates that high-dosage epinephrine may be more effective than low-dosage epinephrine in dogs.[18] Epinephrine is available in a 1:1000 (1 mg/ml) concentration, and a shortcut for high-dosage (0.1 mg/kg) epinephrine is 1 ml/10 kg. Epinephrine may be given intravenously, intraosseously, or intratracheally and may be repeated at 5-minute intervals during CPR.

Vasopressin is a noncatecholamine vasopressor that is also included in CPR guidelines (see Chapter 177, Vasopressin).[1,3] It has a longer half-life than epinephrine and, unlike catecholamines, is effective in the presence of acidosis. Vasopressin also lacks potentially harmful β-adrenergic effects. The dosage of vasopressin is 0.8 unit/kg. Vasopressin may be given intravenously, intraosseously, or intratracheally and may be repeated at 5-minute intervals during CPR.

4.5.3.4 Antiarrhythmic Agents

Antiarrhythmic medication administration during CPR is limited to patients with either ventricular fibrillation or pulseless ventricular tachycardia that is not responsive to initial defibrillation (see Chapter 190, Antidysrhythmic Agents). Agents indicated in these cases include lidocaine and amiodarone. Lidocaine is a Class Ib antiarrhythmic agent that is administered at a dosage of 2 mg/kg IV, IO, or IT. Lidocaine is commonly available in a 2% (20 mg/ml) solution, and a shortcut dosage is 1 ml/10 kg. Some preparations of lidocaine that are used for local anesthesia contain preservatives, and preservative-free products are recommended for intravenous use. It should also be noted that lidocaine may suppress ventricular escape rhythms and, because of this, it should be used with caution following ROSC.

Amiodarone is a Class III antiarrhythmic drug that has recently been included in the human CPR guidelines.[1] There is limited experience with amiodarone in veterinary CPR; however, the dosage is 5 to 10 mg/kg IV. Amiodarone must be diluted, and hypotension during administration is a common occurrence.

4.5.3.5 Buffer Therapy

Although not routinely recommended in all patients, sodium bicarbonate is indicated in animals with preexisting acidosis, or in prolonged arrests lasting longer than 10 minutes. Because alkalinization shifts potassium into the intracellular compartment, sodium bicarbonate is also indicated in patients with severe hyperkalemia. The dosage for sodium bicarbonate is 1 to 2 mEq/kg IV or IO. Sodium bicarbonate inactivates surfactant, so it should not be given via the intratracheal route. Sodium bicarbonate typically is found as a 1 mEq/ml solution, and a shortcut dosage is 1 ml/kg.

4.5.3.6 Electrolyte Therapy

Calcium administration is not routinely recommended in CPR, because excess calcium may exacerbate ischemia-reperfusion injury. However, calcium gluconate is recommended in patients with severe hyperkalemia and in patients with known hypocalcemia. The dosage is 50 to 100 mg/kg IV or IO.

Magnesium sulfate is recommended in patients with known hypomagnesemia. Magnesium sulfate is also recommended with torsades de pointes, a rare form of polymorphic ventricular tachycardia that is extremely uncommon in veterinary patients. The dosage of magnesium sulfate is 30 mg/kg IV or IO.

4.5.4 Defibrillation

Electrical defibrillation is the only effective method to restore spontaneous circulation in a patient with ventricular fibrillation and is also indicated in patients with pulseless ventricular tachycardia. A more detailed discussion about the techniques and safety concerns regarding defibrillation may be found elsewhere in this text (see Chapter 53, Cardioversion and Defibrillation). In general, the following sequence for performing defibrillation is recommended.

First, the ECG rhythm of ventricular fibrillation or pulseless ventricular tachycardia is verified. Second, proper placement of the paddles is confirmed. Third, the operator announces the intention to defibrillate the patient, halts ongoing CPR, and calls, “Clear.” Fourth, following the call of “Clear,” the operator visually confirms that no personnel are in contact with the patient or table. Finally, firm pressure is applied with the paddle and the countershock is delivered.

The ECG is then monitored for the efficacy of the countershock and the patient is immediately reassessed for the return of spontaneous circulation. An energy setting of 2 to 10 joules/kg is selected for the initial external defibrillation attempt (or 0.2 to 1.0 joule/kg for internal defibrillation, see Box 4-1), with an increase in energy of approximately 50% for each subsequent attempt. 19

4.5.5 Anesthesia-Related Arrests

Anesthesia-related arrests are rare occurrences in most veterinary hospitals. However, because these arrests generally are recognized immediately and often have reversible causes, successful resuscitation is common. Anesthetic-related arrests should first be managed by turning off gas anesthesia and flushing the circuit with oxygen, or by discontinuing injectable drugs and administering reversal agents as indicated (e.g., flumazenil 0.02 to 0.04 mg/kg for benzodiazepines, naloxone 0.02 to 0.04 mg/kg for opioids, and yohimbine 0.1 mg/kg or atipamezole [equal volume to that of agonist] for α_2-agonists, xylazine and medetomidine, respectively). CPR should be instituted immediately. Open-chest CPR should be performed in patients undergoing thoracotomy and considered in patients undergoing celiotomy (via transdiaphragmatic access). Finally, an aggressive search for underlying causes of the arrest, such as hemorrhage, hypotension, hypoventilation, hypoxemia, or arrhythmias, should be conducted with immediate correction of identified problems.

4.6 MONITORING DURING CARDIOPULMONARY RESUSCITATION

Several methods of patient monitoring are available during CPR. Palpation of femoral pulses is one of the easiest parameters to monitor. Although the presence of pulses is often an encouraging finding, it should be noted that it is the pulse pressure, and not the blood pressure, that determines the pulse. Thus the ability to feel a pulse does not necessarily equate to adequate arterial blood pressure or perfusion. Conversely, $ETCO_2$ monitoring does provide a marker of blood flow during CPR. If ventilation remains constant, the $ETCO_2$ value is directly correlated to pulmonary perfusion and cardiac output during CPR, with higher $ETCO_2$ associated with increased myocardial perfusion pressure and increased rates of successful resuscitation.[19] Additionally, a large increase in the $ETCO_2$ level during CPR is often an indication of ROSC. $ETCO_2$ monitors are readily available and the technique is very easy to perform, making this an ideal monitoring tool during CPR.

ECG monitoring is essential during ongoing CPR, because changes in the underlying rhythm often dictate the type and timing of interventions. In some instances, such as with slow ventricular rhythms, the ECG tracing may represent either cardiopulmonary arrest or ROSC. Because of this, the ECG should be interpreted in conjunction with physical findings and other information (e.g., $ETCO_2$). If an apparent escape rhythm is present, audible heart sounds, palpable pulses, or markedly increased $ETCO_2$ should be present. If this is not the case, the rhythm represents pulseless electrical activity and CPR should be resumed.

Blood gas findings may be misleading during CPR. This is due to the large disparity between arterial and venous samples during low blood flow states. The arterial blood gas results may appear relatively normal, often demonstrating a respiratory alkalosis secondary to excessive ventilation in the face of diminished pulmonary blood flow. On the other hand, the venous blood gas indicates both respiratory and metabolic acidosis, and this is much more representative of the ischemia and decreased clearance of metabolic byproducts occurring in the local tissue environment.[20] Although this makes assessing the adequacy of ventilation from a venous sample impossible, overall the venous blood gas is a more useful monitoring tool during CPR.

4.7 POSTRESUSCITATION CARE

The care of a patient following ROSC is often as important to long-term survival as CPR itself. The likelihood of recurrent arrest is extremely high, especially if a reversible cause of the arrest is not identified and aggressively managed. Additionally, many postresuscitation syndromes occur secondary to the low blood flow and subsequent ischemia-reperfusion injury that occurs following circulatory arrest and CPR.[21,22] These syndromes include cardiovascular instability characterized by arrhythmias, myocardial dysfunction, and hypotension secondary to loss of vasomotor tone and is a common problem. Acute renal failure or compromise of the gastrointestinal mucosal barrier (so-called shock gut) secondary to hypoperfusion may also occur. Systemic inflammatory response syndrome may develop, with associated pulmonary involvement (acute lung injury [ALI] or acute respiratory distress syndrome [ARDS]), dysregulation of coagulation, and subsequent multiorgan dysfunction. Transient cerebral dysfunction is also very common after protracted cardiopulmonary arrest, although permanent neurologic abnormalities are rare in veterinary patients that survive to hospital discharge.[7] Finally, iatrogenic injury, including incisions for vascular access or thoracotomy, as well as rib fractures from external chest compressions, may also be present following CPR.

Intensive monitoring and aggressive therapy are generally necessary to optimize outcomes. Cardiac output, arterial blood pressure, and systemic oxygen transport should be maintained with fluid therapy, vasopressor or inotropic support, oxygen administration, and blood transfusion as necessary. Cerebral protection is also indicated and includes mannitol administration, head elevation, maintenance of normal blood pressure and oxygen delivery, as well as ensuring normocapnia. Many patients hypoventilate following an episode of cardiopulmonary arrest, so mechanical ventilation is often necessary following ROSC. It should be stressed that although hypercapnia should be avoided due to cerebral vasodilation and increases in intracranial pressure, hypocapnia should also be avoided, because hyperventilation may cause excessive vasoconstriction and decreased cerebral blood flow. Intentional induction of hypothermia (so-called protective hypothermia) is advocated in humans following CPR to minimize cerebral injury.[23] This has not yet translated into clinical veterinary practice; however, it is recommended that mildly hypothermic patients (>97° F) should not be aggressively rewarmed. As the postresuscitation period progresses, the timing of surgical intervention for either primary conditions underlying the arrest or for iatrogenic injury should be determined on a case-by-case basis. In many instances, it is useful to stage procedures to minimize the likelihood of recurrent arrest.

5 Chapter 5 Hyperthermia and Fever*

James B. Miller, DVM, MS, DACVIM

5.1 KEY POINTS

- Thermoregulation is controlled by a region of the hypothalamus. It responds to thermoreceptors in the brain and peripheral nervous system to maintain a narrow range of body temperature by increasing either heat production or loss.
- Hyperthermia describes any elevation in core body temperature above accepted normal values.
- A true fever is the body's normal response to infection between injury and is part of the acute phase response. It is controlled by the thermoregulatory center in the hypothalamus.
- Other forms of hyperthermia are a result of an imbalance between heat production and heat loss. Hyperthermic patients are approached differently from those with a fever, both diagnostically and therapeutically.
- A fever may be beneficial to the host by decreasing bacterial growth and inhibiting viral replication. Most fevers are not a threat to life unless body temperature exceeds 107° F (41.6° C).
- A fever will increase water and caloric requirements, and this must be considered when treating the febrile patient.
- In most cases, an accurate diagnosis should be obtained before initiating nonspecific therapy for a fever.
- Nonsteroidal antiinflammatory drugs will reduce a fever without blocking the rest of the acute phase response. Glucocorticoids will reduce a fever, but they also block the inflammatory reaction.
- Total body cooling may be counter-productive and usually is reserved for afebrile hyperthermia or when fevers approach 107° F.
- Antibiotics should not be used nonspecifically for fever management without a strong indication of infection that may be susceptible to their action.

* Modified from Miller JB: Hyperthermia and fever of unknown origin. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 6, St Louis, 2005, Saunders.

5.2 INTRODUCTION

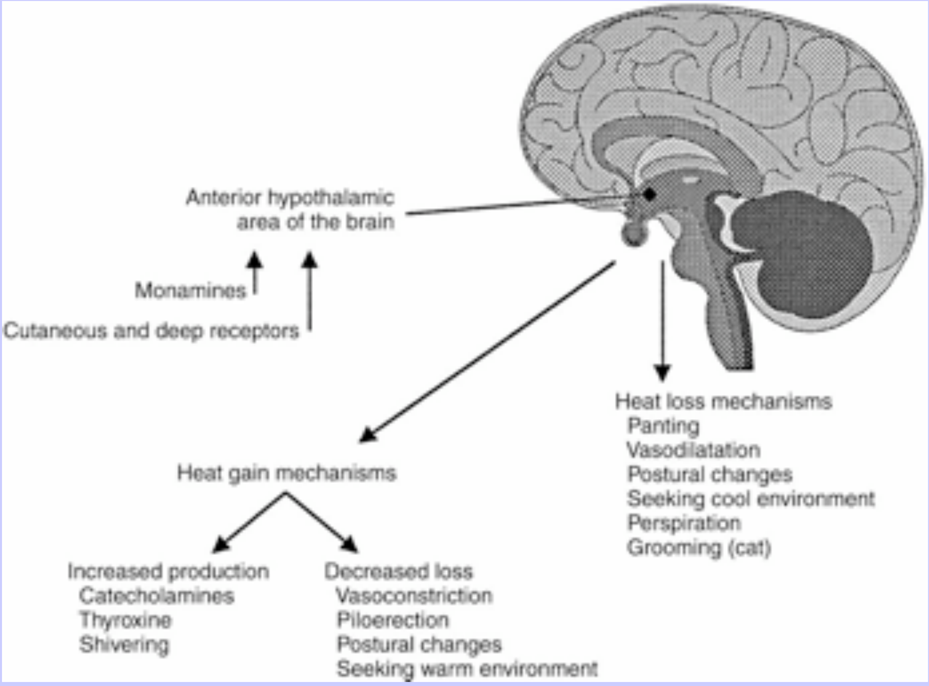
Obtaining a body temperature measurement is important in the evaluation of all patients, especially the critical care patient. A rectal temperature higher than 102.5° F is considered elevated in the unstressed dog or cat. The method of measurement must also be taken into account because ear, axillary, or toe web measurements will be lower than rectal temperatures. An intravascular thermistor is considered most accurate, but often impractical in the clinical setting.

Too frequently the veterinarian associates any elevation in body temperature with true fever. The assumption is often made that the fever is caused by an infectious agent, even if there is no obvious cause. If the patient's fever resolves after antibiotics are given, the assumption is made that it was caused by a bacterial infection. A normal body temperature is often assumed to indicate the absence of disease. This approach to fever, hyperthermia, or normothermia can be misleading and result in improper diagnoses and therapy (or the lack thereof).

5.3 THERMOREGULATION

Thermoregulation is the balance between heat loss and heat production. Metabolic, physiologic, and behavioral mecha-nisms are used by homeotherms to regulate heat loss and production. The thermoregulatory control center for the body is located in the central nervous system in the preoptic area of the anterior hypothalamus (AH).[1] Changes in ambient and core body temperatures are sensed by the peripheral and central thermoreceptors, and information is conveyed to the AH via the nervous system. The thermoreceptors sense that the body is below or above its normal temperature (set point) and subsequently cause the AH to stimulate the body to increase heat production and reduce heat loss through conservation if the body is too cold, or to dissipate heat if the body is too warm (Figure 5-1). Through these mechanisms, the dog and cat can maintain a narrow core body temperature range in a wide variety of environmental conditions and activity levels. With normal ambient temperatures, most body heat is produced by muscular activity, even while at rest. Cachectic or anesthetized patients or those with severe neurologic impairment may not be able to maintain a normal set point or generate a normal response to changes in core body temperature.

Figure 5-1 Schematic representation of normal thermoregulation. From Miller JB: Hyperthermia and fever of unknown origin. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 6, St Louis, 2005, Saunders.



5.4 HYPERTHERMIA

Hyperthermia is the term used to describe any elevation in core body temperature above the accepted normal range for that species. When heat is produced or stored in the body at a rate greater than it is lost, hyperthermia results.[2,11] The term *fever* is reserved for those hyperthermic animals in which the set point in the AH has been reset to a higher temperature. In hyperthermic states other than fever, temperature elevation is not a result of the body attempting to raise its temperature but is due to the physiologic, pathologic, or pharmacologic changes that cause heat gain to exceed heat loss. Box 5-1 outlines the various classifications of hyperthermia.

5.5 TRUE FEVER

True fever is a normal response of the body to invasion or injury and is part of the "acute phase response."[3] Other parts of the acute phase response include increased neutrophil numbers and phagocytic ability, enhanced T and B lymphocyte activity, increased acute phase protein production by the liver, increased fibroblast activity, and increased sleep. Fever and other parts of the acute phase response are initiated by exogenous pyrogens that lead to the release of endogenous pyrogens (Figure 5-2).[4]

5.5.1 Box 5-1 Classification of Hyperthermia

5.5.1.1 True Fever

Production of endogenous pyrogens

5.5.1.2 Inadequate Heat Dissipation

5.5.2 Exogenous Pyrogens

True fever may be initiated by a variety of substances including infectious agents or their products, immune complexes, tissue inflammation or necrosis, and several pharmacologic agents. Collectively, these substances are called *exogenous pyrogens*. Their ability to directly affect the thermoregulatory center is probably minimal and they primarily cause the release of endogenous pyrogens by the host. Box 5-2 lists some of the more important known exogenous pyrogens.

Figure 5-2 Schematic representation of the pathophysiology of fever. From Miller JB: Hyperthermia and fever of unknown origin. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 6, St Louis, 2005, Saunders.

Tissue Inflammation and Necrosis

From Miller JB: Hyperthermia and fever of unknown origin. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine,* ed 6, St Louis, 2005, Saunders.

5.5.3 Endogenous Pyrogens

In response to stimulation by an exogenous pyrogen, proteins (cytokines) released from cells of the immune system trigger the febrile response. Macrophages are the primary immune cells involved, although T and B lymphocytes and other leukocytes may play significant roles. The proteins produced are called *endogenous pyrogens* or *fever-producing cytokines*. Although interleukin-1, interleukin-6, and tumor necrosis factor-α are considered the most important fever-producing cytokines, at least 11 cytokines are capable of initiating a febrile response (Table 5-1).

Some neoplastic cells are also capable of producing cytokines that lead to a febrile response. The cytokines travel via the bloodstream to the AH where they bind to the vascular endothelial cells within the AH and stimulate the release of prostaglandins (PGs), primarily PGE_2 and possibly $PGF_{2\alpha}$. The set point is raised and the core body temperature rises through increased heat production and conservation.

Table 5-1 Proteins With Pyrogenic Activity

Endogenous Pyrogen	**Principal Source**
Cachectin (TNF-α)	Macrophages
Lymphotoxin (TNF-β)	Lymphocytes (T and B)
IL-1α	Macrophages and many other cell types
IL-1β	
Interferon-α	Leukocytes (esp. monocyte-macrophages)
Interferon-β	Fibroblasts
Interferon-γ	T lymphocytes
IL-6	Many cell types
Macrophage inflammatory protein 1α	Macrophages
Macrophage inflammatory protein 1β	
IL-8

5.6 INADEQUATE HEAT DISSIPATION

5.6.1 Heat Stroke

Heat stroke is a common result of inadequate heat dissipation (see Chapter 167, Heat Stroke). Exposure to high ambient temperatures may increase heat load at a faster rate than it can be dissipated from the body. This is 23 especially true 24 in larger breeds of dogs and obese or brachycephalic animals. Heat stroke may occur rapidly, especially in closed environments with poor ventilation (e.g., inside a car with the windows closed), even on only moderately hot days. Environmental temperatures inside a closed car exposed to direct sun may exceed 120° F (48° C) in less than 20 minutes, even when the outside temperature is only 75° F (24° C). Death may occur in less than an hour, especially in the predisposed animal types described above.

Heat stroke will not respond to antipyretics used for the management of a true fever. The severely hyperthermic patient must have total body cooling immediately to prevent organ damage or death. Mechanisms of heat loss from the body include the following: radiation (electromagnetic or heat exchange between objects in the environment), conduction (between the body and environmental objects that are in direct contact with the skin, as determined by the relative temperatures and gradients), convection (the movement of fluid, air, or water over the surface of the body), and evaporation (disruption of heat by the energy required to convert the material from a liquid to a gas, as with panting). There are numerous strategies for cooling the hyperthermic patient (Box 5-3), and the technique(s) chosen should be based on the severity of the animal's condition, temperature, and response to therapy.

In most veterinary patients, total body cooling is best accomplished by administering oxygen and intravenous fluid therapy (see Chapters 19 and 65, Oxygen Therapy and Shock Fluids and Fluid Challenge, respectively), water baths and rinses using tepid water, and placing a fan near the animal. If the water applied to the animal is too cold, there is a tendency for peripheral vasoconstriction that will inhibit radiant heat loss and slow the cooling process. Cooling should be discontinued when body temperature approaches normal (approximately 103° F or 39.4° C) to prevent iatrogenic hypothermia.

5.6.1.1 Box 5-3 Cooling Options for the Hyperthermic Patient

5.6.1.1.1 Oxygen and Intravenous Isotonic Fluid Therapy

5.6.1.1.1.1 Surface Cooling Techniques

- Clip fur if indicated
- Tepid water applied to skin or whole body (manually or via bath)
- Fan
- Ice packs over areas with large vessels (neck, axilla, inguinal region)
- Combination of the above

5.6.1.1.2 Internal Cooling Techniques

- Rectal administration of cool isotonic fluids
- Gastric lavage
- Open body cavity
- Peritoneal dialysis

5.6.1.1.3 Extracorporeal Techniques

5.6.1.1.3.1 Antipyretic Drugs

- Antiprostaglandins
- Dantrolene

Dipyrone

Aminopyrine

COX-2 inhibitors

Glucocorticoids

Additional NSAIDs

COX-2, Cyclooxygenase-2; *NSAIDs,* nonsteroidal antiinflammatory drugs.

5.6.2 Hyperpyrexic Syndrome

Hyperpyrexic syndrome is associated with moderate to severe exercise in hot and humid climates. This syndrome may be more common in hunting dogs or dogs that “jog” with their owners. In humid environments, evaporative cooling via panting is minimal. In addition, heavy exercise may cause the cardiovascular system to supply skeletal muscles with adequate blood flow while compromising peripheral heat loss by not enabling proper vasodilation in the skin.

Many hunting dogs and dogs that run with their owners will continue to work or run until they become weak, stagger, and collapse. In suspected cases of hyperpyrexic syndrome, owners should obtain a rectal thermometer and evaluate the dog's rectal temperature at the first sign that the dog is becoming weak or does not want to continue. Owners should be instructed that rectal temperatures above 106° F (41° C) require immediate total body cooling, and temperatures above 107° F (41.6° C) may lead to permanent organ damage or death.

5.6.3 Exercise-Induced Hyperthermia

The body temperature will rise with sustained exercise of even moderate intensity because of heat production associated with muscular activity. Even when extreme heat and humidity are not factors, the dog occasionally will reach temperatures that require total body cooling. This is especially true in dogs that do not exercise frequently, are overweight, or have respiratory disease.

Eclampsia results in extreme muscular activity that can lead to significant heat production and result in severe hyperthermia. Total body cooling should be initiated if the patient is hyperthermic, in conjunction with therapy for the eclampsia (see Chapters 56 and 140, Calcium Disorders and Dystocia and Obstetric Crises, respectively).

Seizure disorders due to organic, metabolic, or idiopathic causes are encountered frequently in small animals (see Chapter 98, Seizures and Status Epilepticus). Hyperthermia associated with severe muscular activity can result, especially if the seizures are prolonged or occur in clusters. The initial concern of the clinician should be to stop the seizures, but when significant hyperthermia is present, total body cooling is also recommended.

5.6.4 Pathologic and Pharmacologic Hyperthermia

The pathologic and pharmacologic types of hyperthermia encompass several disorders that will impair the heat balance equation. Hypothalamic lesions may obliterate the thermoregulatory center, leading to impaired responses to both hot and cold environments. Malignant hyperthermia (MH) has been reported in the dog and cat. It leads to a myopathy and subsequent metabolic heat production, secondary to disturbed calcium metabolism that is initiated by pharmacologic agents such as inhalation anesthetics (especially halothane) and muscle relaxants such as succinylcholine. Extreme muscle rigidity may or may not be present. Removal of the offending causative agent and total body cooling may prevent death. Dantrolene is a specific and effective therapy for malignant hyperthermia and is dosed at 2.5 to 5 mg/kg IV.

Hypermetabolic disorders may also lead to hyperthermic states. Endocrine disorders such as hyperthyroidism and pheochromocytoma can lead to an increased metabolic rate or vasoconstriction, resulting in excess heat production and/or decreased ability to dissipate heat, or both. These conditions rarely lead to severe hyperthermia that requires total body cooling.

5.7 BENEFITS AND DETRIMENTS OF HYPERTHERMIA

5.7.1 Benefits

Fever is part of the acute phase response and is a normal response of the body. Even poikilotherms such as fish and reptiles will respond to a pyrogen by seeking higher environmental temperatures to raise their body temperatures.[5] It would be logical to think that a true fever is beneficial to the host. Most studies have shown that a fever will reduce the duration of morbidity and mortality from many infectious diseases. A fever decreases the ability of many bacteria to use iron, which is necessary for them to live and replicate.[5] Blocking the fever with nonsteroidal antiinflammatory drugs (NSAIDs) in rabbits with *Pasteurella* infections significantly increases mortality rates. Many viruses are heat sensitive and cannot replicate in high temperatures. Raising the body temperature in neonatal dogs with herpesvirus infections significantly reduces the mortality rate.

5.7.2 Detriments

Hyperthermia leads to an increased metabolic state and level of oxygen consumption that raise both caloric and water requirements by approximately 7% for each degree Fahrenheit (0.6° C) above accepted normal values. In addition, hyperthermia leads to suppression of the appetite center in the hypothalamus but usually not the thirst center. Animals that have sustained head trauma or a cerebrovascular accident may suffer more severe brain damage if coexisting hyperthermia is present.

Body temperatures above 107° F (41.6° C) often lead to increases in cellular oxygen consumption that exceed oxygen delivery, resulting in deterioration of cellular function and integrity. This may lead to disseminated intravascular coagulation (DIC) (see Chapter 117, Hypercoagulable States) with thrombosis and bleeding, or serious damage to organ systems including the brain (cerebral edema and subsequent confusion, delirium, obtundation, seizures, coma), heart (arrhythmias), liver (hypoglycemia, hyperbilirubinemia), gastrointestinal tract (epithelial desquamation, endotoxin absorption, bleeding), and kidneys (acute renal failure; see Chapter 167, Heat Stroke). Additional abnormalities might include hypoxemia, hyperkalemia, skeletal muscle cytolysis, tachypnea, metabolic acidosis, tachycardia, tachypnea, and hyperventilation.

Exertional heat stroke and malignant hyperthermia may lead to severe rhabdomyolysis, hyperkalemia, hypocalcemia, myoglobinemia and myoglobinuria, and elevated levels of creatine phosphokinase. Fortunately, true fevers rarely lead to body temperatures of this magnitude and are usually a result of other causes of hyperthermia that should be managed as medical emergencies.

5.8 CLINICAL APPROACH TO THE HYPERTHERMIC PATIENT

In evaluating presented with a hyperthermic patient, the problem should be approached in a logical manner to avoid making erroneous conclusions.[2] A complete history and physical examination should be performed unless the patient is critically ill or severely hyperthermic (temperature higher than 106° F) and the patient is obviously attempting to dissipate heat (panting, postural changes) or is comatose. In such cases, immediate total body cooling and supportive care should be initiated.

In stable patients, a thorough physical examination and specific questions concerning previous injuries or infections, exposure to other animals, disease in other household pets, previous geographic environment, and previous or current drug therapy are beneficial. This approach enables the clinician to decide if the elevated body temperature is a true fever. Temperatures less than 106° F (41° C), unless prolonged, are usually not life threatening, and caution should be taken when administering antipyretic therapy is considered before performing a proper clinical evaluation.

5.9 NONSPECIFIC THERAPY FOR FEBRILE PATIENTS

Mild to moderate elevations in body temperature are rarely fatal and may be beneficial to the body. As stated before, hyperthermia may inhibit viral replication, increase leukocyte function, and decrease the uptake of iron by microbes (which is often necessary for their growth and replication). If a fever exceeds 107° F, a significant risk of permanent organ damage and DIC exists. The benefits of nonspecific therapy versus its potential negative effects should be considered before initiating such management.

Nonspecific therapy for true fever usually involves inhibitors of prostaglandin synthesis. The compounds most commonly used are the NSAIDs. These products inhibit the chemical mediators of fever production and allow normal thermoregulation. They do not block the production of endogenous pyrogens.[2] These products are relatively safe, although acetylsalicylic acid is potentially very toxic to the cat (cyclooxygenase-2 [COX-2] inhibitors are relatively safe) and animals with gastrointestinal ulceration or renal disease should not receive these drugs. Dipyrone, an injectable nonsteroidal antiinflammatory drug sometimes used in cats, may lead to bone marrow suppression, especially when given over a prolonged period.

Total body cooling with water, fans, or both, in a febrile patient will reduce body temperature; however, the thermoregulatory center in the hypothalamus will still be directing the body to increase the body temperature. This may result in a further increase in metabolic rate, oxygen consumption, and subsequent water and caloric requirements. Unless a fever is life threatening, this type of nonspecific therapy is counterproductive.

Glucocorticoids block the acute phase response, fever, and most other parts of this (adaptive) response. In general, their use should be reserved for those patients in whom the cause of the fever is known to be noninfectious and blocking the rest of the acute phase response will not be detrimental (and may prove beneficial). The most common indications include some immune-mediated diseases in which fever plays a significant role and glucocorticoid therapy is often part of the chemotherapeutic protocol (e.g., immune-mediated hemolytic anemia, immune-mediated polyarthritis).

Phenothiazines can be effective in alleviating a true fever by depressing normal thermoregulation and causing peripheral vasodilation. The sedative qualities of the phenothiazines and their potential for hypotension caused by the phenothiazines should be considered before administration to the febrile patient.

5.10 THE FEBRILE INTENSIVE CARE PATIENT

Fever is a common problem in critically ill veterinary patients. The clinician must attempt to exclude noninfectious causes and then determine the infection site and likely pathogens in those with infections. Intensive care patients frequently have both infectious and noninfectious causes of fever, which necessitates a systematic and comprehensive diagnostic approach. Altered immune function, indwelling catheter devices, and more invasive monitoring and treatment approaches put these patients at high risk for inflammation and infection.

Noninfectious causes of fever in intensive care patients commonly include phlebitis or thrombophlebitis, postoperative inflammation, posttransfusion reactions, pancreatitis, hepatitis, cholecystitis, aspiration pneumonitis, acute respiratory distress syndrome, and neoplastic processes.

Nosocomial infection in critically ill patients is an important cause of new-onset fevers. Although incidence studies have not been performed in veterinary patients, the reported range in people is 3% to 31%. Commonly implicated sources include the lungs (aspiration or ventilator-associated pneumonia), bloodstream, catheters, incisions, and the urinary tract. An initial diagnostic evaluation might include a complete blood count, thoracic and abdominal imaging, and close inspection of all catheter sites or incisions. Additional diagnostic tests that might be indicated include culture and sensitivity testing of blood, urine, airway fluid, pleural or peritoneal effusions, postoperative incisions, cerebrospinal fluid, joint fluid, nasal discharge, and/or diarrhea.

Antibiotics are indicated for the febrile patient only when a specific pathogen is known or strongly suspected.[2] The use of antibiotics in these patients without knowledge that a microbial agent is causing the fever can lead to bacterial resistance (see Chapter 194, Antimicrobial Use in the Critical Care Patient). If there is no obvious source of infection and the patient is not deteriorating or neutropenic, antibiotic additions or changes should be delayed until more definitive information is obtained.

6 Chapter 6 Hypotension

Jeffery P. Simmons, DVM, MS, DACVECC

James S. Wohl, DVM, MPA, DACVIM, DACVECC

6.1 Key Points

- Blood pressure is a combination of the effects of various elements. These include heart rate, stroke volume, and systemic vascular resistance.
- Hypotension occurs when at least one of the controls of blood pressure is overcome or neutralized.
- Treatment of hypotension involves treating the underlying cause and targeting the patient's normal control mechanisms.

6.2 INTRODUCTION

Hypotension, or low arterial blood pressure, is not a disease. Instead, hypotension is a clinical manifestation of many different diseases. Although a wide variety of diseases can cause hypotension, it results from a failure of common regulatory mechanisms. Understanding these mechanisms helps to guide the diagnosis and treatment of hypotensive disorders.

6.3 COMPONENTS OF BLOOD PRESSURE

6.3.1 Physiology of Blood Pressure

Blood pressure is the force that the flow of blood puts on the walls of the vessels. The three measurements of arterial blood pressure are systolic arterial pressure (SAP), diastolic arterial pressure (DAP), and mean arterial pressure (MAP). SAP and DAP measurements correspond to the respective phase of the cardiac cycle. MAP equates to overall pressure throughout the cardiac cycle. Because most of the cardiac cycle is spent in diastole, so too most of the mean blood pressure is affected by the diastolic blood pressure. This can be demonstrated by one of the formulas used to calculate MAP: $\text{MAP} = ([\text{SAP} - \text{DAP}] \div 3) + \text{DAP}$. When considering the perfusion pressure of organs, the MAP is more important than either SAP or DAP.[1,2] However, coronary perfusion occurs during diastole.

The cardiovascular determinants of blood pressure are cardiac output and systemic vascular resistance (SVR). Therefore blood pressure can be represented by the following formula:

$$\text{BP} = \text{CO} \times \text{SVR}$$

where *BP* is blood pressure, *CO* is cardiac output, and *SVR* is systemic vascular resistance. *Cardiac output* is the product of the heart rate and the stroke volume ($\text{CO} = \text{HR} \times \text{SV}$). *Stroke volume* is the amount of blood ejected with each heartbeat and is affected by the preload, contractility, and afterload.[1] *Vascular resistance* refers to the effects of vascular tone and blood viscosity on flow through a blood vessel. Resistance to blood flow through a vessel increases as the blood becomes more viscous and as the vessel becomes more constricted. Thus hypotension is typically the result of a decrease in the heart rate, stroke volume, the systolic vascular resistance of the entire arterial vasculature, or, more commonly, a combination.[2]

6.3.2 Pathophysiology of Blood Pressure

Within physiologic limits, neural, hormonal, and local metabolites regulate the control of systemic blood pressure. All blood vessels containing smooth muscle are innervated by fibers of the sympathetic arm of the autonomic nervous system. Sympathetic fibers innervating resistance vessels are noradrenergic and vasoconstricting in function, except in the skeletal muscle, where sympathetic fibers are cholinergic and vasodilatory. Noradrenergic fibers course through the adventitia of arterioles and release the neurotransmitter norepinephrine in a persistent or tonic fashion. Intracellular events following receptor binding of norepinephrine result in contraction of the smooth muscle. Constriction of resistance vessels is mediated by an increase in the frequency of sympathetic noradrenergic release of norepinephrine. In contrast, vasodilation results from a decrease in the rate of tonic sympathetic discharge of norepinephrine.[1-3]

Sympathetic noradrenergic innervation of cardiac muscle mediates increases in heart rate (chronotropic effect) and force of contraction (inotropic effect). Cholinergic fibers carried in the vagus nerve mediate a decrease in heart rate and oppose the chronotropic effects of sympathetic discharge. Both sympathetic and vagal fibers discharge in a tonic fashion, although vagal tonic discharge predominates at rest.[1,2]

The rate of tonic sympathetic discharge is controlled by a group of neurons in the medulla oblongata called the *vasomotor center*. Vasomotor center neurons activate sympathetic preganglionic neurons on the intermediolateral gray matter of the spinal cord. These fibers leave the spinal cord and converge at sympathetic ganglia. Postganglionic nerves arise from the sympathetic ganglia and terminate in the adventitia of blood vessels. Stimulation of vasomotor center neurons occurs directly during hypoxia and hypercapnia. The resultant increase in sympathetic tonic discharge leads to a rise in systemic blood pressure.

The vasomotor center receives afferent fibers from arterial and venous baroreceptors and from carotid and aortic chemoreceptors. Baroreceptors are stretch receptors located in the left atrium, aortic arch, and carotid sinus. Upon distention or increased pressure in these structures, baroreceptor discharges are increased, leading to inhibition of the sympathetic nervous system and activation of the parasympathetic nervous system. This results in vasodilation, bradycardia, and a decrease in contractility in an attempt to decrease MAP. Conversely, when hypotension is present, the rate of baroreceptor discharge decreases, and this minimizes the inhibitory (vasodilatory) influence on the vasomotor center results in activation of the sympathetic nervous system and inhibition of the parasympathetic nervous system. This feedback system controls arterial blood pressure within physiologic limits of approximately 50 mm Hg and 150 mm Hg.[3] Beyond these limits, the rate of baroreceptor discharge has been maximized or minimized, respectively, and cannot cause a further change in blood pressure. 27 28

Local hypoxia or hypercarbia (acidosis) resulting from arterial hypotension stimulates chemoreceptors in the carotid sinus and aortic bodies. Afferent fibers from the chemoreceptors stimulate the vasomotor center and result in vasopressor and tachycardic responses. The chemoreceptor feedback system is less important than the baroreceptor reflex for acute changes in blood pressure.[4,5]

Stretch receptors in the atria and pulmonary artery respond to distention of the venous system. Stimulation of these stretch receptors results in inhibition of the vasomotor center, vasodilation, and a decrease in blood pressure. Similar to what occurs with the baroreceptors of the arterial system, the absence of venous distention and increased atrial filling pressure removes this inhibitory influence on the vasomotor center.

Circulating hormones released during inflammation have vasodilating properties on resistance vessels.[5,6] Adrenal medullary norepinephrine and epinephrine, vasopressin, and angiotensin II are examples of circulating hormones that have vasoconstricting properties on vascular smooth muscle. Metabolites derived from endothelial cells, inflammatory cells, and platelets exert a paracrine effect on vasomotor tone and can influence systemic blood pressure. Prostacyclin is a metabolite of arachidonic acid produced by endothelial cells. Prostacyclin inhibits platelet aggregation and causes vasodilation. Nitric oxide (NO) is a gaseous molecule derived from arginine within endothelial cells. There is a tonic production and release of NO in the presence of the calmodulin-dependent enzyme NO synthase in the cell membrane. This constitutive synthesis by NO synthase is in contrast to inducible production of NO by inducible NO synthase located in the cytosol. Inducible nitric oxide production occurs in response to inflammatory stimulation. Both forms of NO cause vascular smooth muscle relaxation by activating guanylyl cyclase. Various cytokines (interleukin [IL]-1B, IL-2, IL-6, tumor necrosis factor, and interferon-γ) and lipopolysaccharide derived from the cell membrane of gram-negative bacteria are also potent inducers of cytosolic NO synthase.[6,7]

Thromboxane A_2 and endothelins are metabolites that cause vasoconstriction of vascular smooth muscle. Thromboxane A_2 is synthesized from arachidonic acid in the presence of phospholipid A_2 by platelets. In addition to facilitating platelet aggregation, thromboxane A_2 is a vasoconstricting agent. Endothelins are a group of vasoconstricting polypeptides produced by endothelial cells. When administered intravascularly in experimental animals, endothelins produce an initial fall in blood pressure followed by a prolonged pressor response. Endothelins also have positive inotropic and chronotropic properties.

The baroreceptor-mediated increase in sympathetic output is the initial and most important physiologic response to hypotension. Although adrenal medullary secretion of catecholamines is increased, it is the local release of norepinephrine by postganglionic nerve fibers at the arteriolar level that is responsible for the generalized vasoconstrictor response. Vasoconstriction is greatest in the skin, kidneys, and viscera, shunting blood to the systemic circulation. The brain and heart experience vasodilation in an attempt to maximize blood flow to these vital organs. Increased circulating levels of angiotensin II, aldosterone, and vasopressin also assist the pressor response by direct vasoconstriction or expansion of intravascular volume (see Chapter 177, Vasopressin).

In refractory shock, hypotension persists despite physiologic compensation and an adequate intravascular fluid volume. Vascular spasm or extreme vasodilation of precapillary arterioles, blunting of vasomotor function due to prolonged cerebral ischemia, increased capillary permeability and fluid loss, and myocardial dysfunction result from persistent tissue hypoxia. Distributive (or vasogenic) shock, a common result of diseases such as sepsis or anaphylaxis, is associated with extreme vasodilation of some vascular beds and vasoconstriction in other tissues. Vasoplegia is the lack of responsiveness of blood vessels to physiologic regulatory mechanisms. Overproduction of NO, depletion of endogenous vasopressin, downregulation of catecholamine receptors, and disruption of vascular smooth muscle calcium metabolism are thought to be responsible for vasoplegia and refractory shock.

Cardiogenic causes for hypotension may also occur. This can occur with either primary or secondary cardiac diseases.[1,3] Primary cardiac diseases occur when the pathologic process originates within the heart, as seen in dilated cardiomyopathy or third-degree atrioventricular block. Secondary cardiac diseases occur when pathology originates outside the heart, but either suppresses normal heart function or causes secondary sites of pathology in the heart. Diseases that induce systemic inflammatory response syndrome, for instance, may cause the release of cardiac suppressing factors or decrease the heart's response to sympathetic nervous system stimulation.[4]

6.4 MEASURING BLOOD PRESSURE

6.4.1 Normal Values

Because MAP is most closely related to the overall perfusion pressure, hypotension is best identified as an abnormally low MAP, typically defined as less than 60 mm Hg (Table 6-1). At this pressure, the ability of the kidney to maintain glomerular filtration rate is impaired and cerebral perfusion may be compromised. Because there is no exact correlation of systolic or diastolic pressure to MAP, these values should be used cautiously and are not as consistent in peripheral vessels. Thus blood pressure in the aorta can be approximated by femoral or dorsal pedal arterial blood pressure, but much greater variation occurs with systolic and diastolic blood pressures (see Chapter 203, Hemodynamic Monitoring).

Table 6-1 Normal Arterial Blood Pressure Values in Dogs and Cats

	Dogs	Cats
Systolic arterial pressure	90 to 140 mm Hg	80 to 140 mm Hg
Diastolic arterial pressure	50 to 80 mm Hg	55 to 75 mm Hg
Mean arterial pressure	60 to 100 mm Hg	60 to 100 mm Hg

28

29

6.4.2 Direct Measurement

Blood pressure can be measured either directly or indirectly, but direct measurement is more accurate. To measure directly, a catheter must be placed in an artery (most commonly the dorsopedal or femoral artery) and connected to a pressure transducer that allows for continuous measurement and reading of SAP, DAP, and MAP. In addition, the catheter may be used for arterial blood sampling and analysis.

The disadvantages of this method are the increased technical difficulty, invasiveness, cost of the equipment, and the risk of thrombosis, bleeding, inflammation, or infection (see Chapter 49, Arterial Catheterization). Despite these risks, direct blood pressure measurement is often indicated in unstable critically ill patients.[2,8]

6.4.3 Indirect Measurement

Indirect blood pressure measurement techniques are generally less expensive, less time consuming, and less technically demanding. However, they are usually less accurate in very small animals or those suffering from hypotension, peripheral edema, vasoconstriction, and arrhythmias. Although there are multiple methods for measuring blood pressure indirectly, all involve placing a pressure cuff device over the artery. To maximize accuracy, the appropriate-sized cuff must be used (width should be 40% of the circumference of the leg). The different techniques have various benefits and disadvantages that will be discussed with a description of each.

6.4.3.1 Doppler Ultrasonography

Doppler ultrasonography involves using a piezoelectric crystal placed on a peripheral artery to determine flow throughout that artery. Shaving the area and using ultrasonography gel on the probe ensure adequate contact over the artery. The crystal probe is connected to an amplifier that converts the ultrasonic waves to sound waves. A blood pressure cuff connected to a sphygmomanometer is then placed proximal to the probe, and the cuff is inflated until the artery is fully occluded, causing a loss of sound. The pressure of the cuff is reduced slowly and when the sound returns, the pressure of the cuff correlates to the SAP. The pressure at which the sound does not change is theoretically equal to DAP. However, this is a very subjective method for determining diastolic pressure.[2,8]

The Doppler method is the most accurate of the indirect methods for patients that are hypotensive or weigh less than 10 kg. Other advantages include lower cost and portability. Disadvantages include the inability to determine DAP, and thus MAP, and inaccurate readings in smaller animals compared with direct measurement. Values obtained with this method in cats may be lower by 10 to 15 mm Hg than SAP obtained from direct methods, and may therefore more closely approximate MAP.[2,8,9]

6.4.3.2 Oscillometric Sphygmomanometry

Oscillometric sphygmomanometry involves the connection of a cuff to a device that detects oscillations produced by changes in artery wall diameter during blood flow. Inflating the cuff collapses the artery. As the cuff is deflated, the amplitude of the oscillations increases at systolic pressure, reaches a maximum at MAP, and decreases at the diastolic pressure. The MAP is typically measured, but the systolic and diastolic pressures are calculated. Most machines have an automatic timer for performing repeated measurements and an alarm for dangerously low or high readings. Other advantages include ease of use and a measured MAP. Disadvantages are the cost of the machine and decreased accuracy compared with direct measurements. Accuracy is most affected when variation in blood pressure occurs from beat to beat, as seen with stress or with movement. Other causes of inaccuracy include small patient size, vasoconstriction, and arrhythmias.[2,8]

6.4.3.3 Photoplethysmography

Photoplethysmography uses infrared radiation to measure blood volume. This blood volume is held constant by the machine and thus cuff pressure equals intraarterial pressure, with a displayed waveform that is proportional to the strength of the signal. The sensor is designed for human fingertips and therefore may be useful only in small dogs and cats. Also, pigmentation may affect the sensor's ability to acquire an accurate measurement. Advantages include its ability to measure beat-to-beat variation in blood pressure, and disadvantages include its limited usefulness in awake and larger animals.[2,8]

6.5 CLINICAL SIGNIFICANCE OF HYPOTENSION

The clinical signs and significance of hypotension depend on the underlying cause, severity, and duration. In general, decreased blood pressure reduces organ perfusion pressure, although there is not a linear correlation of blood pressure to organ blood flow.[1] The most severe clinical signs are associated with organ failure caused by the decrease in oxygen delivery. Manifestations may include, but are not limited to, acute renal failure, melena, vomiting, arrhythmias, mentation changes, tachypnea, and coagulopathies.

Clinical signs that are seen commonly in hypotensive animals include tachycardia, abnormal pulse quality (weak or bounding), pale mucous membranes, slow capillary refill time, mental dullness, hypothermia, cold extremities, decreased urine output, and weakness.[2] Mucous membranes in dogs with sepsis or systemic inflammatory response syndrome (SIRS) are often injected rather than pale. Cats with hypotension due to sepsis or SIRS often have bradycardia and rarely have injected mucous membranes.[2]

6.6 BASICS OF THERAPY

The most important aspect of treating a hypotensive patient is to address the underlying cause if possible. It is of utmost importance to differentiate between primary cardiogenic causes and other causes of hypotension (Table 6-2). Primary cardiogenic causes such as severe arrhythmias and dilated cardiomyopathy do not respond to fluid therapy, often worsen following fluid administration, and may result in severe pulmonary edema. Cardiogenic causes are often differentiated based on physical examination, thoracic radiography, electrocardiography, and echocardiography. If cardiogenic causes are suspected, specific therapy may include positive inotropic medications, diuretics, and even vasodilatory agents (see Chapter 35, Cardiogenic Shock).

Once primary cardiogenic disease is excluded, the general therapy for hypotension, beyond treating the specific
disease, usually begins with aggressive intravenous fluid therapy. The goal of fluid therapy is to increase preload, 29
stroke volume, and cardiac output and to correct specific deficits (such as anemia), if present (see Chapter 65, Shock 30
Fluids and Fluid Challenge).

Table 6-2 Causes of Hypotension and Recommended Diagnostic Modalities

Cause of Hypotension	Sample Diseases	Diagnostic Modalities
Cardiogenic		
Primary	Cardiomyopathy Valvular disease Arrhythmias SIRS-sepsis Electrolyte abnormalities Severe hypoxia Severe acidosis or alkalosis	*General:* Radiographs, ECG, CBC, serum chemistry analysis *Special:* Echocardiogram, arterial blood gas analysis, pulmonary capillary wedge pressure, CVP
Secondary		
Decreased Preload		
Hypovolemia	Severe dehydration Addisonian crisis Hemorrhage Burns Effusions Pericardial disease Severe pleural disease GDV Caval syndrome	*General:* CBC, serum chemistry analysis, urinalysis, radiographs *Special:* Pericardiocentesis or thoracocentesis, echocardiogram
Decreased venous return		
Decreased Vascular Tone		
—	SIRS—sepsis Electrolyte abnormalities Severe hypoxia Severe acidosis or alkalosis Anaphylaxis Drug or toxins	*General:* CBC, serum chemistry analysis, arterial blood gas analysis *Special:* Systemic vascular resistance index (pulmonary artery catheter and arterial catheter required)

CBC, Complete blood count; *CVP,* central venous pressure; *ECG,* electrocardiogram; *GDV,* gastric dilatation-volvulus; *SIRS,* systemic inflammatory response syndrome.

If the goals of fluid therapy are met and hypotension persists, the cause of hypotension is either secondary cardiogenic or vasodilatory (see Table 6-2). Treatment of secondary cardiogenic hypotension generally requires inotropic support with β-adrenergic agonists (see Chapters 35 and 176, Cardiogenic Shock and Vasoactive Catecholamines, respectively). Conversely, α-agonists or vasopressin are used to manage vasodilatory hypotension (see Chapters 176 and 177, Vasoactive Catecholamines and Vasopressin, respectively). The choice to use either therapeutic strategy is a clinical decision based on whether poor cardiac output or low systemic vascular resistance is predominantly responsible for the hypotension.

Differentiating between vasodilation and decreased contractility is very difficult without a pulmonary artery catheter and or arterial catheter (see Chapter 203, Hemodynamic Monitoring). Some basic tenets that can be suggested are that low vascular resistance often is accompanied by hyperemic mucous membranes and warm extremities. Secondary cardiogenic causes tend to cause pale mucous membranes and prolonged capillary refill times, but caution must be exercised because compensatory noncardiogenic shock states often appear similar.

Many diseases that cause vasodilation can cause decreased cardiac contractility or vice versa. With that in mind, the decision to manage with an inotrope or vasopressor is often empiric. The decision can be made easier by considering the possible benefits and consequences. If a positive inotrope is given to an animal with vasodilatory shock, potential consequences include arrhythmias and/or vasodilatation. Alternatively, using a vasopressor when decreased cardiac contractility is present will worsen cardiac output by increasing afterload. Clinical judgment and response to empiric therapy are often used to guide vasopressor therapy. Mixed α-agonist and β-agonist therapy may be necessary in animals with hypotension from both cardiogenic and vasodilatory causes.

6.7 CONCLUSION

Understanding hypotension requires knowledge of physiologic regulatory mechanisms and determinants of blood pressure. These control mechanisms reveal how the body responds to diseases that can cause hypotension and how the veterinarian can best treat these patients. Ultimately the treatment for hypotension is to treat the underlying disease. However, the initial treatment for hypotension is often supportive. The appropriate supportive therapy will focus on increasing cardiac output, systemic vascular resistance, or both.

7 Chapter 7 Oliguria

Theresa M. Rieser, VMD, DACVECC

7.1 KEY POINTS

- Oliguria is defined as a decrease in urine production below the minimal acceptable rate of 1 to 2 ml/kg/hr.
- Oliguria can occur as a normal physiologic response or as a manifestation of pathology within the renal system.
- Differentiating between physiologic and pathologic oliguria is essential to making appropriate clinical decisions and assessing the severity of disease.
- Physiologic oliguria is usually characterized by a high urine specific gravity and maximal reabsorption of urine sodium.
- Pathologic oliguria resulting from renal failure is characterized by an inappropriately isosthenuric urine and an increase in fractional excretion of sodium.
- Pathologic oliguria usually is seen with severe renal impairment but also can be seen when urine cannot be eliminated from the body.

7.2 INTRODUCTION

Oliguria is defined as abnormally small production of urine. Normal urine output for the dog and the cat is 1 to 2 ml/kg/hr.[1] Oliguria has been defined as urine output ranging from less than 0.27 ml/kg/hr to less than 1 to 2 ml/kg/hr.[1] Oliguria can be classified as prerenal, renal, or postrenal and may represent either an appropriate physiologic response or a pathophysiologic process. It is essential to differentiate physiologic from pathologic oliguria when making clinical decisions and assessing the severity of disease in a critically ill patient.

7.3 PHYSIOLOGIC OLIGURIA

Physiologic oliguria is an appropriate decrease in urine production in response to physiologic stimuli (Box 7-1). When considering the causes of physiologic oliguria, the concept of effective circulating volume (ECV) is paramount. The ECV refers to the portion of extracellular fluid that is in the arterial circulation and is effectively perfusing tissues. A useful physiologic reflection of ECV is the pressure perfusing the arterial baroreceptors, because changes in pressure (or stretch), rather than volume or flow, is generally perceived at these sites.[2] Reductions in ECV, due to either true loss of volume (i.e., hypovolemia) or perceived low volume (i.e., decreased cardiac output), result in the same physiologic responses.[3]

The ECV is sensed in a variety of locations in the body, including baroreceptors in the aortic and carotid bodies, as well as the afferent arterioles of the kidney.[2] For example, when the ECV is decreased in a hypovolemic animal, the subsequent decrease in baroreceptor stimulation results in a number of physiologic responses. The first and most rapid response is mediated by the sympathetic nervous system and is manifested by an increase in heart rate, contractility, and systemic vascular resistance. In addition to these immediate changes, there is also an increase in the secretion of renin, angiotensin II, arginine vasopressin, and aldosterone. Increased reabsorption of sodium and water, as well as additional vasoconstriction, results. There is also an increase in thirst, which serves to further augment ECV if the patient drinks water.

7.3.1 Box 7-1 Causes of Oliguria

7.3.1.1 Prerenal Oliguria

- Hypovolemia
- Dehydration
- Blood loss
- Third space losses
- Decreased cardiac output
- Congestive heart failure
- Cardiac tamponade
- Sepsis
- Vasodilation
- Sepsis
- Cirrhosis
- Nephrotic syndrome
- Vasodilatory drugs

7.3.1.2 Renal Oliguria

- Acute tubular necrosis
- Ischemia

Nephrotoxicity

Chronic renal failure (end stage)

7.3.1.3 Postrenal Oliguria

Ureteral obstruction

Urethral obstruction

Urinary tract rupture

Oliguria that occurs in response to a decrease in ECV is an appropriate physiologic response and is not a result of acute renal failure. It is important to remember that although this response to a decrease in ECV is appropriate, it may prove maladaptive in certain clinical situations, such as congestive heart failure. In most instances of physiologic oliguria, a urinalysis will reveal a maximally concentrated urine (specific gravity >1.040) and a fractional excretion of sodium of less than 1%.[2,4-6] However, these changes may not be present if the animal has been receiving diuretics (e.g., furosemide or mannitol), has inappropriate neurohormonal abilities (e.g., hypoadrenocorticism), or suffers from a disease causing hyperosmolality (e.g., diabetes mellitus). 31

32

7.4 PATHOLOGIC OLIGURIA

Pathologic oliguria typically is seen with severe renal injury. The decrease in urine output in this instance is a reflection of the decrease in glomerular filtration rate (GFR) in the profoundly diseased kidney. Postrenal diseases such as urethral obstruction can also result in oliguria.[1,4] In addition to the common causes for postrenal obstruction, such as stones or mucous plugs, less common causes including neoplasia, strictures, and urinary bladder herniation should be considered.[6]

The first task for the clinician is to determine whether oliguria is pathologic or nonpathologic. As discussed earlier, patients with physiologic oliguria have decreased urine output as a result of maximal water and sodium reabsorption by the kidney. With renal failure–induced oliguria, there is a decrease in GFR and often a defect in sodium reabsorption. In animals with acute tubular necrosis, a number of pathologic processes contribute to the impairment of renal function and the ultimate decrease in GFR and urine output. These include increases in tubular cell apoptosis, sloughing of tubular cells into the tubular lumen, alterations in tubular cell membrane polarity, loss of the integrity of tight junctions between renal tubular cells, increased intracellular calcium concentration, obstruction of tubular lumens with cellular debris and sloughing tubular cells (these form the coarse granular casts that are a hallmark of acute tubular necrosis), an increased number of inflammatory mediators, and alterations of renal vascular tone[7] (see Chapter 135, Acute Renal Failure).

7.5 APPROACH TO THE OLIGURIC PATIENT

When evaluating a patient with suspected oliguria, the volume of urine output must first be determined. This is best accomplished by performing a quantitative measurement of urine output using a closed urine collection system. If this is not possible, useful information can be gleaned using frequent evaluations of the patient's weight and measurements of urine voided onto diapers (by weight). If urine output is found to be less than 1 to 2 ml/kg/hr, the clinician must determine if the observed oliguria is physiologic or pathologic. An assessment of the physical parameters of volume status such as skin turgor and mucous membrane moisture may be helpful, but it is important to remember their limitations.[8] If a closed urinary collection system is in place, it should be assessed to confirm that it is patent and positioned properly. Mean arterial blood pressure should be measured; a decrease in the mean arterial blood pressure below 70mm Hg will result in a decrease in both renal blood flow and GFR.[2] This prerenal decrease in renal perfusion will result in a decrease in urine output, but it does not equate to acute renal failure. Measurements of lactate levels, capillary refill time, and core-toe web temperature will provide information about perfusion that can be helpful in determining the difference between prerenal and renal oliguria. In animals with questionable volume status, central venous pressure monitoring may also be used to guide fluid therapy. (See Chapter 203, Hemodynamic Monitoring.)

One of the most useful laboratory tests in the evaluation of an oliguric patient is the urinalysis. A full urinalysis, including both urine dipstick testing and sediment evaluation, should be performed. In addition, the calculation of fractional excretion of sodium may be of great value (Box 7-2). In any critically ill patient, it is prudent to submit a urine culture in addition to the urinalysis because pyelonephritis can lead to acute renal failure. Animals with a decreased ECV will frequently have a high urine specific gravity (>1.035). In addition, the fractional excretion of sodium is usually <1.0%; this reflects the drive to maximally reabsorb sodium, and thus water, to augment the ECV. By contrast, the patient with renal oliguria will have an isosthenuric urine and an increase in fractional excretion of sodium.[4-7] This reflects a tubular insult or neurohormonal dysfunction that has caused impaired water and sodium reabsorption. The urine fractional excretion of sodium is a useful test, but there can be overlap in patients that have received diuretics, suffer from a hyperosmolal disease state (e.g., diabetes mellitus), or have acute tubular necrosis in addition to a chronic disease that promotes sodium reabsorption.[4,5,7] Other indicators of acute tubular necrosis include glucosuria despite a normal blood glucose concentration and the presence of coarse granular casts within the urine sediment. Proteinuria and hematuria may also be present.[6,7]

7.6 INTERVENTIONS FOR THE OLIGURIC PATIENT

When caring for a patient with physiologic oliguria, treatment should be tailored to the underlying problem (see Chapters 135 and 180, Acute Renal Failure and Diuretics, respectively). For example, if the animal is dehydrated secondary to severe vomiting and diarrhea, therapy should be directed at replacing the volume deficits and correcting the cause of the vomiting and diarrhea. If a decrease in cardiac output is suspected, therapy should be directed toward that process.

A variety of management strategies have been recommended for renal oliguria. A great deal of effort has been focused on interventions that convert oliguria to nonoliguria, because oliguria is a negative prognostic indicator and is difficult to manage medically.[9] One of the mainstays of therapy in the oliguric patient has been loop diuretics such as furosemide. The logic behind this therapy is that increasing the volume of ultrafiltrate in the tubular lumen will help to flush out tubular debris that otherwise may obstruct the lumen and contribute to further damage. In addition, because furosemide inhibits the Na^+-K^+-$2Cl^-$ pump of the ascending limb of the loop of Henle, it was thought that the subsequent decrease in renal tubular energy requirements would also be of benefit. Many studies have been done to investigate the usefulness of furosemide, but none of them has shown a clear therapeutic benefit.[9]

A second commonly used therapy for the oliguric patient is the osmotic diuretic mannitol. Like furosemide, mannitol increases the volume of ultrafiltrate and thus may be of benefit in flushing debris from the tubular lumen. 32 33

In addition, mannitol has free-radical scavenging capabilities. The production of oxygen free-radical species has been implicated in the progression of acute tubular necrosis, so scavenging of these agents would theoretically be of benefit.[1,7] No human or veterinary clinical trials have shown this to be the case.[1] Mannitol should be used with caution because it can result in aggressive expansion of the vascular volume and volume overload if it is not excreted.

7.6.1 Box 7-2 Calculation of the Fractional Excretion of Sodium

$$FE_{Na} = \frac{U_{Na} \times P_{Cr}}{P_{Na} \times U_{Cr}} \times 100$$

FE_{Na} = fractional excretion of sodium

U_{Na} = urine sodium concentration

P_{Cr}= plasma creatinine concentration

P_{Na}= plasma sodium concentration

U_{Cr}= urine creatinine concentration

A final treatment of the oliguric patient has traditionally been dopamine. Dopamine is a catecholamine that exerts dopaminergic as well as α-adrenergic and β-adrenergic effects. In both human and veterinary medicine, low dosage (<5 μg/kg/min) administration has been advocated to increase renal blood flow and urine output, with the goal of either preventing or reversing oliguria.[1] Unfortunately, the theoretical benefits of dopamine have not been realized clinically and the recommendation in the human literature is against the use of dopamine at a “renal dosage.”[5,7] There are no clinical trials investigating the efficacy of dopamine in veterinary patients with renal failure.

Additional therapies under investigation for the treatment of acute renal failure include fenoldopam (a selective DA-1 receptor agonist),[10] calcium channel blockers (diltiazem), and atrial natriuretic peptide.[1,5] At this time, there is insufficient evidence to recommend their use in veterinary medicine.

Animals that are oliguric despite medical therapy may require dialysis as a lifesaving measure (see Chapter 137, Hemodialysis and Peritoneal Dialysis).

8 Chapter 8 Deteriorating Mental Status

Marguerite Knipe, DVM, ACVIM (Neurology)

8.1 Key Points

- Consciousness is maintained by the cerebral cortex and the brainstem's reticular activating system.
- Abnormalities in mentation may be seen with metabolic disease, drug administration or toxicity, and structural brain disease.
- Metabolic disease, drugs, or toxins usually cause signs of diffuse cerebral dysfunction.
- Structural disease or injuries typically affect the brainstem or unilateral cerebrum or thalamus.
- Five patient evaluation parameters that will aid in lesion localization and prognosis for recovery include: (1) level of consciousness, (2) motor activity, (3) respiratory patterns, (4) pupil size and reactivity, and (5) oculocephalic reflex.
- Frequent reassessment of the patient with deteriorating mental status permits detection of changes that may require intervention.

8.2 INTRODUCTION

Altered mentation in patients, whether rapidly or slowly progressive, is of particular concern to the clinician in the intensive care unit. It is seen with primary neurologic disease, neurologic complications of other diseases, many systemic diseases, and with some drugs.[1] A decline in mental status is characterized by decreasing responsiveness and interaction with the environment, although agitation and hyperreactivity can also indicate neurologic dysfunction. Rapid neurologic assessment of the declining patient, coupled with knowledge of underlying disease and medication, will permit the formulation of a list of possible causes, diagnostic and therapeutic plans, as well as an estimation of prognosis.

8.3 STATES OF CONSCIOUSNESS

8.3.1 Normal

The animal has a normal demeanor and interaction with its environment. “Normal” varies among animals, and the clinician relies on the client's knowledge of the pet's behavior, as well as the initial neurologic evaluation. For example, docile behavior in a cat, which most clinicians would consider desirable, may be very abnormal if the owner reports the cat is typically fearful and aggressive.

8.3.2 Obtunded

Obtundation is a state of decreased responsiveness or alertness and is graded as mild, moderate, or severe. Lethargy is similar, reflecting decreased level of consciousness with listlessness and drowsiness. Other terms commonly used to describe altered mentation in humans, such as confusion, delirium, and dementia, are difficult to extrapolate to veterinary medicine because these states are characterized by disorientation to time and place, loss of memory, and disorganized speech, which are difficult to impossible to evaluate in the veterinary patient.[2,3]

8.3.3 Stupor or Semicoma

The patient responds only to vigorous or painful stimuli.

8.3.4 Coma

The patient does not respond consciously to any stimuli. Segmental spinal reflexes will be present (in the absence of additional lesions) and possibly exaggerated, and cranial nerve reflexes may be present, depending on the location of the lesion causing the coma.[3,4]

8.4 NEUROANATOMY

Abnormalities in mentation indicate either dysfunction of the reticular activating system in the brain stem or dysfunction of the cerebrum.

8.4.1 Cerebrum

The cerebrum is the region of the brain responsible for the integration of sensory information from the entire body, planning of motor activity, and appropriate responses to this information, emotion, and memory. Functionally distinct regions are present in the cerebral cortex (e.g., occipital lobe associated with vision; temporal lobe associated with auditory function).[5]

8.4.2 Reticular Activating System

The ascending reticular activating system (RAS), or reticular formation, is a network of anatomically and physiologically distinct nuclei in the brain stem that function to “activate” the cerebral cortex and maintain consciousness.[6] Experimentally, stimulation of the RAS in anesthetized cats produced electroencephalogram patterns consistent with the conscious state.[7]

Numerous nuclei in the reticular activating system have projections to the cerebrum, but those in the midbrain, rostral pons, and thalamus are the most important for maintaining consciousness.[2,8] In anesthetized cats, transection of the brain stem at the level of the pons and midbrain produced coma, but transection at the junction of the medulla and cervical spinal cord did not.[9]

8.5 ETIOLOGY OF LESIONS

Lesions causing changes in mentation will be structural, metabolic, or toxic in origin. Clinical signs of diffuse cerebral disease with normal brain stem function are most common with metabolic disease, toxins, or drugs affecting the cerebrum globally (Boxes 8-1 and 8-2). Seizures indicate cerebral cortical dysfunction caused by either 34 extracranial or intracranial disease (see Chapter 98, Seizures and Status Epilepticus). 35 Impairment of the brain stem or thalamus, as well as lateralized cerebral dysfunction (e.g., compulsive circling in one direction, unilateral cortical blindness), is more likely the result of structural disease or injury (Box 8-3).

8.5.1

Box 8-1 Common Metabolic Diseases That May Cause Altered Mentation[2,6]

- Hypoxia (anemia, pulmonary disease, methemoglobinemia)
- Ischemia (cardiac disease, postarrest, hyperviscosity, systemic embolic disease)
- Hypoglycemia
- Hepatic disease (hepatic encephalopathy)
- Renal failure (uremic encephalopathy)
- Endocrine dysfunction (hyperfunction or hypofunction)
  - Pituitary (apoplexy)
  - Thyroid
  - Adrenal (hypoadrenocorticism, pheochromocytoma)
  - Pancreas (diabetes mellitus, especially hyperosmolar)
- Sepsis
- Hyperbilirubinemia (kernicterus)
- Hyperthermia or hypothermia
- Pain
- Central nervous system diseases
  - Continuous seizure activity
  - Postictal state
  - Diffuse meningitis or encephalitis
- Electrolyte or acid-base abnormalities
  - Sodium or water
  - Magnesium
  - Calcium
  - Acidosis (metabolic or respiratory)
  - Alkalosis (metabolic or respiratory)

8.5.2

Box 8-2 Common Drugs That May Cause Altered Mentation[1,2,10]

- Anticonvulsants (barbiturates, bromides)
- Benzodiazepines
- Opiates
- Anesthetic drugs
- Atropine
- Antibiotics (penicillin, cephalosporins, quinolones, aminoglycosides, metronidazole)
- Steroids
- Histamine-2 receptor blockers
- Cardiac glycosides (digitalis)
- Antihypertensives (hydralazine, ACE inhibitors)
- Illicit substances (cannabis, cocaine, amphetamines)

ACE, Angiotensin-converting enzyme.

8.6

EVALUATION

Basic neurologic evaluation of the patient with altered mentation includes assessment of five physiologic variables: (1) level of consciousness or mentation, (2) motor activity, (3) respiratory patterns, (4) pupil size and reactivity, and (5) oculocephalic movements.[2] Coma scales are based on information obtained from these assessments (see Chapter 97, Coma Scales), and knowledge of the pathophysiology affecting these variables will aid in lesion localization and determining progression of disease.

8.6.1

Level of Consciousness

As discussed previously, mentation abnormalities result from structural or metabolic disease affecting the cerebrum or reticular activating system or both. Grading of mentation from normal to comatose and any details specific to the individual patient should be described (e.g., readily opens eyes when name is called).

8.6.2

Motor Activity

The patient may be ambulatory or nonambulatory and may have generalized ataxia, hemiparesis, tetraparesis, or hemiplegia. Obvious gait abnormalities with paresis or paralysis are more indicative of a lesion at, or caudal to, the midbrain, and deficits are ipsilateral to the lesion. Patients with mild or moderate lesions rostral to the midbrain often have minimal gait abnormalities or paresis, although contralateral proprioceptive reactions are absent.[4]

Decerebrate and decerebellate postures are associated with lesions in specific brain regions. Decerebrate rigidity is seen with lesions of the rostral pons and midbrain. Opisthotonus with extensor rigidity of all four limbs is present, and mentation is stuporous to comatose. Decerebellate rigidity may occur with acute cerebellar lesions. Opisthotonus with extensor rigidity of the thoracic limbs and either extension or flexion of the pelvic limbs is present, depending on the location of the cerebellar lesion; the patient should be responsive and have voluntary movement.[3,4]

8.6.2.1 Box 8-3 Structural Lesions That May Alter Mentation

- Neoplasia (primary, secondary)
- Infection (bacterial, fungal, protozoal, viral)
- Inflammation, noninfectious
  - Granulomatous meningoencephalomyelitis
  - Necrotizing encephalitis
- Trauma (hemorrhage, edema, diffuse axonal injury)
- Vascular lesions (infarction, hemorrhage)
- Hydrocephalus, especially if resulting from acute obstruction of cerebrospinal fluid
- Shifts of intracranial structures (herniation), secondary to any of the above

8.6.3 Respiratory Patterns

Some respiratory patterns are associated with lesions in certain areas of the brain (Box 8-4). Animals with brain stem lesions causing respiratory changes have a guarded to poor prognosis.[4] Other diseases must be considered in patients with abnormal ventilation. Hyperventilation can be seen with diabetic ketoacidosis, uremia, hepatic failure, sepsis, and pneumonia. Hypoventilation may result from administration of sedative drugs (especially opiates), generalized neuromuscular disease, and pulmonary disease.[2]

8.6.4 Pupil Size and Reactivity

Pupil size is the result of balance between sympathetic and parasympathetic innervation to the eye. Parasympathetic innervation is particularly important when evaluating for neurologic deterioration because it is mediated through the midbrain and cranial nerve III (loss of parasympathetic innervation results in mydriasis).[4] Most abnormalities of pupil size and pupillary light reflexes are the result of structural lesions of the brain,[6] but metabolic encephalopathies and some drugs (benzodiazepines, opiates) can cause bilateral miosis, whereas parasympatholytic agents (atropine) may cause mydriasis[1,4] (Box 8-5).

8.6.5 Oculocephalic Reflex

Physiologic nystagmus, or “doll's eye” reflex, consists of conjugate eye movements in response to vestibular input 35
(turning the head from side to side). Loss of the oculocephalic reflex occurs with lesions of the medial 36
longitudinal fasciculus in the pons and midbrain, which coordinates functions of cranial nerves III, IV, and VI, which innervate the extraocular eye muscles, and usually indicates a poor prognosis.[4] Lesions of the individual nuclei or cranial nerves III, IV, or VI will also result in an abnormal oculocephalic reflex, but a persistent, nonpositional strabismus will be present in the affected eye.[3] Extreme caution should be taken when manipulating the heads of patients with a history of trauma, until cervical fractures or luxations have been ruled out.

8.6.5.1 Box 8-4 Respiratory Patterns Associated With Intracranial Lesions[1,2,6]

Cheyne-Stokes breathing: Periods of hyperpnea alternating with periods of apnea. Can be seen with diffuse cerebral or thalamic disease and metabolic encephalopathies.

Central neurogenic hyperventilation: Persistent hyperventilation that may result in respiratory alkalosis. Associated with midbrain lesions.

Apneusis: Breathing pauses for a period at full inspiration. Associated with pontine lesions.

Irregular or “ataxic” breathing: Irregular frequency and depth of respiration that typically precedes complete apnea. Associated with lesions of lower pons and medulla.

8.6.5.2 Box 8-5 Pupillary Abnormalities and Lesion Localization[1,4]

Unilateral mydriatic, unresponsive pupil: Loss of parasympathetic innervation to the eye. Indicates destruction or compression of the ipsilateral midbrain or cranial nerve III, often associated with increased intracranial pressure and unilateral cerebral herniation. Rule out unilateral topical ophthalmic atropine or tropicamide.

Bilateral miosis: Can be seen with metabolic encephalopathies or diffuse midbrain compression with increased intracranial pressure, and may precede mydriatic, unresponsive pupils.

Bilateral, mydriatic, unresponsive pupils: Fixed and dilated pupils. Severe, bilateral compression or destruction of the midbrain or cranial nerve III, typically from bilateral cerebral herniation. Grave prognosis.

8.7 DIAGNOSTIC APPROACH

In all patients with abnormal mentation, the clinician should initially assess systemic and metabolic stability. When patients arrive in the ICU acutely ill, physical examination and historical information such as drug exposure, previous or ongoing illness, and possible trauma are invaluable to determining the cause of mentation abnormalities. Routine blood work will evaluate acid-base status, electrolyte values, hematocrit, and liver and kidney function. Additional tests or blood work should be done based on suspicion of underlying disease. Once systemic disease is ruled out and a lesion is localized to the brain, specific neurodiagnostic tests, particularly intracranial imaging with magnetic resonance imaging or computed tomography, and cerebrospinal fluid analysis should be pursued as indicated.

For patients in the ICU with nonneurologic disease that experience a deterioration in mentation, the status of their underlying disease and metabolic state must be reassessed for any recent changes. If no changes have occurred, then neurologic complications of the primary disease should be considered (e.g., vascular event).

For patients in the ICU with known structural brain disease, the most life-threatening cause for a decline in mentation is increased intracranial pressure and herniation of brain structures. Infarction or hemorrhage secondary to the underlying brain lesion is also possible.

8.8 TREATMENT

Because so many systemic and neurologic diseases can cause abnormal mentation, treatment will be based on the underlying cause. If toxin exposure or drug reaction is suspected, supportive care and withdrawal of medication is indicated. The patient's metabolic parameters should be maintained within normal ranges, and in patients with brain disease and suspected increased intracranial pressure, aggressive medical therapy should be instituted (see Chapter 100, Intracranial Hypertension). Most importantly, vigilant and repeated assessment of the patient with altered mental status by the ICU clinicians and staff will permit early detection of changes so that appropriate diagnostic and therapeutic intervention can be implemented.

9 Chapter 9 Tachypnea and Hypoxemia

Timothy B. Hackett, DVM, MS, DACVECC

9.1 KEY POINTS

- Tachypnea may occur with or without hypoxemia in critically ill animals.
- The diagnostic and therapeutic plan is different for patients with tachypnea and hypoxemia than for those with tachypnea in the absence of hypoxemia.
- Diagnostic tests, and even physical examination, may have to wait until a patient has been sedated and stabilized with supplemental oxygen.
- To develop a rational diagnostic and management plan, clinicians should refine their list of differential diagnoses and localize the problem by thorough history of the current illness, signalment, and observation of the patient's breathing pattern.
- The primary mechanisms of hypoxemia include the following: (1) decreased partial pressure of oxygen in the inspired air, (2) hypoventilation, (3) ventilation-perfusion (V_A/Q) mismatch, (4) shunt, and (5) diffusion impairment.

9.2 INTRODUCTION

An increased respiratory rate or tachypnea is almost always evident in the patient with respiratory distress, but the causes of tachypnea are numerous and it may or may not reflect respiratory tract disease. When developing an appropriate therapeutic and diagnostic plan, it is essential to differentiate between tachypneic patients with and those without concurrent hypoxemia. Hypoxemia can be detected with pulse oximetry or arterial blood gas analysis (see Chapter 208, Blood Gas and Oximetry Monitoring).

9.3 TACHYPNEA WITHOUT HYPOXEMIA

Respiratory rate is controlled by the respiratory center in the brainstem in response to numerous afferent pathways, both central and peripheral in origin. These include the cerebral cortex, central chemoreceptors, peripheral chemoreceptors, stimulation of mechanoreceptors in the airways that sense lung inflation and deflation, stimulation of irritant receptors of the airways and stimulation of C-fibers in the alveoli and pulmonary blood vessels that sense interstitial congestion, and baroreceptors that sense changes in blood pressure.[1] Consequently, numerous disease processes can lead to tachypnea in the absence of hypoxemia. These include hyperthermia, pain and anxiety, brain disease, hypotension, metabolic acidosis, hypercapnia, inhaled irritants, and interstitial lung disease. A thorough history, physical examination, and initial blood test results will allow the clinician to determine which of these disease processes is present in most cases, and therapy should be tailored appropriately.

9.4 TACHYPNEA WITH HYPOXEMIA

When the tachypneic patient is determined to be also hypoxemic, the diagnostic and therapeutic approach will need to be tailored appropriately. Respiratory distress in small animals often presents a therapeutic dilemma. Tachypneic hypoxemic patients can be so compromised that diagnostic tests can stress them to the point of respiratory and cardiac arrest. A diagnosis should not come at the expense of the patient. Restraint for catheterization, radiographs, and physical examination may have to wait until the patient is relaxed and breathing more easily.

When an animal has difficulty oxygenating blood, breathing becomes more labored. Although terms such as *dyspnea* or *anxiety* should be avoided in veterinary medicine (our patients cannot tell us they're having difficulty breathing or fear), we should assume that these patients are experiencing tachypnea and orthopnea associated with hypoxemia. This natural response leads to more complications because the stressed patient needs more oxygen and rapid breathing may not be as efficient as relaxed, normal breathing. For this reason, tranquilizers and sedative drugs may prove very useful in the early treatment of respiratory distress.

Inspired oxygen concentration may be increased using a face mask, nasal cannula, or an induction chamber attached to an anesthesia circuit's oxygen supply. Oxygen cages increase inspired oxygen while allowing the clinician time to observe the patient and localize the problem.

It is important to observe the patient, refine the list of differential diagnoses, and determine the nature of the problem. A rapid, shallow (restrictive) respiratory pattern suggests higher than normal elastic forces within the lung. A deep, noisy (inspiratory) pattern is seen with increased airway resistance from airway obstruction. With a restrictive pattern, auscultation can help differentiate pleural space disease (pneumothorax, hydrothorax) from parenchymal diseases (pneumonia, pulmonary edema). Signalment and history can help determine a cause of airway obstruction (brachycephalic airway disease, history of a cough, playing with small toys).[2-4]

A basic understanding of the work of breathing and mechanisms of impaired gas exchange will help the clinician develop a rational diagnostic and treatment plan.

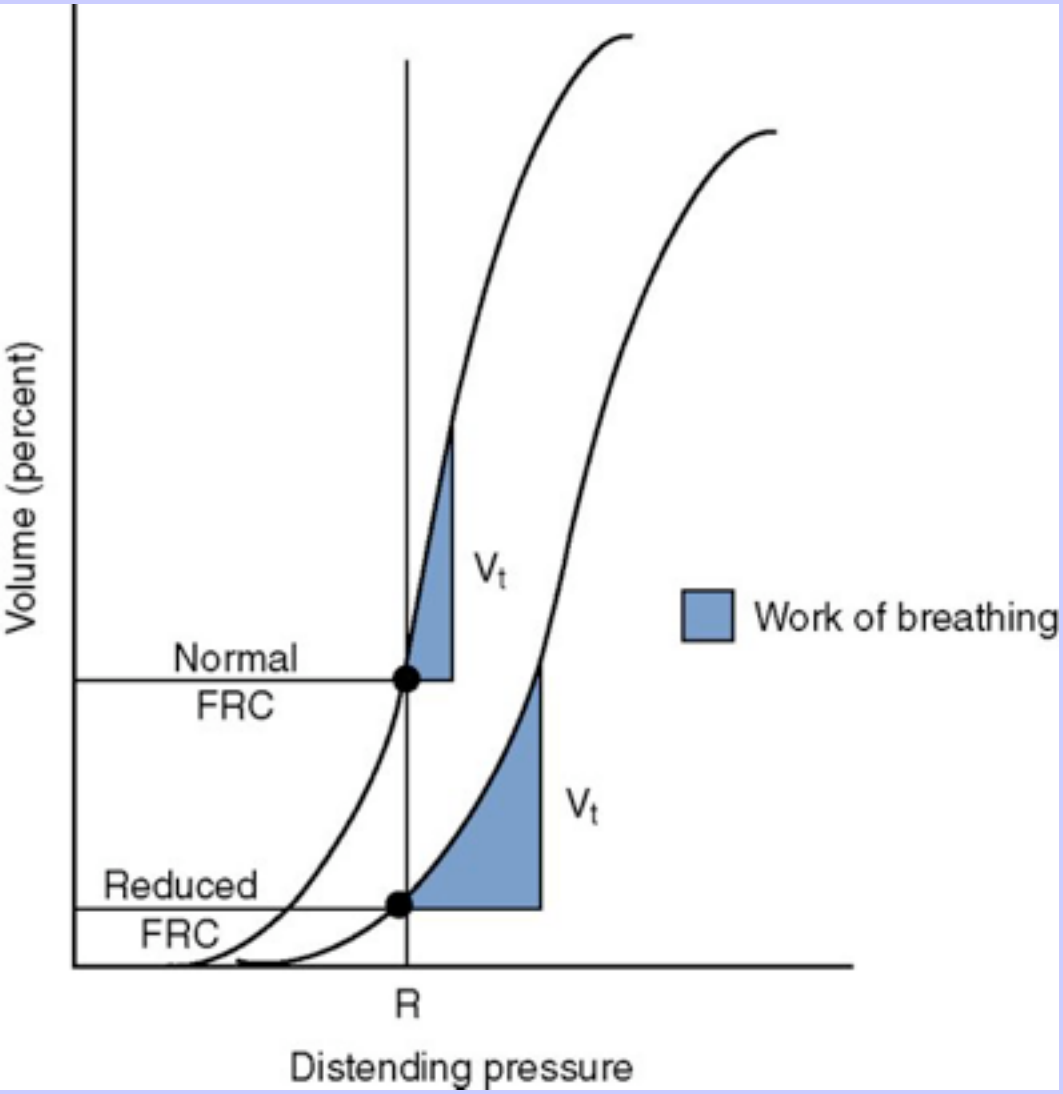
9.5 WORK OF BREATHING

For normal respiration and gas exchange, fresh gas must be brought into the alveoli through the process of alveolar ventilation. The oxygen cost of quiet breathing is extremely small, less than 3% of total resting oxygen consumption. With voluntary hyperventilation (as is seen with respiratory distress), it is possible to increase cost of breathing to 30% of resting oxygen consumption. For animals with obstructive or restrictive lung disease, oxygen cost of breathing can limit their exercise tolerance.[1,5]

Muscles of the respiratory system must overcome two major forces in normal respiration: elastic recoil and airway resistance. The functional residual capacity (FRC) is defined as the volume of air remaining in the lungs after a normal expiration. FRC is the volume of the lungs at rest and is determined by the static properties of the respiratory system.[1,5] Fibrous structures of the lung provide elastic recoil. The fibrous structures of the lung favor pulmonary collapse, while the fibrous structures of the chest wall favor thoracic expansion. The balance between lung elastic recoil and thoracic wall recoil ultimately determines the FRC. The FRC is reduced in patients with reduced lung compliance.[1,5]

To understand how FRC is clinically significant we must understand compliance. Pulmonary compliance is reflected by the slope of the pressure-volume curve (Figure 9-1). The slope of this curve represents the volume change per unit pressure.[1,5] When the slope of this curve is steep, a small change in pressure results in a large change in volume. This makes for efficient ventilation requiring minimal energy to effect gas movement. Diseases affecting pulmonary compliance can increase the work required for normal ventilation. Pulmonary atelectasis, pneumonia, pulmonary edema, fibrosis, and pleural space diseases (causing pulmonary collapse) are examples of conditions resulting in decreased pulmonary compliance.

Figure 9-1 The pressure-volume curve. The steep curve to the left represents a normal lung. At rest *(R)*, the lung volume is a balance between the elastic recoil of the chest wall and the elastic forces of the lung. The lungs are in balance, held open at the steepest portion of the curve. This represents the best pulmonary compliance, where a small change in distending pressure is sufficient to maintain tidal volume (V_t). The curve to the right represents a diseased lung with reduced compliance where the curve and slope of the curve are flatter. This patient needs more distending pressure (work) to effect the same tidal volume. The shaded area represents the work of breathing.



9.6 AIRWAY RESISTANCE

Airway resistance is the pressure difference between the alveoli and the mouth divided by flow rate and is determined by Poiseuille's law: $R = 8\eta l \div \pi r^4$ where R = airway resistance, η = viscosity, l = length, and r = radius. Note the critical importance of tube radius; if the radius is halved, the resistance increases 16-fold. In contrast, doubling the length only doubles resistance. Note also that the viscosity of the gas, but not its density, affects the pressure-flow relationship. The site of most airway resistance is the medium-sized bronchi. The smallest airways contribute very little to resistance, because the combined cross-sectional area of these airways is much larger than that of the intermediate bronchi.[1,5]

Airway resistance is determined by lung volume, bronchial smooth muscle tone, and dynamic airway compression. At lower lung volumes, radial traction supporting the bronchi is lost and airway caliber is reduced. Bronchial muscle contraction narrows airways and increases resistance. Bronchoconstriction is mediated through reflex stimulation of irritant receptors in the upper airways or increased parasympathetic activity. Increased sympathetic tone leads to bronchodilation, as do sympathomimetic drugs such as isoproterenol, epinephrine, and norepinephrine. Dynamic airway collapse is seen with forceful respiration. Sudden changes in intrathoracic pressure can affect the large airways.

9.7 HYPOXEMIA

Hypoxemia occurs when the partial pressure of oxygen in the arterial blood (PaO_2) is less than 80 mm Hg (sea level). There are five primary causes of a reduced PaO_2 in arterial blood:

1. Decreased partial pressure of inspired oxygen (PiO_2)
2. Hypoventilation
3. Ventilation-perfusion (V_A/Q) mismatch
4. Shunt
5. Diffusion impairment

Decreased inspired oxygen, as occurs at high altitudes, causes hypoxemia. In this instance hypoxemia is not due to a pathologic problem. The average barometric pressure (BP) at sea level is 760 mm Hg. PiO_2 is determined by the total BP minus the vapor pressure of water (VP_{H2O}) at body temperature (47 mm Hg at 37° C) times the fraction of inspired oxygen (FiO_2). The FiO_2 of unsupplemented air (room air) is approximately 21%.

$$\begin{aligned}
\mathrm{PiO}_2(\text{sea level}) &= \mathrm{FiO}_2(\mathrm{BP} - \mathrm{VP}_{\mathrm{H_2O}})\\
&= 0.21(760 - 47)\\
&= 150\ \text{mm Hg}\\
\mathrm{PiO}_2(5000\ \text{ft}) &= \mathrm{FiO}_2(\mathrm{BP} - \mathrm{VP}_{\mathrm{H_2O}})\\
&= 0.21(640 - 47)\\
&= 124\ \text{mm Hg}
\end{aligned}$$

Animals living at higher altitudes will compensate by increasing alveolar ventilation. The result is normal oxygenation with a lower partial pressure of carbon dioxide (PCO_2), or mild hyperventilation.[5]

A low PiO_2 can also occur when an animal is connected to a breathing circuit, such as an anesthesia machine, if the 38
oxygen supply to the patient is interrupted. The oxygen source should be the first thing that is evaluated when 39
hypoxemia is identified in the patient on a breathing circuit.

Hypoventilation results in less fresh gas reaching the alveoli (decreasing alveolar ventilation). By bringing less fresh air to the alveoli to dilute waste gases, hypoventilation causes a rise in blood PCO_2; an elevated PCO_2 is by definition hypoventilation. Because the gas exchange surfaces in the lungs are normal, hypoxemia from hypoventilation is corrected by increasing the FiO_2 with supplemental oxygen. There is a linear relationship between PCO_2 and PaO_2. As the PCO_2 rises (hypoventilation), PaO_2 falls. A function of the respiratory exchange ratio, this inverse linear relationship is nearly 1:1. For every torr (mm Hg) the PCO_2 goes up, PaO_2 will go down approximately 1 torr. Arterial PO_2 can fall to extremely low levels only if severe hypoventilation occurs in the patient that is breathing room air.[1,5] Another important metabolic consequence of extreme hypoventilation is respiratory acidosis.

Ventilation-perfusion (V_A/Q) mismatch occurs when ventilation and blood flow are not closely matched in gas exchange units. Normally ventilation and perfusion are closely matched so that blood is directed to well-ventilated alveoli (Figure 9-2). When the V_A/Q is not matched, the result is inefficient gas exchange. Regions of the lung that receive more ventilation than perfusion (high V_A/Q) tend to increase the PaO_2, while areas that receive less ventilation than perfusion (low V_A/Q) will contribute to a lower PaO_2. If regions of the lung are not ventilated at all but are perfused (i.e., the extreme of low V_A/Q), the functional result is a shunt. Pulmonary conditions that cause incomplete alveolar collapse (pneumonia, pulmonary edema, atelectasis) are the most common cause of low V_A/Q.[4,5] Hypoxic pulmonary vasoconstriction describes a reflex vasoconstriction of pulmonary vessels in response to low alveolar oxygen tension. This compensatory reflex serves to reduce perfusion to poorly ventilated alveoli, improving V_A/Q matching and optimizing gas exchange (see Figure 9-2).[4,5]

Figure 9-2 Normal V_A/Q relationship. On the left, normal ventilated alveoli are all perfused equally. On the right, when the second lung unit from the left has reduced ventilation, a corresponding decrease in perfusion (hypoxic pulmonary vasoconstriction) improves the V_A/Q relationship.

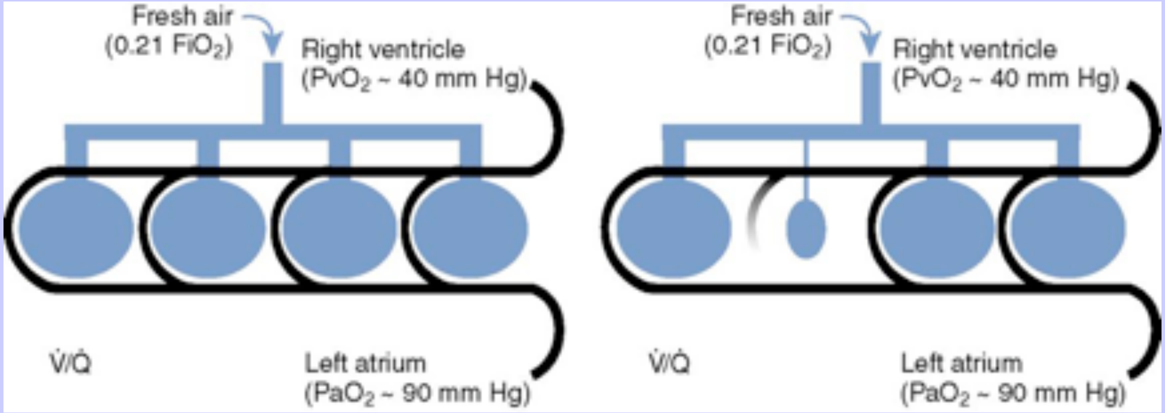


Figure 9-3 In the diagram on the left, the right two lung units have collapsed and are not ventilated. Blood still flows past them, resulting in a shunt. The diagram on the right depicts the same lungs with a higher fraction of inspired oxygen from supplemental oxygen. The partial pressure of oxygen in arterial blood increases minimally (58 mm Hg compared with 52 mm Hg); the patient is still hypoxemic.

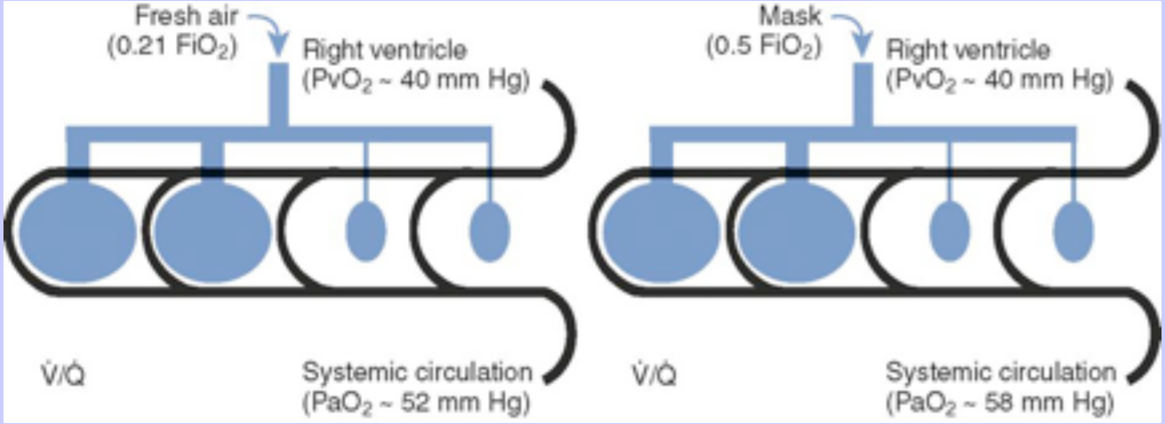

Shunt occurs when venous blood bypasses gas exchange areas of the lung and mixes with oxygenated arterial blood. The venous admixture can result from either cardiac or pulmonary shunt. Examples of cardiac shunt include

Eisenmenger's ventricular septal defect and tetralogy of Fallot. Pulmonary shunt can result from pulmonary masses, complete lung atelectasis, or pulmonary disease causing regions of alveolar collapse and/or obstruction. Shunt is the most important cause of clinically significant hypoxemia, because it is not very responsive to oxygen therapy (Figure 9-3). This is because the oxygen content of the blood perfusing the ventilated alveoli can be increased only minimally with an increased FiO_2 and is insufficient to compensate for the very low oxygen content of the blood perfusing the unventilated alveoli.[1,5]

Diffusion impairment implies that normal equilibration between alveolar gas and pulmonary capillary blood does not occur. Diffusion of oxygen across the alveolar-arterial membrane depends on the concentration difference of oxygen across the membrane and the surface area and thickness of the gas exchange membrane.

In a resting animal, a red blood cell spends ¾ of a second in the pulmonary capillary. Normally the PO_2 of the capillary blood approaches that of the alveolar gas in one third of that time. Strenuous exercise may decrease transit time, but because of the ½-second reserve, normal equilibration can occur. Some diseases and conditions (smoke inhalation, oxygen toxicity) can cause thickening of the blood-gas interface, slowing diffusion to the point that equilibration is incomplete. Hypoxemia caused by diffusion impairment can be corrected by administering supplemental oxygen to the patient, raising the concentration difference.

Carbon dioxide is 20 times more soluble than oxygen. For this reason carbon dioxide retention is not usually a problem with diffusion impairment. PCO_2 is often lower in these patients, because they hyperventilate in an attempt to reverse the hypoxemia. Pulmonary diseases that decrease the area of gas exchange or increase the thickness of the alveolar-arterial membrane can cause impaired gas exchange. Examples of such diseases include pulmonary interstitial fibrosis and chronic emphysema.[4,5]

If gas exchange is impaired, some insight into the responsible mechanism can be gained by noting the response to breathing 100% oxygen. If hypoxemia is caused by hypoventilation or diffusion impairment, oxygen supplementation will rapidly and objectively correct the hypoxemia. If there is no response to supplemental oxygen, then shunt is the most likely mechanism of impaired gas exchange. Low V_A/Q also should be responsive to supplemental oxygen. Clinically however, whenever low V_A/Q is present, pulmonary shunt is almost always also present, so often only a partial response to supplemental oxygen is observed.

9.8 CONCLUSION

Tachypnea may occur with or without concurrent hypoxemia. Evaluation of oxygenation status is essential in the tachypneic patient, because hypoxemia necessitates rapid therapeutic and diagnostic interventions. With an understanding of the work of breathing and the mechanisms of hypoxemia, the critical care clinician can gain insight into the reasons for tachypnea and hypoxemia in the critically ill patient. An obstructive breathing pattern can help bring focus on causes of airway obstruction, and a restrictive breathing pattern should draw our attention to intrathoracic pulmonary parenchymal diseases.

10 Chapter 10 Shock

Armelle M. de Laforcade, DVM, DACVECC

Deborah C. Silverstein, DVM, DACVECC

10.1 KEY POINTS

- Shock is defined as inadequate cellular energy production and most commonly occurs secondary to poor tissue perfusion from low or unevenly distributed blood flow. This leads to a critical decrease in oxygen delivery (DO_2) compared to oxygen consumption (VO_2) in the tissues.
- There are numerous ways to classify shock, and many patients suffer from more than one type of shock simultaneously. A common classification scheme includes hypovolemic, distributive, and cardiogenic causes.
- For all forms of shock except cardiogenic shock, the mainstay of therapy involves rapid vascular access and administration of large volumes of isotonic crystalloid fluids. Studies have not shown a clear benefit of one type of fluid over another; however, failure to administer an adequate volume of fluids may contribute significantly to mortality.
- End points of resuscitation such as normalization of heart rate and blood pressure, improved pulse quality, and resolution of lactic acidosis are necessary to tailor therapy to the individual patient.
- Oxygen therapy and avoidance of stress are key components to the treatment of cardiogenic shock. Sedation and intubation may be required in dyspneic patients who fail to respond to diuretic therapy.

10.2 INTRODUCTION

Shock is defined as inadequate cellular energy production. It most commonly occurs secondary to poor tissue perfusion from low or unevenly distributed blood flow that causes a critical decrease in oxygen delivery (DO_2) in relation to oxygen consumption (VO_2). Although metabolic disturbances (e.g., cytopathic hypoxia, hypoglycemia, toxic exposures) and hypoxemia (e.g., severe anemia, pulmonary dysfunction, methemoglobinemia) can lead to shock, it most commonly results from a reduction in DO_2 secondary to one of three major mechanisms: loss of intravascular volume (hypovolemic shock), maldistribution of vascular volume (distributive shock), or failure of the cardiac pump (cardiogenic shock). Box 10-1 lists all of the functional classes of shock. An index of suspicion based on signalment and a brief history may help differentiate between these various causes of shock. Early recognition of cardiovascular instability, along with a combination of physical examination findings and point of care testing suggestive of reduced perfusion are all that is necessary to initiate therapy. Rapid, aggressive therapy and appropriate monitoring, along with the removal of any underlying causes, are necessary to optimize the chance for a successful outcome.

10.3 CLINICAL PRESENTATION

Hypovolemic shock is commonly associated with internal or external blood loss, or excessive loss of other body fluids (severe vomiting, diarrhea, polyuria, burns). In hypovolemic states, reduced cardiac output due to diminished venous return triggers compensatory mechanisms that attempt to raise the circulating blood volume. An increase in

sympathetic activity causes vasoconstriction, increased cardiac contractility, and tachycardia with a resultant rise in cardiac output. Extreme vasoconstriction and microvasculature alterations induce mobilization of fluid from the interstitial and extracellular spaces to the intravascular space. Additionally, a reduction in renal blood flow activates the renin-angiotensin-aldosterone system, which further upregulates the sympathetic nervous system and causes sodium and water retention via the production of both aldosterone and antidiuretic hormone, respectively. Since the net effect of these responses is to increase intravascular volume, clinical signs of shock may be subtle initially, characterized by mild to moderate mental depression, tachycardia with normal or prolonged capillary refill time, cool extremities, tachypnea, and a normal blood pressure. Pulse quality is often normal, and this stage is generally referred to as "compensated shock." With ongoing compromise of systemic perfusion, compensatory mechanisms 41
are inadequate and often begin to fail. Pale mucous membranes, poor peripheral pulse quality, depressed mentation, 42
and a drop in blood pressure become apparent as the animal progresses to decompensated shock. Ultimately, reduced organ perfusion results in signs of end organ failure (e.g., oliguria) and ultimately death.

10.3.1

Box 10-1 Functional Classifications and Examples of Shock

Hypovolemic: A decrease in circulating blood volume

Hemorrhage

Severe dehydration

Trauma

Cardiogenic: A decrease in forward flow from the heart

Congestive heart failure

Cardiac arrhythmia

Cardiac tamponade

Drug overdose (anesthetics, β-blockers, calcium channel blockers, etc.)

Distributive: A loss of systemic vascular resistance

Sepsis

Obstruction (heartworm disease, saddle thrombosis)

Anaphylaxis

Metabolic: Deranged cellular metabolic machinery

Hypoglycemia

Cyanide toxicity

Mitochondrial dysfunction

Cytopathic hypoxia of sepsis

Hypoxemic: A decrease in oxygen content in arterial blood

Anemia

Severe pulmonary disease

Carbon monoxide toxicity

Methemoglobinemia

Rather than causing an absolute reduction in circulating blood volume/hypovolemia, diseases such as sepsis and gastric dilatation and volvulus lead to maldistribution of blood flow and result in distributive shock. Dogs with sepsis or a systemic inflammatory response syndrome (SIRS) can show clinical signs of hyperdynamic or hypodynamic shock (seeChapters 11 and 107, Systemic Inflammatory Response Syndrome and Septic Shock, respectively). The initial hyperdynamic phase of sepsis or SIRS is characterized by tachycardia, fever, bounding peripheral pulse quality and hyperemic mucous membranes secondary to cytokine (e.g., nitric oxide)-mediated peripheral vasodilatation. This is often referred to as vasodilatory shock. If septic shock or SIRS progresses unchecked, a decreased cardiac output and signs of hypoperfusion often ensue due to cytokine effects on the myocardium or myocardial ischemia. Clinical changes may then include tachycardia, pale (and possibly icteric) mucous membranes with a prolonged capillary refill time, hypothermia, poor pulse quality, and a dull mentation. Hypodynamic septic shock is the decompensatory stage of sepsis, and without intervention will result in organ damage and death. Lastly, the gastrointestinal tract is the shock organ in dogs, so shock often leads to ileus, diarrhea, or melena.

The hyperdynamic phase of shock is rarely recognized in cats. Also, in contrast to dogs, changes in heart rate in cats with shock are unpredictable; they may exhibit tachycardia or bradycardia. In general, cats typically present with pale mucous membranes (and possibly icterus), weak pulses, cool extremities, hypothermia, and generalized weakness or collapse. In cats, the lungs seem to be the organ most vulnerable to damage during shock or sepsis and signs of respiratory dysfunction are common.[1-3]

Dogs with gastric dilatation-volvulus may have normal circulating blood volume; however, compression of the major vessels secondary to severe gastric dilatation causes decreased venous return and reduced cardiac output. This is a form of relative hypovolemia. Although the classifications of shock are useful in understanding the underlying mechanism of cardiovascular instability, it is important to remember that different forms of shock can occur simultaneously in the same patient. A dog with gastric dilatation-volvulus, for example, will often have a component of hypovolemic shock secondary to blood loss associated with rupture of the short gastric vessels. Dogs with septic peritonitis may experience tissue hypoxia due to reduced of systemic vascular resistance, but likely suffer from hypovolemia as well if severe cavitary effusions or protracted vomiting are present.

10.4 DIAGNOSTICS AND MONITORING

There are some basic diagnostic tests that should be completed for all shock patients in order to assess the extent of organ injury and identify the etiology of the shock state. A venous or arterial blood gas with lactate measurement, a complete blood cell count, blood chemistry panel, coagulation panel, blood typing, and urine analysis should be performed. Thoracic and abdominal radiographs, abdominal ultrasound, and echocardiography may be indicated once the patient is stabilized.

Additional monitoring techniques that are essential in the diagnosis and treatment of the shock patient include continuous ECG monitoring, blood pressure measurement, and pulse oximetry (see Monitoring section). Gradual resolution of tachycardia often signals successful return of cardiovascular stability, whereas persistent tachycardia indicates ongoing cardiovascular instability. It is important to note that the best form of monitoring is a thorough physical examination, and frequent patient assessment will also provide important clues regarding response to therapy.

10.4.1 Monitoring Tissue Perfusion and Oxygen Delivery

The magnitude of the oxygen deficit is a key predictor of outcome in shock patients. Therefore optimizing oxygen delivery and tissue perfusion is the goal of treatment and sufficient monitoring tools are necessary to achieve this objective. A well-perfused patient possesses the following characteristics: central venous pressure between 5 and 10 cm H_2O (2 to 5 cm H_2O in cats); urine production of at least 1 ml/kg/hr; mean arterial pressure between 70 and 120 mm Hg; normal body temperature, heart rate, heart rhythm, and respiratory rate; and moist, pink mucous membranes with a capillary refill time of less than 2 seconds. Monitoring these parameters is the tenet of patient assessment. Additional monitoring tools that may prove beneficial include the measurement of blood lactate, indices of systemic oxygenation transport, and mixed venous oxygen saturation.

10.4.2 Blood Lactate Levels

Critically ill patients with inadequate oxygen delivery, oxygen uptake, or tissue perfusion often develop a hyperlactatemia and acidemia that are reflective of the severity of cellular hypoxia. A lactic acidosis in human patients carries a greater risk for developing multiple organ failure, and these people demonstrate a higher mortality rate than those without an elevated lactate concentration.[4] High blood lactate levels may also aid in predicting mortality in dogs.[5-7] The normal lactate concentration in adult dogs and cats is less than 2.5 mmol/L; lactate concentrations greater than 7 mmol/L are severely elevated.[5] However, normal neonatal and pediatric patients may have higher lactate concentrations.[8] In addition, sample collection and handling procedures can affect lactate concentration.[9] Serial lactate measurements taken during the resuscitation period help to gauge response to treatment and to evaluate resuscitation end points; the changes in lactate concentrations are a better predictor of survival than are single measurements.

10.4.3 Cardiac Output Monitoring and Indices of Oxygen Transport

The measurement of indices of systemic oxygen transport is a direct method of assessing the progress of resuscitation in shock patients. A right-sided cardiac catheter or pulmonary artery catheter (PAC, also termed Swan-Ganz catheter or balloon-directed thermodilution catheter) is typically used to monitor these parameters 42
(see Chapter 50, Pulmonary Artery Catheterization). The PAC enables the measurement of central venous and 43
pulmonary arterial pressure, mixed venous blood gases (PvO_2 and SvO_2), pulmonary capillary wedge pressure (PCWP), and cardiac output. With this information, further parameters of circulatory and respiratory function can be derived (i.e., stroke volume, end-diastolic volume, systemic vascular resistance index, pulmonary vascular resistance index, arterial oxygen content, mixed-venous oxygen content, DO_2 index, VO_2 index and the oxygen extraction ratio). Although cardiac output is typically determined using thermodilution methods, other techniques are available (see Chapter 203, Hemodynamic Monitoring).

A PAC allows the clinician to assess the cardiovascular and pulmonary function of shock patients. The response to treatment and titration of fluid therapy, vasopressors, and inotropic agents can also be monitored. Cardiac output and systemic DO_2 should be optimized using intravascular volume loading until the PCWP approaches 10 to 12 mm Hg. A high PCWP (>15 to 20 mm Hg) will promote the formation of pulmonary edema, further impairing oxygenation and overall oxygen transport. Despite potential benefits, the use of a PAC does not necessarily translate into reduced mortality in the critically ill shock patient; it is an invasive monitoring technique that is not without risk.[10] In addition, the accuracy of measurements provided by the PAC relies on catheter placement, calibration of transducers, coexisting cardiac or pericardial disease, and correct interpretation of waveforms and values.

10.4.4 Mixed Venous Oxygen Saturation (SvO_2) and Central Venous Oxygen Saturation ($ScvO_2$)

Changes in the global tissue oxygenation (oxygen supply-to-demand) can be assessed using SvO_2 measurements. Assuming VO_2 is constant, SvO_2 is determined by cardiac output, hemoglobin concentration, and SaO_2. SvO_2 is decreased if DO_2 decreases (low CO, hypoxia, severe anemia) or if VO_2 increases (fever). With conditions such as the hyperdynamic stages of sepsis and cytotoxic tissue hypoxia (e.g., cyanide poisoning), SvO_2 is increased. A reduction in SvO_2 may be an early indicator that the patient's clinical condition is deteriorating. In addition, SvO_2 may be an alternative to measuring cardiac index during resuscitative efforts.

Ideally, SvO_2 is measured in a blood sample from the pulmonary artery. However, in animals that do not have a PAC, venous oxygen saturation can be measured from the central circulation, using a central venous catheter in the cranial vena cava. SvO_2 is then termed $ScvO_2$ (central venous oxygen saturation). Although the $ScvO_2$ values are generally higher than SvO_2 in critically ill patients with circulatory failure, the two measurements closely parallel one another. Therefore a pathologically low $ScvO_2$ likely indicates an even lower SvO_2. A recent prospective, randomized study comparing two algorithms for early goal-directed therapy in patients with severe sepsis and septic shock showed that maintenance of a continuously measured $ScvO_2$ above 70% (in addition to maintaining central venous pressure above 8 to 12 mm Hg, [MAP] pressure above 65 mm Hg, and urine output above 0.5 ml/kg/hr) resulted in a 15% absolute reduction in mortality compared to the same treatment without $ScvO_2$ monitoring.[11] Though it is not clear if these exact parameters can be readily applied to veterinary patients, early recognition of shock followed by aggressive goal driven resuscitation is likely crucial to successful treatment of shock.

10.5 TREATMENT

Treatment of shock is based on early recognition of the condition and rapid restoration of the cardiovascular system so that DO_2 to the tissues is normalized as soon as possible. The mainstay of therapy for all forms of shock except that of shock of cardiogenic origin is based on rapid administration of large volumes of intravenous fluids to restore an effective circulating volume and tissue perfusion. Vascular access is essential for successful treatment of shock, but can be difficult due to poor vascular filling and a collapsed cardiovascular state. Since speed of fluid administration is proportional to the diameter of the catheter lumen and inversely proportional to its length, short, large-bore catheters should be placed in a central or peripheral vein. In cases in which intravenous access is difficult or delayed due to cardiovascular collapse, a cut-down approach or intraosseous catheterization may be necessary (see Chapters 61 to 63, Peripheral Venous Catheterization, Intraosseous Catheterization, and Central Venous Catheterization, respectively).

The type of fluid selected for the treatment of shock may vary (see Chapter 65, Shock Fluids and Fluid Challenge). Replacement isotonic crystalloids such as lactated Ringer's solution, 0.9% sodium chloride (NaCl), or Normosol R form the mainstay of therapy for shock, administered rapidly at doses equivalent to 1 blood volume (90 ml/kg for the dog, 40 to 60 ml/kg for the cat). The administered fluid rapidly distributes into the extracellular fluid compartment so that only approximately 25% of the delivered volume remains in the intravascular space by 30 minutes after infusion,[12] and some animals will therefore require additional resuscitation at this time point. In patients that are bleeding, it may even be advantageous to perform hypotensive resuscitation (to an MAP of ~60 mm Hg) until the hemorrhage is controlled, because aggressive fluid therapy in this setting can worsen bleeding and outcome.[13] For animals with coexisting head trauma, the isotonic crystalloid of choice is 0.9% NaCl because it contains the highest concentration of sodium and is least likely to contribute to cerebral edema. The “shock doses” of crystalloids serve as useful guidelines for fluid resuscitation of the shock patient; however, the actual volume administered should be titrated according to the patient's clinical response in order to prevent volume overload. Excessive fluid administration is often evidenced by pulmonary or peripheral edema due to any combination of increased hydrostatic pressure, hypoalbuminemia, and increases in vascular endothelial permeability. Animals with uncontrolled hemorrhage or deranged compensatory mechanisms may not respond adequately to crystalloid resuscitation and will require additional therapeutic, diagnostic, and monitoring strategies. Additional fluid therapy options in these patients include synthetic colloid solutions, hypertonic saline, blood products, and hemoglobin-based oxygen carrying (HBOC) solutions.

Synthetic colloids such as hetastarch or dextran 70 are hyperoncotic to the normal animal and therefore pull fluid into the vascular space following intravenous administration. They therefore cause an increase in blood volume that is greater than that of the infused volume and help to retain this fluid in the intravascular space in animals with 43
normal capillary permeability. They are appropriately used for shock therapy in acutely hypoproteinemic animals 44
(total protein <3.5 g/dl) with a decreased colloid osmotic pressure. They can also be used with isotonic or hypertonic crystalloids to maintain adequate plasma volume expansion with lower interstitial fluid volume expansion and to expand the intravascular space with smaller volumes over a shorter time period. Due to the prevalence of occult cardiac disease in cats, hetastarch or dextran-70 is typically administered more conservatively in this species, at doses ranging from 5 to 10 ml/kg compared to 10 to 20 ml/kg in dogs. With the exception of human trauma patients, studies have failed to support a survival benefit with the use of colloids compared to crystalloids in resuscitation

from shock. In the specific population of human trauma patients, crystalloid use has been associated with reduced mortality compared to colloid therapy.[14] Human albumin, a natural, hyperoncotic and hyperosmotic colloid solution with rising popularity in veterinary medicine, is another therapeutic option when crystalloid therapy alone has failed to restore or maintain an effective circulating blood volume. Preliminary studies in dogs found that albumin therapy increases circulating albumin concentrations, total solids, and colloid osmotic pressure, although the effect on mortality remains unknown. Potential complications are reportedly rare in critically ill animals and are similar to those for any blood product transfusion (i.e., fever, vomiting, increased respiratory effort), in addition to the potential for increasing clotting times. However, few studies have been published evaluating the safety of human albumin in animals. Recent reports of albumin administration to normal research dogs revealed potentially fatal reactions to the product, especially with repeated dosing.[15] Caution is therefore advised at this time.

The use of 7% to 7.5% sodium chloride (hypertonic saline) can be lifesaving in the emergency setting. The long shelf life and affordability of this solution render it a necessity in the veterinary emergency hospital. Following administration of hypertonic saline, there is a transient (<30 minutes) osmotic shift of water from the extravascular to the intravascular compartment. It is administered in small volumes (5 ml/kg) intravenously over 5 to 10 minutes. In addition to the fluid shift caused by hypertonic saline, there is evidence that it also helps to reduce endothelial swelling, modulates inflammation, increases cardiac contractility, causes mild peripheral vasodilation, and decreases intracranial pressure. The effects of this solution are immediate, with a decrease in heart rate and improvement of pulse quality typically noted within 1 to 2 minutes of administration. Though short-lived, this transient improvement in cardiovascular state may provide the necessary time for other therapies to take effect. Hypertonic saline should always be used in combination with other resuscitative fluids due to the osmotic diuresis and rapid sodium redistribution that occur following administration. A mixture of hypertonic saline and a synthetic colloid may further augment and prolong the rise in blood volume compared to hypertonic saline alone. Several studies in dogs suggest that the combination of hypertonic saline and dextran-70 is associated with more rapid improvement in hemodynamic status and with lesser overall crystalloid requirements than when crystalloids are used alone.[16,17]

Blood component therapy is frequently used during resuscitation of the shock patient. Most fluid-responsive shock patients will tolerate acute hemodilution to a hematocrit of less than 20%. In the dog, splenic contraction secondary to catecholamine release may mask the presence of anemia, and a reduced total protein concentration can be used to raise the index of suspicion for blood loss in this species. Both the dose of packed red blood cells and speed of administration may vary depending on the underlying condition and the hemodynamic state of the patient. In animals with acute blood loss that are unresponsive to fluid therapy alone, fresh whole blood or packed red blood cells and fresh frozen plasma should be used in an attempt to stabilize clinical signs of shock and maintain the hematocrit above 25% and the clotting times within the normal range (see Chapter 66, Transfusion Medicine). Packed red blood cells and fresh frozen plasma are administered at a dose of 10 to 15 ml/kg and fresh whole blood at a dose of 20 to 25 ml/kg. Although all blood products should be administered over at least 1 to 2 hours in order to monitor for a transfusion reaction and avoid volume overload, it may be necessary to administer these products in bolus doses in animals with severe internal or external blood loss. A blood type should be determined in all animals, especially cats, before transfusions are given. Packed red blood cells are given to increase oxygen content in animals with severe anemia or in conjunction with fresh frozen plasma in coagulopathic shock patients. Plasma products are most commonly used in animals with profound blood loss, a coagulopathy, or severe hypoalbuminemia (large volumes of intravenous fluids in a short period of time may also have a dilutional effect on circulating coagulation factors). Its ability to increase colloid osmotic pressure is limited compared to the hyperoncotic synthetic colloids, but it does supply albumin, an important carrier of certain drugs, hormones, metals, chemicals, toxins, and enzymes. Platelets are only present in fresh blood within 24 hours of collection and their use is indicated in animals with thrombocytopenia/thrombocytopathia-induced bleeding disorders or massive hemorrhage.

Finally, HBOC solutions may be beneficial for the treatment of shock. In states of anemia, the HBOC solutions may increase oxygen delivery to tissues and increase perfusion of capillary beds affected by microvascular thrombosis due to the small size of the free hemoglobin. Despite these theoretical benefits and the long shelf life of this product, HBOC solutions are not widely used due to inconsistent supply, undesirable side effects and lack of clear benefit over other solutions available.

Shock patients that remain hypotensive despite intravascular volume resuscitation often require vasopressor and/or inotrope therapy. Because oxygen delivery to the tissue is dependent on both cardiac output and systemic vascular resistance, therapy for hypotensive patients includes maximizing cardiac output with fluid therapy as discussed above and inotropic drugs and/or modifying vascular tone with vasopressor agents (see Chapters 6, 176, and 177, Hypotension, Vasoactive Catecholamines, and Vasopressin, respectively). Commonly used vasopressors include catecholamines (epinephrine, norepinephrine, dopamine) and the sympathomimetic drug phenylephrine. In addition, vasopressin, corticosteroids, and glucagon have been used as adjunctive pressor agents.

Unlike hypovolemic or distributive shock, cardiogenic shock is characterized by a systolic or diastolic cardiac dysfunction resulting in hemodynamic abnormalities such as increased heart rate, decreased stroke volume, 44 decreased cardiac output, decreased blood pressure, increased peripheral vascular resistance, and increases in the 45 right atrial, pulmonary arterial, and pulmonary capillary wedge pressures (see Chapter 35, Cardiogenic Shock). These pathologic changes result in diminished tissue perfusion and increased pulmonary venous pressures, resulting in pulmonary edema and dyspnea. Supplemental oxygen therapy and minimal handling are extremely important to avoid further decompensation in patients with cardiogenic shock. A brief physical examination consisting of thoracic auscultation alone may identify the presence of a cardiac murmur or gallop rhythm and pulmonary crackles. In cats, hypothermia may be very helpful in differentiating heart failure from other causes of dyspnea.

Successful treatment of cardiogenic shock depends on rapid evaluation of signalment, a brief physical examination, and avoidance of stress. The diuretic furosemide (2 to 8 mg/kg) administered intravenously or intramuscularly is that mainstay of therapy for congestive heart failure. Animals that fail to show clinical signs of improvement following repeated doses of diuretics may require more specific therapy targeting the underlying cardiac abnormality (e.g., systolic dysfunction, diastolic failure, arrhythmias). Ultimately, the dyspneic patient in cardiogenic shock that fails to respond to therapy should be anesthetized, intubated, and positive pressure ventilated with 100% oxygen to stabilize the animal, remove the anxiety associated with shortness of breath, and allow the clinician to perform a thorough physical examination and pursue further diagnostics such as thoracic radiographs and echocardiography.

Early recognition and initiation of therapy are essential for successful treatment of the shock patient. Therapy for the shock patient is complicated by the need for rapid decision-making in the absence of a complete medical history. In all forms of shock other than cardiogenic shock, intravenous fluid administration is the mainstay of therapy. Although underresuscitation or delayed onset of therapy could clearly contribute to a negative outcome, excessive or overaggressive resuscitation may also have undesirable consequences, including a dilutional coagulopathy and pulmonary edema. The combination of breed, signalment, and physical examination findings will help the emergency clinician identify the type of shock present, and serial evaluation with clearly defined end points of resuscitation are essential for successful management of the shock patient.

11 Chapter 11 Systemic Inflammatory Response Syndrome

Armelle M. de Laforcade, DVM, DACVECC

11.1 Key Points

- Systemic inflammatory response syndrome (SIRS) is a widespread response to an infectious or a noninfectious insult and, if left untreated, can lead to multiple organ failure and death.
- Under normal conditions, the release of proinflammatory mediators and acute phase proteins triggers a compensatory antiinflammatory response that leads to restoration of a homeostatic state.
- Criteria used to identify SIRS are nonspecific and may lead to over-diagnosis of this condition.
- Severe systemic inflammation often leads to vascular hyporesponsiveness, increased endothelial permeability, and a hypercoagulable state.
- Treatment of SIRS consists of supportive care and treatment of the underlying disease.

11.2 INTRODUCTION

Systemic inflammatory response syndrome (SIRS) is a term introduced by the American College of Chest Physicians and Society of Critical Care Medicine consensus conference in 1992 to acknowledge the importance of systemic activation of inflammation as a contributor to organ failure in sepsis.[1] The inherent heterogeneity of patients with sepsis and the observation of similar clinical courses in disease states lacking an infectious cause led to the breakdown of sepsis into a trigger (bacterial invasion) and a response to that trigger (the inflammatory response). From this realization emerged the concept of SIRS, or a systemic response to an insult that is infectious or noninfectious in origin.

Although SIRS is most commonly associated with sepsis, other disease states known to cause widespread release of endogenous mediators and subsequent systemic inflammation in people include trauma, burns, major surgery, and pancreatitis.[2] These insults can progress to multiple organ failure, shock, and death due to the magnitude of the inflammatory response alone (and in the absence of infection).[2,3] SIRS describes a clinical state rather than a disease entity. Proposed criteria for diagnosis consist of two out of the following four clinical signs: (1) hypothermia or hyperthermia, (2) leukocytosis or leukopenia, (3) tachycardia, and (4) tachypnea.[1] Studies relating the magnitude of the inflammatory response to outcome highlight the importance of early recognition of systemic inflammation and treatment of the underlying disease process.[4]

11.3 SYSTEMIC INFLAMMATION

Systemic inflammation may be triggered by products of both gram-positive and gram-negative bacteria. Factors known to stimulate macrophages and monocytes include lipopolysaccharide (from gram-negative bacteria), lipoteichoic acid (gram-positive bacteria), peptidoglycan and flagellin (gram-positive and gram-negative bacteria), and mannan (fungi). Normally leukocyte activation resulting from exposure to these proteins, and subsequent release of tumor necrosis factor-α (TNF-α), lead to an inflammatory response designed to protect the host. Excessive activation of inflammation, however, may contribute to multiple organ failure and death.

Although the release of mediators such as TNF-α, interleukin (IL)-1, IL-6, prekallikreins, bradykinin, platelet activating factor, and others in response to leukocyte activation has been well characterized, this proinflammatory response is accompanied by activation of antiinflammatory measures designed to counteract the proinflammatory state. This compensatory antiinflammatory response syndrome (CARS) is characterized by the release of antiinflammatory mediators, including IL-10, transforming growth factor-β (TGF-β), and IL-13; production of soluble receptors and receptor antagonists for cytokines such as TNF-α; and reduction of B and T lymphocyte production. Although clearly beneficial in its ability to control the proinflammatory state, excessive stimulation of the compensatory antiinflammatory response may contribute to immunoparalysis and increased susceptibility to nosocomial infections seen in the late stages of sepsis.[5-7]

11.4 CONSEQUENCES OF SYSTEMIC INFLAMMATION

Disruptions in homeostasis caused by production of proinflammatory mediators include loss of vascular tone, disruption of the endothelial permeability barrier, and stimulation of coagulation (see Chapter 107, Septic Shock). Loss of vascular tone is thought to occur secondary to excessive inducible nitric oxide synthase (iNOS) production, the precursor to nitric oxide release, and possibly a deficiency of vasopressin (a potent vasoconstrictor hormone). Disruption of the endothelial permeability barrier is a direct result of cytokine production.[8,9]

A hypercoagulable state, induced by cytokine-mediated tissue factor expression on the surface of leukocytes, leads to fibrin deposition in the microvasculature and is thought to contribute to organ failure in proinflammatory states. Endogenous anticoagulant systems such as antithrombin, protein C, and tissue factor pathway inhibitor are overwhelmed in states of systemic inflammation. Interestingly, studies have supported a close relationship between inflammation and coagulation.[10,11] Thrombin resulting from the activation of coagulation stimulates leukocyte activation and further cytokine production.

TNF-α downregulates the activation of protein C, which is known to have antiinflammatory properties in addition to its role as an anticoagulant. Administration of drotrecogin-α, or recombinant human activated protein C, significantly improved survival in humans with sepsis.[12] Studies suggest, however, that the beneficial effect of protein C may be due to its antiinflammatory effect rather than its anticoagulant properties.[13]

11.5 SIRS AND SEPSIS

Although SIRS has been identified as an important component of sepsis, it can occur in the absence of infection, yet have a clinical course resembling that of sepsis. Parameters such as body temperature, heart rate, and respiratory rate are useful to identify systemic inflammation, but they lack sensitivity and specificity for the diagnosis of sepsis. The time required to obtain culture results precludes their usefulness in differentiating nonseptic SIRS from septic SIRS in most clinical situations. This need to differentiate sepsis from SIRS of noninfectious origin has led to the search for biologic markers that would identify the presence (or lack of) bacterial infection in patients with clinical signs of SIRS. C-reactive protein (CRP) and procalcitonin (PCT) have both been studied extensively in humans. Additionally, use of the PIRO (predisposition, insult or infection, response, and organ dysfunction) acronym was adopted following the 2001 Sepsis Definitions conference to more accurately stage sepsis and describe the clinical manifestations of the infection and the host response (see Chapter 106, Sepsis).

11.6 MARKERS OF SEPSIS

CRP is an acute phase protein produced by hepatocytes in response to inflammatory cytokine release, including TNF-α and IL-1β. CRP release peaks 36 to 50 hours following secretion and it has a half-life of 19 hours. Although studies support a rise in CRP in humans with sepsis,[14] elevations have also been documented secondary to other inflammatory processes such as trauma, surgery, acute pancreatitis, and myocardial infarction.[15] Some studies have also suggested that CRP levels reflect the severity of the inflammatory process, but these levels have not been shown to differ between survivors and nonsurvivors.[16] Because of the prolonged half-life and lack of specificity, CRP is not considered the ideal marker for the diagnosis of sepsis.

PCT, the precursor molecule to calcitonin, has also been investigated as a potential marker of sepsis. Normally produced by the thyroid gland, PCT during sepsis is thought to originate from mononuclear leukocytes following endotoxin and cytokine stimulation.[17] PCT is released hours after endotoxin release, and peak levels persist for up to 24 hours. Although the exact role of PCT in sepsis is still unknown, it is known to increase iNOS–mediated nitric oxide release and therefore may play a role in amplification of the inflammation.[18]

Studies have documented elevated PCT levels in bacterial infections complicated by systemic inflammation and little to no change in PCT in localized infections or in infections of viral etiology. These findings support the use of PCT to differentiate between bacterial sepsis and SIRS of nonbacterial origin in humans.[19] In some studies, PCT levels correlate with disease severity and may have prognostic value for sepsis and septic shock. Overall, PCT is thought to represent a superior marker of sepsis than CRP in humans.

11.7 TREATMENT OF SIRS IN HUMANS

Because systemic inflammation is a critical component of sepsis, studies investigating the benefit of therapeutic interventions for sepsis have focused on modulation of the inflammatory response. Cytokine blockade, in particular, has been investigated extensively as a means to control inflammation, prevent end-organ damage, and improve survival in severe sepsis and septic shock. TNF-α blockade using TNF antibody administration failed to improve survival consistently in people with sepsis and was shown in some studies to have detrimental effects.[20,21] Similarly, the use of receptor antagonists to TNF, platelet activating factor, and IL-1 failed to improve 28-day survival in those with severe sepsis.[22,23]

The antiinflammatory benefits of ibuprofen were also studied in a prospective, randomized, double-blinded, placebo-controlled trial. A survival benefit was not shown in humans with sepsis.[24] High-dose glucocorticoids, commonly used before the 1990s, were often administered to control the inflammatory response. This practice was discontinued due to failure to increase survival and, in some studies, increased mortality.[25] Human intravenous immunoglobulin was shown to increase survival in a small study of humans with gram-negative sepsis.[26] The immune-modulating properties of statins, drugs commonly used to control cholesterol in humans, have led to studies investigating their effect in diseases known to be associated with systemic activation of inflammation. Their potential benefits in people with SIRS and sepsis have yet to be determined.[27] By far, the results of the PROWESS study, showing a survival benefit with recombinant human activated protein C in humans with severe sepsis and septic shock, have made the greatest impact on the treatment of sepsis.[12] Recombinant human activated protein C has received a grade B recommendation in the most recent Survival Sepsis Campaign in people, but veterinary studies are lacking.[28]

11.8 SIRS IN SMALL ANIMALS

Knowledge relating to SIRS in animals is based on studies of animal models of sepsis and related diseases, and studies investigating the inflammatory response in naturally occurring animal diseases are lacking. Historically, studies of sepsis have often included both dogs and cats; however, increasing evidence supports significant differences in the manifestation of systemic inflammation in these species.

Common causes of SIRS in animals include sepsis, heat-stroke, pancreatitis, immune disease, neoplasia, severe polytrauma, and burns. Criteria for SIRS have been extrapolated from human studies for dogs and cats, but few prospective studies have been performed to validate these criteria. In one study of 30 septic and 320 nonseptic dogs, criteria found to have the greatest sensitivity for the diagnosis of SIRS were determined and are listed in Table 11-1.[29]

In both animals and humans, the criteria used for identification of SIRS may lead to over-diagnosis of this condition. In cats, proposed criteria for SIRS were derived from a retrospective study in which severe sepsis was identified at necropsy. This study identified inappropriate (or relative) bradycardia (HR <140 beats/min) in 66% of cats with severe sepsis.[30] Although the criteria for SIRS that were proposed as a result of this study have yet to be validated prospectively, relative bradycardia was also identified in 16% of cats with septic peritonitis.[31] This finding supports the fundamental difference between cats and dogs in the hemodynamic response to systemic inflammation.

Several studies have been performed investigating the alterations in hemostasis in dogs with systemic inflammation. In one study, all 9 dogs with parvoviral enteritis had evidence of hypercoagulability based on results of thromboelastography and a reduction in measured antithrombin activity.[32] In another study examining dogs with naturally occurring sepsis, protein C and antithrombin activities were reduced significantly in dogs with sepsis compared with controls, also suggesting the predominance of hypercoagulability in this disease process.[33] Potential uses of markers of inflammation in animals with SIRS include the differentiation between infectious and noninfectious causes of systemic inflammation, as well as the determination of severity of disease and response to therapy.

CRP is the acute phase protein that has received the most attention in the veterinary literature to date. In one study of dogs with naturally occurring pancreatitis, serum CRP concentrations were elevated in all 16 dogs with acute pancreatitis compared with controls, and CRP concentration decreased in all dogs that were hospitalized for 5 days.[34] Increased CRP concentration has been documented in a variety of disease states including autoimmune hemolytic anemia, various neoplasias,[35] chronic valvular disease,[36] and other diseases known to cause acute inflammation. The usefulness of CRP measurements in differentiating infectious from noninfectious SIRS in animals with naturally disease has not yet been investigated.

Studies investigating inflammatory mediators in animals with naturally occurring disease are lacking. In one study examining dogs with parvoviral enteritis, 7 of 17 had measurable TNF activity.[37] Proinflammatory cytokines have also been documented in other disease states that are thought to have an inflammatory component (e.g., cranial cruciate rupture in the dog).[38]

Clinical manifestations of SIRS are often nonspecific and may vary depending on the underlying disease process. In general, signs of SIRS often resemble those of sepsis, and in most cases they are both are managed similarly. Loss of appetite and depression are reported frequently in animals experiencing systemic inflammation. In addition to the clinical signs listed in Table 11-1, animals may exhibit injected mucous membranes and bounding peripheral pulses, suggesting a compensated hyperdynamic state, or vomiting and diarrhea (especially if the problem is gastrointestinal in origin). A high index of suspicion for SIRS may also be based on CBC changes such as a neutrophilic leukocytosis, with or without a left shift, and toxic cytologic changes to the neutrophils. Alterations frequently found on the biochemistry panel include hyperglycemia or hypoglycemia, hypoalbuminemia, elevated alanine aminotransferase and aspartate aminotransferase and, in some cases, hyperbilirubinemia. Changes in blood glucose are thought to occur secondary to altered carbohydrate metabolism, with increased gluconeogenesis causing hyperglycemia in the early phase of infection and inflammation, and hypoglycemia occurring later in the disease process when glucose utilization exceeds production. Reduced albumin concentration occurs secondary to reduced manufacture by the liver in favor of production of acute phase proteins, and also to loss induced by changes in endothelial permeability. Liver enzyme concentrations likely are altered by changes in perfusion and decreased oxygen delivery to tissues. Finally, cholestasis may be the cause of elevated serum bilirubin, although it has also been suggested that immune-mediated hemolysis may play a role. Endotoxins can cause intrahepatic cholestasis and icterus as well.

Table 11-1 Proposed Criteria for the Diagnosis of SIRS in Dogs and Cats

	Dogs: 2/4 Changes Required	**Cats: 3/4 Changes Required**
Temperature (°F)	<100.6 or >102.6	<100 or >104
Heart rate (beats/min)	>120	<140 or >225
Respiratory rate (breaths/min)	>20	>40
WBC (×10^3); % bands	<6 or >16; >3%	>19 or <5

SIRS, Systemic inflammatory response syndrome; *WBC,* white blood cells. Proposed criteria for the diagnosis of SIRS include at least two (in dogs) or three (in cats) of the changes listed. Criteria described for dogs were found to have a sensitivity of 97% and a specificity of 64% for the diagnosis of SIRS.[48]

It is important to note that cats and dogs differ in their manifestation of SIRS, with cats more likely to experience hypotension, hypoglycemia, and hyperbilirubinemia than dogs. Ultimately, clinical manifestations of SIRS resemble those of sepsis, with the finding of infection ultimately necessary to differentiate these two conditions.

The mainstay of treatment for patients with SIRS consists of treatment of the underlying disease process and supportive care. If infection is found or suspected along with clinical signs of SIRS, then treatment for sepsis consisting of source control, antibiotic therapy, and cardiovascular support should be initiated. Although SIRS may not always be of infectious origin, antibiotics frequently are added when an infectious cause is suspected but no specific infection is diagnosed. Until culture results are available, antibiotic therapy should be broad-spectrum so that gram-positive, gram-negative, and anaerobic organisms are covered. Common combinations include a cephalosporin, enrofloxacin, and metronidazole, or ampicillin and enrofloxacin (see Chapters 106 and 194, Sepsis and Antibiotic Use in the Critical Care Patient, respectively).

Once culture and sensitivity results are available, antibiotic therapy should be tailored to target the identified pathogen. More aggressive antibiotic therapy may be warranted if a hospital-acquired infection is suspected. Intravenous therapy generally consists of replacement fluids such as lactated Ringer's solution or Normosol-R. Fluid therapy is aimed at resolving hypovolemia, maintaining daily requirements, and replacing any ongoing losses, and should be tailored to the individual patient (see Chapter 64, Daily Intravenous Fluid Therapy). It is important to note that inflammatory mediators associated with systemic inflammation also lead to changes in endothelial permeability;

therefore excessive crystalloid administration may result in interstitial fluid accumulation and clinical signs of peripheral edema.

Other therapies may include oxygen supplementation (see Chapter 19, Oxygen Therapy), nutritional support by enteral or parenteral routes (see Chapters 13 and 14, Enteral Nutrition and Parenteral Nutrition, respectively), and stress ulcer prophylaxis (see Chapter 181, Gastrointestinal Protectants).

Monitoring the patient with SIRS consists of regular evaluations of volume and perfusion status using repeated physical examinations, measurement of serum lactate concentrations, central venous pressure measurements, serial body weights, and comparison of intake to output. Intermittent blood pressure measurements may be helpful, and vasopressor therapy is indicated if fluid therapy alone fails to resolve hypotension (see Chapter 176, Vasoactive Catecholamines). The hematocrit and serum electrolyte, albumin, and glucose concentrations should be monitored regularly. Complications of SIRS include cardiovascular collapse, disseminated intravascular coagulation, and multiple organ dysfunction.

11.9 CONCLUSION

Systemic inflammation has received widespread attention as a key component of sepsis in both people and in animals. SIRS is classically associated with diseases such as pancreatitis and sepsis in dogs and cats, but may be underrecognized as a contributor to cardiovascular collapse and organ failure in animals with other diseases (i.e., polytrauma, neoplasia). Cats in particular may be more susceptible to noninfectious SIRS, a clinical state that often appears similar to that of sepsis and may result in organ failure and death.

Supportive care aimed at preserving organ function and treatment of the underlying disease process remain the mainstays of therapy. Low-dose glucocorticoid and intravenous immunoglobulin administration warrant further study in animals with naturally occurring disease.

12 Chapter 12 Nosocomial Infections and Zoonoses

Shelley C. Rankin, PhD

12.1 Key Points

- Nosocomial (hospital acquired) infection is defined as any infection that is neither present nor incubating when a patient is admitted to a hospital.
- Risk factors for nosocomial infection in the intensive care unit (ICU) include severity of underlying illness, prolonged length of stay, mechanical ventilation, and indwelling devices.
- Multiple antibiotic resistance is common among nosocomial pathogens.
- Methicillin-resistant *Staphylococcus aureus* is an emerging disease in dogs and cats.
- Zoonosis is a disease that can be transmitted from animals to humans. A more technical definition is a disease that normally exists in animals but that can infect humans.
- The reservoirs of nosocomial pathogens include people, animals, fomites, air currents, water and food sources, insects, and rodents, and it has long been known that the spread of pathogens in hospitals occurs primarily via the hands of personnel.
- Establishment of nosocomial infection control committees must become a priority in veterinary hospitals.

12.2 INTRODUCTION

In human health care settings, nosocomial infection is defined as any infection that is neither present nor incubating when a patient is admitted to a hospital. In 1988, the Centers for Disease Control and Prevention proposed more specific definitions, and it is now generally accepted that infections are considered to be nosocomial if they develop at least 48 hours after hospital admission without proven prior incubation.[1] In addition, if infections occur up to 3 days after discharge or within 30 days of a surgical procedure, they are attributed to the admitting hospital.[1] These definitionsare largely accepted in human health care and, although they may require refinement in veterinary medicine, they stand unchallenged.

It is well recognized that hospitalization of sick animals can lead to an increased risk of infection, and various policies have been proposed to reduce the risk of nosocomial infection in veterinary medicine.[2,3] In addition to patient care concerns, many nosocomial pathogens are well recognized as zoonotic agents, so infection control policies should address the issue of animal to human transmission.[2]

12.3 NOSOCOMIAL INFECTIONS IN DOGS AND CATS

One of the first published reports of nosocomial infection in a veterinary hospital described *Klebsiella* infection in dogs and one cat in the ICU at the New York State College of Veterinary Medicine in 1978.[4] Since that time there have been a few well-characterized studies, but many of these have centered on large animal facilities with various *Salmonella enterica* serotypes as the causative organisms.[5-7] Specific reports of nosocomial infection in dogs and cats remain limited.[5] Since 1978, organisms such as *Serratia marcescens, Salmonella* spp, *Clostridium perfringens, Acinetobacter baumannii, Escherichia coli,* and *Clostridium difficile* have been implicated as causes of nosocomial infection in dogs and cats.[5,8-12] The bacteria responsible for nosocomial infection in ICUs originate either from the patient's own endogenous flora or from exogenous sources. Nosocomial infections derived from endogenous flora may occur in patients receiving chemotherapy, glucocorticoid therapy, or antibiotic therapy. In contrast to endogenous infections, exogenous infections are more likely to be preventable by standard or specific precautions devised to reduce the overall rate of transmission.[13] A review of nosocomial infections in veterinary medicine provides data on the prevalence of urinary tract infections, surgical site infections, bloodstream infections, pneumonia, and diarrhea.[14]

12.4 RISK FACTORS

Although ill defined in veterinary medicine, independent risk factors for nosocomial infection acquisition in the critically ill patient can be extrapolated from human studies. Prolonged length of hospital stay, mechanical ventilation, and indwelling devices, such as intravascular or urinary catheters and nasogastric or endotracheal tubes, are well-recognized risk factors.[1] Many intrinsic, patient-related factors have also been identified and include patient demographics (e.g., age, gender), comorbidities, and severity of underlying illness, which is the most widely reported risk factor. Patient-specific risk factors are related to general health and immune status, respiratory status, neurologic status, and fluid status. A significant risk factor in the ICU is trauma, especially when associated with open fractures. Several less well-acknowledged factors have also been suggested as contributing factors. Among them, understaffing and overcrowding in the ICU have been well documented as causes of cross-transmission of nosocomial infections.[1]

12.5 MULTIPLE ANTIBIOTIC-RESISTANT NOSOCOMIAL PATHOGENS

In an excellent review of the problem of antimicrobial drug use and resistance in veterinary medicine, Prescott and colleagues state that, “Despite a possible wealth of data in filing cabinets in veterinary clinical microbiology laboratories around the world, there have been virtually no systematic investigations of changes in antimicrobial drug resistance in bacteria isolated from companion animals over time, using standard methodologies for assessing resistance.”[15] The situation has changed little since that statement was made in 2002.

Although it is often speculated that organisms isolated from nosocomial infection outbreaks in veterinary patients now have an increasingly broad spectrum of antimicrobial resistance, there are no active nosocomial infection surveillance systems in this field. Much of the antibiotic resistance data are derived from “local” surveillance, and a lack of standardization results in data that are incomparable from one setting to another.[16] In terms of the impact of multidrug-resistant (MDR) bacteria with regard to nosocomial infection, the data that have been published agree that resistant bacteria can reduce the effectiveness of management.[15]

Data on trends in resistance patterns among nosocomial pathogens from veterinary sources are few, but the wealth of surveillance data from human health care systems can often be used as a predictor of what to expect from nosocomial pathogens in veterinary patients.[17-19] Local surveillance of antibiotic resistance in animal isolates is preferred, but in the absence of such data, extrapolation from human surveillance data is encouraged.

Bacterial resistance to β-lactam antibiotics and the β-lactamase inhibitors is becoming increasingly common and threatens to reduce the clinical spectrum of these drugs. In particular, organisms that produce extended-spectrum β-lactamases (ESBLs) and plasmid-mediated AmpC enzymes are posing unique challenges in clinical situations.

Although the prevalence of ESBLs is not known, it is thought to be increasing, and in many parts of the world 10% to 40% of strains of *E. coli* and *K. pneumoniae* produce such enzymes. Novel β-lactamases are also becoming especially important among diverse gram-negative pathogens such as *Pseudomonas aeruginosa, S. enterica* serotype typhimurium, *Proteus mirabilis,* and *A. baumannii.* [20] The source of these novel enzymes is unknown, but their presence on plasmids and ready transferability among pathogens of different genera are of concern. Organisms that produce ESBLs are found commonly in those areas of the hospital environment where antibiotic use is frequent and the patient's condition is critical, and these resistant organisms cause increased morbidity and mortality.[20]

12.6 ZOONOSES

The simplest definition of a *zoonosis* is a disease that can be transmitted from animals to humans. A more technical definition is a disease that normally exists in animals but that can infect humans. Some authors further subdivide the concept into zooanthroponosis, infections that humans can acquire from animals, and anthropozoonosis, a disease of humans that is transmissible to other animals. A comprehensive literature review has identified 1415 species of infectious organism known to be pathogenic to humans and out of these, 868 (61%) are zoonotic.[21] Overall, 19% are viruses or prions, 31% are bacteria or rickettsia, 13% are fungi, 5% are protozoa, and 32% are helminths. Thirty-five percent of zoonoses can be transmitted by direct contact, 61% by indirect contact and 22% by vectors, and for 6%, 50 the transmission route is unknown. Only 33% of zoonotic species are known to be transmissible between humans 51 and only 3% are considered to have their main reservoir in human populations; the main reservoir of the remainder is in animal populations. Zoonoses are more likely to be transmitted by indirect contact or vectors, and are less likely to be transmitted by direct contact when compared with all pathogens.

The list of zoonoses found in animals in the ICU is long, but because some organisms are generally more prevalent, they will have a greater potential for transfer to humans and to cause disease. The enteric pathogens, such as *Campylobacter, Salmonella, C. difficile,* and *E. coli* are commonly isolated from animals in the ICU, and all of these organisms have been responsible for nosocomial outbreaks in that setting.[6,7,12] *Campylobacter* species can occur in large numbers as commensals in companion animals, and there is a strong correlation between diarrhea and the ability to recover *C. jejuni* from healthy dogs. *Salmonella* on the other hand, is not a normal commensal of dogs and cats and its presence in feces likely indicates infection. Enteropathogenic *E. coli* (EPEC) have been isolated from dogs and cats with enteritis, and strains have emerged as important causes of diarrhea in puppies. *E. coli* is also the most common cause of urinary tract infections in dogs and cats in the ICU, and many strains are now resistant to a wide spectrum of antimicrobial agents. Zoonotic transmission of resistant urinary isolates of *E. coli* from companion animals to humans has been suggested.[22] *C. difficile* and *Enterococcus* species are now considered emerging zoonotic agents, and this is also true of *S. aureus,* particularly methicillin-resistant *S. aureus* (MRSA).

Pathogenic *Leptospira* spp have the potential to infect humans and also cause nosocomial infection in animals housed with infected or shedding animals (see Chapter 135, Acute Renal Failure). Leptospires often colonize proximal convoluted kidney tubules and may be excreted in urine for extended periods by dogs that show no clinical signs. The carrier state may be as short as a few days or may extend throughout the life of the animal. The primary routes of infection for dogs are direct contact (oral, conjunctival), venereal and placental transfer, bite wounds, and ingestion of contaminated meat.

The cutaneous mycoses of animals caused primarily by *Microsporum* and *Trichophyton* species are well recognized zoonotic agents that cause ringworm in humans and can be acquired from contact with infected animals or from fomites. Dermatophyte spores gain entry to the skin through minor trauma such as abrasions.

Uncommon, perhaps emerging, zoonotic agents that may be found in veterinary patients may also include a variety of *Mycobacterium* species, *Malassezia pachydermatis, Candida albicans, Brucella canis,* and MDR strains of both *P. aeruginosa* and *K. pneumoniae*. Undoubtedly, as veterinary nosocomial infection surveillance systems improve, a host of additional pathogenic or MDR organisms will be reclassified as zoonotic.

12.7 EMERGING NOSOCOMIAL INFECTIONS IN DOGS AND CATS

Consistent with a generalized increase in β-lactam resistance, several reports in the veterinary literature have described an increase in the prevalence of MRSA strains isolated from dogs and cats.[23,24] In 1998, a Korean veterinary hospital representative reported three small nosocomial clusters of MRSA infection in hospitalized dogs. Isolates were obtained from 12 dogs and were recovered from the anterior nares, catheters, conjunctiva, a postoperative wound, and a skin lesion.[25] A further description of MRSA infection in dogs from the United Kingdom reported that in 8 of 11 dogs the infection was likely contracted during surgical procedures, the most common of which were repair of traumatic fractures.[26] Of the 11 dogs, 3 suffered from chronic pyoderma that was not responsive to routine antibiotic treatment. The MRSA infection resolved or improved in 9 of those cases after appropriate antibiotic therapy. Treatment of individual MRSA cases must begin with review of the antibiotic susceptibility profile of individual isolates, and selective antimicrobial therapy should be based upon those results.

In addition to MRSA, methicillin-resistant *S. intermedius* and *S. schleiferi* may present a more pressing threat to veterinary medicine. In a survey done at the Matthew J. Ryan Veterinary Hospital of the University of Pennsylvania, the rates of methicillin resistance in these three pathogens isolated between 2003 and 2004 were 32%, 17%, and 49%, respectively (unpublished data).

C. difficile was implicated as the causative organism in an outbreak of diarrhea in dogs in a small animal veterinary teaching hospital.[12] Of note, no cases were identified in the ICU, and this was attributed to stringent infection control measures. *C. difficile*–associated disease (CDAD) occurs as a result of intestinal colonization and toxin production by toxigenic strains. A diagnosis of CDAD is made following detection of both an enterotoxin, designated Toxin A, and a cytotoxin, designated Toxin B, in fecal specimens. Some animals are known to carry toxigenic strains of *C. difficile* without toxin production, so demonstration of the organism in feces by anaerobic culture is not confirmatory. Sources of nosocomial *C. difficile* include colonized or infected animals, indirect contact via hospital personnel, or environmental reservoirs of potentially pathogenic spores that are known to be resistant to commonly used disinfectants. Treatment of CDAD depends on a number of factors that include co-infection with additional enteric pathogens. Metronidazole or vancomycin is generally the antibiotic of choice.

Vancomycin-resistant *Enterococcus faecium* (VRE) has not yet been implicated in nosocomial infections of dogs and cats. However, VRE has been identified in a canine urinary tract infection, and monitoring at veterinary teaching hospitals in the United States and Europe has revealed VRE carriage in healthy dogs.[27,28] Most VRE isolates are highly resistant to many other antimicrobial classes, and the gene responsible for vancomycin resistance is resident on a transposable element; the exchange of this element has been demonstrated between human and canine *E. faecium*. Therefore the use of vancomycin alone may not be a necessary prerequisite for selection of VRE in small animals.[27]

Overall, the number of reports of infection or colonization in animal species of pathogens that have traditionally been thought to have a reservoir only in humans has increased since the earliest reports of MRSA in the 1960s and 1970s. This trend can be considered a significant public health concern given the potential for direct spread of MDR pathogens between humans and animals. It is reasonable to assume that infected dogs and cats can serve as 51 reservoirs for these pathogenic organisms. However, the alternative hypothesis, that humans can also be a reservoir for MDR infectious agents that can be transmitted to dogs and cats, now seems equally feasible.

12.8 NOSOCOMIAL INFECTION PREVENTION AND CONTROL

The reservoirs of nosocomial pathogens include humans, animals, fomites, air currents, water and food sources, insects, and rodents, and it has long been known that the spread of pathogens in hospitals occurs primarily via the hands of personnel.[1] Therefore frequent hand washing is of the utmost importance and the use of gloves in handling patients may also help to decrease the incidence of nosocomial infection. In 1989, Murtaugh and Mason proposed that nosocomial infection control committees be established in veterinary hospitals, especially at the larger teaching and referral centers.[29] Some veterinary institutions were receptive to this proposal, but there are still no national or international standards for veterinary hospital infection control. Much of what is written is borrowed from human health care guidelines, and worldwide surveillance statistics of veterinary nosocomial infection rates are not available.

The guidelines for prevention and control of nosocomial infection are simple and comprise three main approaches. First, methods are needed to prevent cross-contamination and to control potential sources of pathogenic microorganisms that can be transmitted from patient to patient or from hospital personnel to patient. Secondly, guidelines are needed to direct the appropriate use of prophylactic, empiric, and therapeutic antimicrobial use. Finally, strategies to limit the emergence or spread of MDR pathogens should be developed and targeted against organisms known to be prevalent in individual institutions. Some of these approaches may at first seem to be restrictive, but infection control guidelines are intended only to improve the process of care. Infection control measures when instituted in human health care settings have been unpopular, and compliance is difficult to maintain. It has been suggested that noncompliance is connected with many aspects of human behavior, including the yearning of human beings for liberty, the false perception of an invisible risk, and the underestimation of individual responsibility in the epidemiology of the institution.[1]

In conclusion, the importance of nosocomial transmission, particularly in the ICU, cannot be overemphasized. Although the intrinsic risk factors of individual animal patients for the development of nosocomial infection are difficult to assess, the risk of transmission of pathogenic and MDR organisms can and should be reduced to a minimum whenever possible.

13 Chapter 13 Enteral Nutrition

Laura Eirmann, DVM

Kathryn E. Michel, DVM, MS, DACVN

13.1 KEY POINTS

- The goal of enteral nutrition is to provide the patient with adequate caloric and nutrient intake to prevent the adverse consequences of malnutrition.
- Every critically ill patient must have an assessment performed to determine an appropriate nutrition plan. Patient reevaluation and nutrition plan reassessment need to occur throughout the hospitalization.
- As a general guideline, enteral feeding as far proximal as possible in the gastrointestinal (GI) tract is the preferred route of delivering nutritional support.
- Feasibility of enteral nutrition is based on patient factors such as GI function and ability to protect the airway, as well as nonpatient factors such as cost, predicted length of hospitalization, technical expertise, and level of patient monitoring.
- The daily caloric goal for most critically ill patients will be the resting energy requirement. Evaluating whether a patient achieves this level of intake requires detailed feeding orders and documentation of patient intake.
- Potential complications of enteral nutrition include patient factors such as inadequate intake, GI side effects, metabolic derangements, and infectious complications, as well as nonpatient factors such as mechanical complications related to the feeding device.

13.2 INTRODUCTION

The goal of enteral nutrition is to provide the patient with adequate caloric and nutrient intake via the gastrointestinal (GI) tract in order to prevent the adverse consequences of malnutrition. Hospitalized patients frequently have decreased voluntary food intake for many reasons, including nausea, pain, and anxiety. At the same time, critically ill patients have metabolic alterations mediated by catecholamines, corticosteroids, and inflammatory mediators such as interleukin-1 and tumor necrosis factor (TNF)-α, which alter metabolism resulting in a catabolic state.[1] Decreased voluntary intake coupled with a catabolic state places critically ill patients at high risk for malnutrition, necessitating nutritional support. Malnutrition in the critically ill patient leads to depletion of endogenous proteins, which may have serious adverse effects on tissue synthesis, immunocompetence, maintenance of gut integrity, and intermediary drug metabolism.[2] Malnutrition in humans is associated with increased complication rates, duration of hospitalization, and cost.[3] While analogous studies have not been conducted in veterinary medicine to date, it seems reasonable to assume that comparable outcomes would be expected in malnourished veterinary patients.

13.3 NUTRITIONAL ASSESSMENT

Intervention begins with a nutritional assessment of the individual patient. The goal is to determine whether the patient is at low, moderate, or high risk for malnutrition. The process begins with a review of the history and medical record. The clinician obtains a comprehensive, detailed dietary history regarding all foods ingested before and during the current illness, including pet foods, table foods, and nutritional supplements. Both a subjective assessment of appetite and an objective determination of the amount of food consumed are recorded. The logistics of feeding management, such as number of meals per day, are noted. The clinician must assess nutritional adequacy because clients frequently feed their pets unbalanced diets during periods of illness to encourage intake. Past or current GI signs should be noted because these may affect the nutritional plan. A thorough medication history is required because some medications affect appetite or nutrient metabolism.

Veterinary patients who have not consumed or are not anticipated to consume their resting energy requirement (RER) for 3 to 5 days or who have lost 10% of usual or optimal body weight (5% for pediatric patients) are at high risk of malnutrition and require nutritional support once their immediate hydration, hemodynamic, acid-base, blood glucose, and electrolyte abnormalities are stabilized.[2]

A physical examination is performed to assess body weight, body condition, and muscle mass. The clinician should be aware that a patient might have excessive fat stores but low muscle (lean body) mass.[4] The metabolic derangements of critical illness often lead to a precipitous loss of lean body mass, placing the patient at high risk for protein calorie malnutrition. Careful physical examination may also detect signs of malnutrition such as poor skin or coat quality. Physical examination may reveal abnormalities that preclude certain feeding modalities. For example, facial trauma necessitates enteral feeding that bypasses the oral cavity.

Routinely measured laboratory parameters such as complete blood count, serum biochemistry, and urinalysis are poor indicators of overall nutritional status. However, hypoalbuminemia, anemia, or low blood urea nitrogen (BUN) levels may occur secondary to malnutrition. The underlying disease factors into risk assessment for malnutrition and often dictates several components of the nutrition plan, including route of delivery and the nutrient composition of the diet. Some diseases such as protein-losing enteropathy, protein-losing nephropathy, chylothorax, burns, and draining wounds cause excessive loss of body protein, requiring an aggressive nutrition plan to meet caloric and protein needs. Conversely, a patient with protein intolerance such as hepatic encephalopathy might need a plan to meet the patient's caloric needs without further elevating nitrogenous wastes in the bloodstream.

History, physical examination, and diagnostic findings determine the patient's risk for malnutrition. As a general 53 54 guideline, higher risk patients require a more aggressive nutritional intervention plan and closer monitoring for both positive response and complications of dietary intervention. However, the risk of malnutrition may change over time. Patient reevaluation and nutrition plan reassessment must occur throughout hospitalization.

13.4 DETERMINING THE ROUTE OF NUTRITIONAL SUPPORT

13.4.1 Enteral Versus Parenteral

Nutritional support can be delivered via the GI tract (enteral route), via the vasculature (parenteral route), or using a combination of the two. Both routes require a hemodynamically stable patient with no major acid-base or electrolyte abnormalities. The route of nutrient delivery is determined by patient factors such as GI function and ability to protect the airway, and nonpatient factors such as cost, predicted length of hospitalization, technical expertise, and level of patient monitoring. Enteral feeding is preferable to parenteral feeding because it is physiologically sound, less costly, and safer.[5] The physiologic benefits of enteral feeding include prevention of intestinal villous atrophy, maintenance of intestinal mucosal integrity, which decreases the risk of bacterial translocation, and preservation of GI immunologic function. Contraindications for enteral feeding are uncontrolled vomiting, GI obstruction, ileus, malabsorption or maldigestion, or inability to protect the airway. However, if the patient is unable to protect the airway, the clinician may select a route of nutrient delivery distal to the pharynx or esophagus if the concern is aspiration during swallowing, or distal to the pylorus if the concern is aspiration during vomiting or regurgitation. Figure 13-1 outlines the decision process for selecting an appropriate enteral feeding route.

13.4.2 Oral Intake Versus Enteral Feeding Device

When enteral feeding is appropriate, the clinician selects the mode of nutrient delivery, sets a caloric goal, and chooses an appropriate diet. Enteral feeding as far proximal in the GI tract as the patient can tolerate is preferred. Voluntary oral intake has distinct advantages. It requires no special equipment or techniques and allows the owner to participate in patient care. If the oral route is selected, the clinician must write specific feeding orders. The technical staff offers the amount written on the feeding orders and records the amount consumed. The clinician then determines if the nutrition goal was met. If intake does not meet the goal, the clinician reassesses the patient, diet, and environment. The clinician may change the diet (e.g., more palatable diet, warming the food) or change the environment (e.g., quieter ward, owner feeding the pet). Syringe feeding a liquid or blenderized pet food may be attempted for 1 to 2 days but frequently becomes too stressful and time consuming. If the patient shows any signs of nausea, oral feeding should be discontinued immediately, because this can lead to a learned food aversion. Medication to ameliorate nausea and an alternative feeding method should be considered.

An enteral feeding tube removes the variable of voluntary intake. The technical staff delivers a prescribed amount of a specific diet via the feeding tube according to orders written by the veterinarian. These tubes are well tolerated by veterinary patients. A retrospective owner survey concluded that owners were comfortable managing their cats at home with esophagostomy and percutaneous endoscopic gastrostomy tubes.[6] However, enteral feeding device placement usually requires sedation or anesthesia and technical skill. Technicians and owners must be taught how to use feeding devices and monitor for complications. Table 13-1 outlines advantages and disadvantages of the various forms of enteral access used in veterinary patients.

13.5 ENTERAL FEEDING TUBES

13.5.1 Nasoesophageal or Nasogastric Tubes

A 3.5 to 8 Fr silicone or polyurethane feeding tube may be placed through the nares into the distal esophagus (nasoesophageal [NE]) or into the stomach (nasogastric [NG]) (Color Plate 13-1). NE tubes are preferred because the risk of gastric reflux increases if the tube passes the lower esophageal sphincter. However, NG tubes allow for gastric decompression and measurement of gastric residual volume. Radiographic confirmation of correct placement is recommended.

An advantage of NE and NG tubes is that they can be placed easily under local anesthetic or light sedation.[7] This is a good option for patients that are poor candidates for general anesthesia. Facial trauma may preclude placement of this type of tube, and it should not be used in a patient with respiratory disease because it may exacerbate respiratory compromise. Any patient that receives enteral nutrition must have a functional GI tract and the ability to guard the airway if vomiting or regurgitation occurs.

Because only small-bore tubes are used, diet selection is limited to liquids. NE and NG tubes are best for short-term (7 to 14 days) feeding because they can be irritating. An Elizabethan collar (E-collar) and close monitoring are required because the pet may attempt to dislodge the tube. In addition, sneezing or vomiting may dislodge the tube, requiring reassessment for correct placement. Complications associated with NE or NG tubes include epistaxis, rhinitis, sinusitis, dacryocystitis, inadvertent placement or dislodgement of the tube into the airway, esophageal irritation, reflux, or clogging of the tube.

13.5.2 Esophagostomy Tube

A larger feeding tube (usually a 12 to 14 Fr tube for cats and up to a 22 Fr for larger dogs) can be placed in the proximal esophagus at the midcervical level, with the tip positioned in the distal esophagus (Color Plate 13-2). The esophagostomy tube (E-tube) has several advantages. Veterinary patients appear to tolerate them quite well. They can be used for fairly long periods (weeks to months) in both the hospital and outpatient settings. The larger tube allows for a wider selection of diets, including blenderized canned pet foods. The tube can be used in patients with facial or oral disease that precludes NE tube placement. As with the NE tube, the patient must have normal GI function, including normal esophageal function and the ability to protect the airway.

Placement of this tube requires general anesthesia and technical skill, although the technique is relatively simple and well described.[8-12] E-tubes can be used for feeding as soon as the patient recovers from anesthesia and can be removed by the clinician at any time. Risks associated with E-tubes include placement in the airway or mediastinum and damage to cervical vascular or nerve tissue. As with the NE tube, a lateral radiograph should be used to verify placement. Complications include cellulitis or infection at the tube site, patient dislodgement, esophageal irritation and reflux, displacement during vomiting or regurgitation, and clogging of the tube.

Does patient have a functional esophagus?
No
Does patient have normal gastric function?
Consider J-tube
Yes
Consider E-tube
Yes
Consider G-tube

13.5.3 Gastrostomy Tube

Larger (usually 16 to 22 Fr mushroom-tipped) feeding tubes can be placed directly in the stomach via surgical placement,[2,13] endoscopic guidance,[2,14] or blind technique using a gastrostomy tube placement device.[2,12-15] All techniques require longer time under anesthesia and more technical skill than is needed for E-tube placement. The 55
56 percutaneous endoscopic gastrostomy and blind technique avoid doing a laparotomy, but if the patient is undergoing abdominal surgery, surgical placement is preferable because the surgeon can visualize placement and pexy the stomach to the abdominal wall. Endoscopic placement is preferred over a blind technique because it allows visualization of the gastric placement site and decreases the risk of iatrogenic injury to abdominal viscera during placement.[12]

Table 13-1 Advantages and Disadvantages of Enteral Feeding Devices

Enteral Feeding Device	Advantages	Disadvantages
NE or NG tube	Ease of placement No general anesthesia NG tube allows for gastric decompression	Limited to liquid diets Short term (<14 days) Can be irritating; requires E-collar Can dislodge if patient sneezes or vomits Contradicted in facial trauma or respiratory disease Increased risk of vomiting with NG vs NE tube
Esophagostomy tube	Blenderized pet foods or liquid diets can be used Well tolerated by patient Ease of placement Can feed as soon as patient awakens from anesthesia Can be removed at any time Good long-term option	Requires general anesthesia Risk of cellulitis or infection at site Can dislodge if patient vomits Can cause esophageal irritation or reflux if malpositioned
Gastrostomy tubes	Blenderized pet foods or liquid diets can be used Well tolerated by patient Good long-term option	Requires general anesthesia Risk of cellulitis or infection at site Risk of peritonitis Must wait 24 hours after placement before feeding Must wait 10 to 14 days before removing
Jejunostomy tube	Requires liquid diet Able to feed distal to pylorus and pancreatic duct	Requires general anesthesia Technically more difficult to place Risk of cellulitis or infection at site Risk of peritonitis Risk of tube migration with secondary GI obstruction Must wait 24hours after placement before feeding Requires CRI feeding Requires very close monitoring Short-term option

CRI, Constant rate infusion; *GI,* gastrointestinal; *NE,* nasoesophageal; *NG,* nasogastric.

The gastrostomy tube (G-tube) provides nutrients distal to the esophagus, providing enteral feeding to patients with esophageal disease. The G-tube is well tolerated, permits bolus meal feedings, and is appropriate for long-term at-home feeding.[6,16] As with the E-tube, the option of blenderized pet foods allows a wider diet selection. The patient must tolerate feeding above the pylorus without vomiting. The tube cannot be used for the first 24 hours after placement to allow return of gastric motility and formation of a fibrin seal at the stoma. The tube should not be removed until the stomach has adhered to the body wall to prevent stomach content leakage and secondary peritonitis. The tube is typically left in place for at least 10 to 14 days, or longer in more severely compromised or malnourished patients. Major complications associated with G-tubes include abdominal visceral injury during percutaneous placement or peritonitis if stomach contents leak into the abdominal cavity secondary to tube displacement or dehiscence. As with any surgically placed feeding device, cellulitis or infection at the stoma site is possible. Improperly placed G-tubes may cause a pyloric outflow obstruction. A G-tube requires closer monitoring and is more costly than techniques previously described.

13.5.4 Jejunostomy Tube

A small-bore feeding tube (usually 5 to 8 Fr) can be placed directly in the proximal jejunum. Feeding distal to the pylorus provides enteral nutrition to patients unable to tolerate gastric feedings. Indications for jejunostomy tubes (J-tubes) include gastroparesis, uncontrolled vomiting, canine pancreatitis, and inability to protect the airway. The most common method used for placing J-tubes is surgically during laparotomy,[17,18] although transpyloric placement techniques via nasojejunal or gastrojejunal feeding tubes have been described.[19-21] Surgical placement allows visualization of tube position and a pexy of the bowel to the abdominal wall. Transpyloric techniques are less invasive, with nasojejunal tubes eliminating the risk of bowel content leakage into the peritoneum. However, transpyloric placement requires advanced technical skill and either endoscopic or fluoroscopic guidance. J-tubes can be used for a moderately short period (days to weeks). Surgically placed or gastrojejunal tubes cannot be used until a fibrin seal has formed at the body wall.

The small diameter of J-tubes limits diet selection to liquids. To minimize the risk of abdominal cramping and vomiting, constant infusion is preferred over bolus feeding. This requires more diligent patient monitoring and does not allow for at-home feeding under most circumstances.

Complications associated with J-tubes include peristomal cellulitis or infection, peritonitis secondary to leakage, retrograde migration of the J-tube, intestinal obstruction secondary to tube migration, and clogging of the tube.

13.6 DETERMINING THE AMOUNT TO BE FED

Hospitalized patients should initially be fed to meet the RER, defined as the amount of energy (calories) needed to maintain homeostasis in the fed state in a thermoneutral environment.[2] Calorimetry is not used in the clinical veterinary setting, so estimates of RER can be calculated by allometric formulas such as $70BW_{kg}^{0.75}$. Calculations for obese patients should be based on optimal body weight to prevent overfeeding. “Illness factors” are no longer widely used in critical care nutrition.[22] The patient must be reassessed to see if the initial caloric estimate is appropriate. The goal during hospitalization is to maintain body weight (excluding fluctuations due to hydration status) and lean body mass. Overfeeding is associated with GI and metabolic complications. Certain disease conditions such as sepsis, head trauma, or burns may require increased caloric intake if the above goals are not met by RER. In patients with prolonged anorexia, gastrointestinal compromise, or metabolic derangements, the caloric goal should be achieved over several days. Typical feeding protocols might provide 30% to 50% RER on day 1, with the goal of reaching full RER over the next several days.

13.7 SELECTING THE DIET

13.7.1 Patient Variables

Highly digestible nutrients from high quality sources should be selected for critical care patients. A patient with a poor appetite may benefit from a more calorie-dense diet because a smaller volume of food will meet the caloric goal. The clinician must determine if any macronutrients or micronutrients should be altered due to the patient's disease condition. For example, enteral protein intake should be 4 to 6 g of protein per 100 kcal (15% to 25% of total energy) for dogs and 6 or more g of protein per 100 kcal (25% to 35% of total energy) for cats.[22] Certain disease conditions such as hepatic encephalopathy may require the clinician to select diets closer to the minimum protein requirement to help prevent protein intolerance. However, when a lower protein diet is fed, adequate calorie and protein intake is essential in order to minimize the risk of protein malnutrition. Conversely, disease conditions associated with a high degree of protein loss may require a diet replete in protein. Other examples of nutrient modulation include sodium in patients with congestive heart failure and fat in patients with hyperlipidemia, canine pancreatitis, and GI diseases leading to fat malassimilation.

13.7.2 Nonpatient Variables

Nonpatient variables contribute to diet selection. Small-diameter NE-, NG-, or J-tubes require liquid diets. Financial constraints and cost of diets may factor into the selection process. Choices are limited by availability (i.e., the hospital inventory) and the clinician's knowledge of various products.

13.8 MONITORING THERAPY

Nutritional assessment occurs at least daily. The clinician reviews past feeding orders to determine if the appropriate diet plan was instituted and if the patient achieved the set goals. If the patient did not meet the dietary goal, the clinician must determine whether the cause was related to patient issues (e.g., nausea, unpalatable diet) or nonpatient issues (e.g., improperly written orders, orders not followed, feeding with-held for procedures). The clinician then updates the plan. Monitoring of body weight daily, hydration status, and laboratory values such as blood glucose, total solids, lipemia check, blood urea nitrogen, and electrolytes must be done to assess the response to dietary intervention and to check for complications. The frequency and specifics of monitoring depend on the patient's disease condition, the mode of dietary intervention, and financial constraints. Patients that are critically ill and those receiving aggressive dietary intervention require the closest monitoring.

13.9 PREVENTING AND MANAGING COMPLICATIONS

13.9.1 Patient-Related Complications

Many feeding complications can be prevented by proper patient evaluation, selection of the appropriate route and amount of nutrient delivery, understanding of the risks associated with the specific feeding plan, and close patient monitoring. Most enteral feeding complications are minor but aspiration, premature dislodgement of a gastrostomy or enterostomy tube, and certain metabolic abnormalities can be life threatening.[23] GI intolerance may manifest as vomiting, diarrhea, or ileus. This complication can compromise the ability to continue enteral feeding. The clinician should assess the feeding plan to confirm that daily intake does not exceed the patient's energy requirements (approximately RER in most cases) and that the day's feeding is divided into multiple small meals. Food should be warmed to body temperature for tube feeding. The patient's disease condition or medications may contribute to nausea, vomiting, ileus, or diarrhea. Altering medications or providing antiemetics or prokinetic agents may allow for continued enteral feeding.

Metabolic complications can arise if a patient is unable to assimilate certain nutrients. For example, a patient with glucose intolerance may need a dietary formulation low in simple carbohydrates to modulate hyperglycemic episodes. Anticipating specific intolerances during nutritional assessment and setting conservative caloric goals not to initially exceed RER will minimize the risk.[23] Refeeding syndrome is a life-threatening metabolic complication that may occur in patients after prolonged anorexia or in certain catabolic states. In this syndrome, on reintroduction of feeding, there is a rapid shift of key intracellular electrolytes from the vascular to the intracellular space causing life-threatening hypokalemia, hypophosphatemia, or hypomagnesemia. This electrolyte abnormality can occur within days of resuming enteral feeding.[24] At-risk patients should be fed conservative amounts initially and monitored closely and electrolyte abnormalities corrected via parenteral or enteral replacement.

Aspiration is a potentially life-threatening complication that can be minimized by careful patient selection and close monitoring. Infections may occur at the peristomal site, along fascial planes, or within the peritoneum. Infectious complications can be minimized with proper tube placement, careful monitoring of tube sites, and basic hygiene during the preparation and delivery of food. 57

58

13.9.2 Nonpatient-Related Complications

Mechanical complications include obstructed tubes or tube migration. Clogging can be prevented by proper management such as flushing with warm water before and after every use. One should avoid using the feeding tube to administer medications. If the tube becomes obstructed, flushing with warm water under alternating pressure and suction may dislodge the debris. A “recipe” for unclogging feeding tubes with pancreatic enzyme, sodium bicarbonate, and water has been described.[25] Proper technique in placing and suturing tubes will minimize the risk of tube migration and dislodgement. E-collars, bandages, and patient monitoring help prevent the patient from removing a tube. The tube should be marked with indelible ink where it exits the body so that migration can be detected. Radiographs can be taken if tube migration is suspected, with use of a contrast agent if leakage into the peritoneal space is suspected. Dislodged or migrated tubes should never be used for feeding without verifying placement.

14 Chapter 14 Parenteral Nutrition

Kathryn E. Michel, DVM, MS, DACVN

Laura Eirmann, DVM

14.1 KEY POINTS

- Parenteral nutrition (PN) is provided by the intravenous (IV) route and is used when nutritional support is indicated for a patient but enteral delivery is not feasible.
- The three basic requirements that must be met for parenteral nutritional support are: (1) the ability to obtain and maintain appropriate vascular access aseptically, (2) the ability to provide 24-hour nursing care and monitoring, including basic point-of-care serum chemistry evaluation, and (3) the means and the expertise to formulate the PN prescription and compound the nutrient admixture.
- Special considerations for the nutritional assessment of a candidate for PN include assessing vascular access, fluid tolerance, and preexisting conditions that may affect the patient's nutrient tolerance or predispose it to metabolic complications.
- Particular attention should be paid to the catheter site for signs of phlebitis or infection. Daily monitoring of hydration status, fluid tolerance, blood glucose concentration, serum electrolyte values, and evidence of lipemia is indicated.

14.2 INTRODUCTION

PN is provided by the IV route. The intraosseous route can also be used for very small patients such as neonatal dogs and cats. Parenteral delivery is used when nutritional support is indicated for a patient but the enteral route is not feasible. Most commonly this happens because per os feeding is contraindicated, as with a patient experiencing nausea and vomiting or a patient unable to guard its airway and thereby at risk of aspirating stomach contents. PN is also indicated in patients in need of nutritional support who are experiencing gastrointestinal malassimilation and are unable to absorb adequate nutrients by the enteral route.

Although enteral nutrition has many advantages over the parenteral route (see Chapter 13, Enteral Nutrition), in patients for whom enteral nutrition is contraindicated or insufficient, PN can be life sustaining. This technique of assisted feeding has been used successfully in many species, including humans, dogs, cats, horses, cattle, birds, and various exotic species.[1-4]

14.3 TECHNICAL REQUIREMENTS

Parenteral nutritional support may not be feasible in every veterinary practice, but the associated technology and equipment is becoming increasingly accessible and affordable for many small animal hospitals. Three basic requirements must be met in order to provide parenteral nutritional support to a patient. First, it must be possible to obtain and maintain appropriate vascular access aseptically. Second, 24-hour nursing care must be available, along with the ability to do at least basic point-of-care serum chemistry evaluation. And third, there must be the means and the expertise to formulate the PN prescription and compound the nutrient admixture.

14.3.1 Vascular Access

To minimize the risk of line sepsis or drug-nutrient interactions, PN must be delivered through a dedicated venous catheter, although a single dedicated port of a multilumen catheter will suffice. A dedicated line is one that is not used for any other purpose, including blood sampling, hemodynamic monitoring, or delivery of other IV fluids or medications. Because some of the nutrient solutions used to formulate the PN admixture are hyperosmolar, central venous access is preferred. The hyperosmolar PN admixture will be diluted by the rapid blood flow in central vessels, thus greatly reducing the risk of phlebitis. However, both centrally and peripherally inserted central venous catheters can be used. It is possible to dilute solutions sufficiently so that they can be delivered through a peripheral venous catheter, but the resulting increased volume that must be delivered will limit the ability to meet nutritional goals in patients with limited fluid tolerance.

Catheters should be composed of nonthrombogenic materials such as polyurethane or silicone, and peripheral catheters should be as long as practically possible. The line placement should be treated as a surgical procedure, with surgical preparation of the catheter site, draping, and sterile gloves. The catheter site should be covered with a sterile dressing that should be inspected and changed daily.

14.3.2 Monitoring and Nursing Care

The best setting for delivering PN is an intensive care or fluid ward that has 24-hour staffing and the capability of doing basic in-house serum chemistry analysis. Most patients requiring PN are critically ill and will need intensive care and monitoring. Even a relatively stable patient who is receiving PN needs to be in a facility that can provide expert nursing care to properly maintain the central venous catheter and monitor the patient. Although PN can be delivered cyclically, it is best delivered as a constant rate infusion. It will be necessary to monitor various serum chemistry values depending on the patient's underlying condition (e.g., electrolytes, glucose, blood urea nitrogen [BUN], albumin), sometimes multiple times in the course of a day. This will be greatly facilitated by having in-house equipment.

14.3.3 Formulating and Compounding Nutrient Admixtures

Veterinary patients usually are not supported with PN for longer than 1, or at most 2, weeks. Therefore it is rare that a patient would receive a nutrient admixture that was formulated to provide complete nutrition. Generally PN solutions provide energy, protein, and water-soluble vitamins, with the optional addition of electrolytes and some of the trace elements. In addition to knowing how to formulate the PN prescription, it is necessary to have ready access to the special nutrient solutions and to know how to compound these solutions for nutrient admixture (Color Plate 14-1). Nutrient solutions must be combined in the proper order to prevent components from precipitating out of solution or suspension, and the entire process must be done under sterile conditions to prevent microbial contamination. Therefore, unless PN is used frequently in a practice, it is far more practical to find a human hospital or home transfusion service that will compound the solutions on request.

14.4 NUTRITIONAL ASSESSMENT

The task of evaluating a patient for nutritional support has been covered in detail in Chapter 13, Enteral Nutrition. Additional considerations for candidates for PN include assessing vascular access, fluid tolerance, and preexisting conditions that may affect the patient's nutrient tolerance or predispose it to metabolic complications.

Ideally PN should be delivered via a dedicated central line; however, central venous access may be unobtainable or contraindicated. For example, central catheter placement via a jugular vein is contraindicated in patients with head trauma or other conditions predisposing to increased intracranial pressure, those at risk of thromboembolic disease (e.g., protein-losing nephropathy or enteropathy, disseminated intravascular coagulation [DIC], hyperadrenocorticism, or those receiving high-dose glucocorticoids), or patients with severe coagulopathies. Fortunately, central vascular access can still be obtained in most patients by using a peripherally inserted central venous catheter (PICC).

Patients should be evaluated for their ability to tolerate the additional fluids that they will receive from the PN admixture. This will not be a problem for most patients; however, animals experiencing heart failure or oliguria will be at risk of volume overload. For patients with reduced fluid tolerance it is especially important to have central venous access to allow the most concentrated nutrient solutions to be used for formulation of the PN admixture. It may be possible to reduce the volume of the other IV fluids that the patient is receiving to accommodate that of the PN. Even so, there will occasionally be patients for whom it will not be possible to meet nutritional goals with parenteral nutritional support due to fluid intolerance.

Metabolic complications of PN are common,[1,2] but most can be minimized, if not avoided, by evaluating each patient for predisposing conditions such as an impaired ability to metabolize a specific nutrient or eliminate its metabolites. Table 14-1 lists some of the more common metabolic complications seen with PN and the conditions that may predispose to them. By anticipating complications, the PN admixture can be formulated in such a way as to reduce the likelihood that they will occur and the magnitude of any problems that do ensue.

14.5 PRESCRIPTION FORMULATION

14.5.1 Calculation of Energy Requirements

Evidence suggests that while critically ill patients are in a catabolic state their energy needs are not necessarily 59
increased above normal.[5,6] Furthermore, excessive calories and nutrients in the form of PN can have adverse 60
consequences including many of the metabolic complications described in Table 14-1, as well as fatty infiltration of the liver and hypercapnia.[7] For these reasons, caloric goals for parenterally fed patients should be conservative and, in most cases, based on an estimate of a patient's resting energy expenditure ($70BW_{kg}^{0.75}$; see Chapter 13, Enteral Nutrition). The caloric goal can then be adjusted based on the patient's response.

Table 14-1 Conditions Predisposing Patients Receiving PN to Metabolic Complications

Complication	**Predisposing Conditions**
Hyperglycemia	Diabetes mellitus, hyperadrenocorticism
Lipemia	Pancreatitis, idiopathic hyperlipidemia, diabetes mellitus, hyperadrenocorticism
Azotemia	Renal failure
Hyperammonemia	Hepatic failure, portosystemic shunt
Refeeding syndrome (hypokalemia, hypophosphatemia, or hypomagnesemia)	Prolonged starvation or catabolic disease, diabetes mellitus

PN, Parenteral nutrition.

14.5.2 Calculation of Protein Requirements

There has been limited investigation of the protein requirements of companion animals receiving PN.[7,8] Most recommendations call for 4 to 6 g of protein per 100 kcal for dogs and 6 g or more of protein per 100 kcal for cats. Some clinicians advocate meeting the patient's energy requirements with nonprotein calories from dextrose and lipids in addition to providing the required protein. This approach has the potential of providing excessive calories, particularly in patients deemed to have high protein requirements. A more conservative approach is to subtract the required protein calories from the patient's total energy requirement and provide the balance as nonprotein calories. Using the recommendations given above, this roughly translates into 15% to 25% of calories for dogs and 25% to 35% of calories for cats delivered as protein. Patients that are protein depleted or have high ongoing losses will require PN admixtures containing protein amounts in the upper ranges. For patients with conditions that impair protein tolerance, it may be necessary to restrict the amount of protein in the PN admixture below the lower end of these ranges.

Amino acid solutions are available in concentrations ranging from 3% to 15%. Because of increasing osmolarity, solutions more concentrated than 6% should not be used for peripherally infused PN. The electrolyte content of these products varies. Because the less concentrated products are used for peripherally infused PN, they often have higher concentrations of electrolytes to preclude the need for further supplementation. The more concentrated solutions can be obtained with or without additional electrolytes. Using the amino acid solutions without supplements for PN formulation and providing electrolytes in the patient's IV fluids allows greater flexibility.

14.5.3 Calculation of Lipid and Carbohydrate Requirements

Once the percentage of protein calories has been established, it is necessary to decide how to apportion the remaining calories between carbohydrate and fat. Although it is possible to provide all nonprotein calories as carbohydrate using dextrose solutions, lipid emulsions have the advantage of being isoosmolar and a more concentrated form of calories. Also, patients are at greater risk of becoming hyperglycemic when fed PN admixtures containing large amounts of dextrose. This is especially a concern in cats.[2] Therefore, unless there is a preexisting condition that would suggest fat intolerance, lipid emulsions can be used to provide 50% to 70% of the nonprotein calories, with the balance delivered as dextrose.

Lipid emulsions are available in 10% (1.1 kcal/ml), 20% (2.0 kcal/ml), and 30% (3.0 kcal/ml) concentrations. They are composed of emulsified soybean or safflower oils with a particle size equivalent to a chylomicron. Dextrose is available in concentrations ranging from 5% to 70%. For centrally infused PN, 50% dextrose (1.7 kcal/ml, 2500 mOsm/L) is typically used. For peripherally infused PN it is necessary to use lower concentrations (e.g., 10%, 0.34 kcal/ml, 500 mOsm/L; or 20%, 0.68 kcal/ml, 1000 mOsm/L) due to osmolarity issues.

14.5.4 Calculation of Micronutrient Requirements

Although parenteral forms of all essential micronutrients are available, typically only injectable B complex and certain electrolytes (phosphorus and magnesium) are included in PN admixtures that are used for companion animals. Some clinicians also add trace element preparations containing zinc, because there is evidence that this nutrient can be depleted rapidly in critically ill patients.[9] Table 14-2 contains dosage guidelines for these nutrients and Box 14-1 contains a sample prescription formulation.

14.6 DELIVERY AND MONITORING

A patient starting PN should receive 50% of goal nutrients the first day as a constant rate infusion over 24 hours and, if that is well tolerated, can receive 100% of its goal the following day. The PN admixture should be delivered via a dedicated catheter or port of a multilumen catheter using a 1.2-μm filter (to prevent lipid embolization) and a fluid pump. The PN admixture should be disconnected only when changing the bottle or bag, and the administration set should also be changed at that time. Gloves should be worn in performing catheter care and changing bottles and administration sets. Ideally patients should be weaned off PN over the course of several hours once they are receiving at least 50% of their goal calories through voluntary intake or enteral feeding. If it becomes necessary to abruptly discontinue PN, 5% dextrose should be added to the patient's IV fluids to prevent hypoglycemia.

Monitoring of patients receiving nutritional support has been reviewed in Chapter 13, Enteral Nutrition. For patients receiving parenteral nutritional support, particular attention should be paid to the catheter site for signs of phlebitis or infection. Hydration status and fluid tolerance should be assessed regularly. Blood glucose, serum sodium, and 60 61 potassium concentrations should be monitored at least once daily. Insulin administration may be indicated if persistent hyperglycemia occurs (0.1 U/kg regular insulin IV, IM, or SC as needed; continuous infusion by IV may be necessary in severely affected animals). Whenever a packed cell volume determination is performed, the hematocrit tube should be examined for evidence of lipemia. Serum phosphorus and magnesium concentrations should be checked after the first day of PN infusion. If serum levels of these electrolytes have decreased significantly, further monitoring is warranted so that patients can receive appropriate supplementation if necessary. Complete blood counts and serum chemistry analysis should be performed as indicated, but at least once weekly while patients are receiving PN. Ammonia levels may be indicated in animals with hepatic insufficiency or hepatic encephalopathy.

Table 14-2 Guidelines for Micronutrient Dosages in PN Admixtures

Micronutrient	**Dosage**
Vitamin B complex*	0.2 to 0.5 ml/100 kcal
Potassium phosphate	8 to 10 mmol/1000 kcal
Magnesium sulfate	0.8 to 1.0 mEq/100 kcal
Zinc	1 μg/kcal

PN, Parenteral nutrition.

* Injectable vitamin B complex does not contain folate because of compatibility issues; thus patients receiving PN for more than a few days may become deficient and should be supplemented with this nutrient via a route other than the PN admixture.

14.7 PREVENTING AND MANAGING COMPLICATIONS

14.7.1 Catheter and Parenteral Nutrition Admixture Complications

Catheter complications include loss of vascular access due to catheter malposition, thrombosis, thrombophlebitis, or catheter-associated infection. The incidence of complications can be reduced greatly with appropriate catheter selection and adherence to strict guidelines for catheter care.

Complications involving the PN admixture include microbial contamination, precipitation of admixture components, and drug-nutrient interactions. These problems can be avoided by proper compounding of the admixture under sterile conditions and infusion of the admixture through a dedicated line. The particles making up a lipid emulsion can come out of suspension in an improperly compounded admixture. Lipid-containing admixtures should be inspected periodically during infusion for signs of separation or layering. An in-line filter will prevent fat embolism in patients receiving lipid-containing PN.

14.7.2 Metabolic Complications

Most metabolic complications can be anticipated based on the patient's nutritional assessment, and can be avoided or minimized by formulating the PN admixture accordingly. Most metabolic disturbances are less likely to occur if estimates of caloric needs are conservative. “Refeeding syndrome” (see Chapter 13, Enteral Nutrition) has been described in patients receiving PN.[1,2] Those at increased risk of the electrolyte abnormalities seen with this condition are patients that have experienced a period of prolonged starvation or catabolism or patients with uncontrolled diabetes mellitus. In correcting electrolyte abnormalities, supplementation in the IV fluids as opposed to the PN admixture allows greater flexibility. Once the amount of electrolyte supplementation for maintenance is established, it can be included in the PN formulation.

14.7.2.1 Box 14-1 Centrally Administered PN Example: High-Protein Formulation for a Cat

Weight: 4.5 kg RER = 216 kcal/day

14.7.2.1.1 Day 1 Calculations

1 Amino acids

(0.3)(108 kcal) = 32 kcal from protein

There are 4 kcal/g in protein

Therefore you need 8 g of protein (32 kcal ÷ 4 kcal/g = 8 g)

8.5% amino acid solution = 0.085 g protein/ml

Therefore you need 94 ml of 8.5% amino acid solution (X ml = 8 g ÷ 0.085 g/ml)

2 Nonprotein calories

(0.7)(108 kcal) = 76 kcal

(a) 50% dextrose to provide 30% nonprotein calories = 23 kcal

50% dextrose solution = 1.7 kcal/ml

Therefore you need 13 ml 50% dextrose solution (X ml = 23 kcal ÷ 1.7 kcal/ml)

(b) 20% lipid emulsion to provide 70% nonprotein calories = 53 kcal

20% lipid emulsion = 2 kcal/ml

Therefore you need 27 ml 20% lipid emulsion (X ml = 53 kcal ÷ 2.0 kcal/ml)

3 Trace elements

Zinc prescribed at 1 μg/kcal delivered

Trace element solution contains zinc 0.8 mg/ml

Therefore you need 0.14 ml of trace element solution (X ml = 108 kcal ÷ [0.8 mg/ml × 1000])

4 Potassium phosphate

Prescribed at 8 mmol/1000 kcal delivered

Therefore you need 0.9 mmol potassium phosphate (X mmol = [8 mmol × 108 kcal] ÷ 1000 kcal)

Potassium phosphate solution = 3 mmol/ml

Therefore you need 0.3 ml potassium phosphate (X ml = 0.9 mmol ÷ 3 mmol/ml)

5 Vitamin B complex

Prescribed at 0.2 ml/100 kcal delivered

Therefore you need 0.2 ml vitamin B complex (X ml = [0.2 ml × 108 kcal] ÷ 100 kcal)

6 Infusion rate

135 ml/24 hr = 5.6 ml/h

r

14.7.2.1.2

Day 2 Calculations

Same as for Day 1—just substitute 216 kcal for 108 kcal

14.8

15 Chapter 15 Respiratory Failure

Linda Barton, DVM, DACVECC

15.1 KEY POINTS

- Respiratory failure is conventionally defined as an arterial partial pressure of oxygen (PaO_2) of less than 60 mm Hg on a fractional concentration of inspired gas (FiO_2) of less than 0.5 or an arterial partial pressure of carbon dioxide ($PaCO_2$) of more than 50 mm Hg.
- Respiratory failure can be categorized as hypercapnic pump failure or hypoxemic lung failure.
- Failure of the lung leads to hypoxemia with normocapnia or hypocapnia.
- Failure of the ventilatory pump results in alveolar hypoventilation, hypercapnia, and mild oxygen-responsive hypoxemia.
- Respiratory muscle fatigue, caused by an imbalance between respiratory muscle energy demands and energy supply, contributes to ventilatory failure in patients with respiratory disease.
- If the underlying cause is not readily reversible, patients with respiratory failure require mechanical ventilation until the cause can be identified and treated.

15.2 INTRODUCTION

The primary function of the respiratory system is the oxygenation of, and elimination of, carbon dioxide from the mixed venous blood. The two major components of the respiratory system are the lung (the gas exchange organ) and the respiratory muscles (the pump that ventilates the lung); each contributes to the performance of this gas exchange function. Disease leading to dysfunction of either of these two components can result in respiratory failure.

Inadequacy of gas exchange is reflected in the patient's blood gas values. Respiratory failure is conventionally defined as a partial arterial pressure of oxygen (PaO_2) of less than 60 mm Hg on a fractional concentration of oxygen in inspired gas (FiO_2) of over 0.5 or an arterial partial pressure of carbondioxide ($PaCO_2$) of more than 50 mm Hg.[1] Clinical signs of impending or existing respiratory failure include an increasing respiratory rate and increased work of breathing as evidenced by the use of accessory muscles of ventilation, and assumption of abnormal body postures.

Failure of each part of the respiratory system results in a distinct clinical picture (Box 15-1). Failure of the ventilatory pump results in alveolar hypoventilation and hypercapnia. Mild oxygen-responsive hypoxemia is seen in hypoventilating patients; however, the hallmark of ventilatory failure is an elevation in $PaCO_2$. In contrast, failure of the lung leads to hypoxemia with normocapnia or hypocapnia. In hypoxemic respiratory failure, the $PaCO_2$ remains normal or decreased because hypoxemia stimulates the ventilatory drive.

Although discussed as separate entities, both types of respiratory failure can coexist in a patient. Most of the lung diseases that lead to hypoxemia also increase the work of breathing and therefore the energy demands of the respiratory muscles. Hypoxia itself decreases the amount of energy available to the respiratory muscles, predisposing them to fatigue. In patients with severe or persistent lung failure, the increased ventilatory demands can exceed ventilatory capacity leading to pump failure secondary to respiratory muscle fatigue.[2]

15.2.1

Box 15-1 Disorders Predisposing to Respiratory Failure

15.2.1.1

Hypercapnic Pump Failure

15.2.1.1.1

Disorders of CNS Respiratory Centers

Overdose of respiratory depressant drugs (sedative, narcotics)

Intracranial disease

Head trauma

15.2.1.1.2

Neuromuscular Disorders

Cervical myelopathies

Myasthenia gravis

Botulism

Organophosphate toxicity

Polyradiculoneuritis

Phrenic nerve injury

Electrolyte disorders (hypophosphatemia, hypomagnesemia)

Severe malnutrition

Respiratory muscle fatigue

15.2.1.1.3

Disorders of Chest Wall and Pleural Function

Flail chest

Pleural effusion

Pneumothorax

Hemothorax

Kyphoscoliosis

Contracted scars over thorax

15.2.1.1.4 Disorders of the Conducting Airways

Laryngeal paralysis

Laryngeal edema

Asthma

Bronchospasm

15.2.1.2 Hypoxemic Lung Failure

Pulmonary contusion

Pneumonia

Pulmonary edema (cardiogenic, noncardiogenic)

Pulmonary thromboembolism

Pulmonary hemorrhage

Aspiration

Smoke inhalation

Near drowning

Interstitial lung disease

CNS, Central nervous system.

15.3 HYPOXEMIC RESPIRATORY FAILURE

Hypoxemic respiratory (lung) failure occurs secondary to a variety of disease processes that interfere with gas exchange at the alveolar level (see Box 15-1). Any of the four pathophysiologic mechanisms of hypoxemia—hypoventilation diffusion impairment, shunt, and ventilation-perfusion mismatch—can contribute to the hypoxemia seen in patients with lung failure. However, mismatch of ventilation and perfusion is the most important cause.[3]

The ratio of alveolar ventilation (V) to pulmonary blood flow (Q) determines the composition of gas leaving the lung. The lung is divided into a large number of gas exchange units, each composed of an alveolus and its associated pulmonary capillary. Ideally the volume of alveolar gas presented to the blood-gas barrier at each gas exchange unit would be matched by the volume of blood perfusing the unit, resulting in a V/Q ratio of 1.0 and complete equilibration of oxygen between the alveolar gas and the pulmonary capillary. In the normal lung, regional differences in ventilation and perfusion result in a small amount of V/Q inequality. Disease processes resulting in lung failure cause marked disturbances in the V/Q ratio, abnormal gas exchange, and hypoxemia.[4]

Pulmonary capillary blood flow in excess of alveolar ventilation produces low V/Q units. The partial pressure of oxygen (PO_2) in the effluent blood of these gas exchange units is low (approaching the PO_2 of mixed venous blood) and causes arterial hypoxemia. Low V/Q units are termed *venous admixture* or *shunt effect* and develop when there is decreased ventilation to normally perfused regions of the lung, or when there are areas in the lung with a greater reduction in ventilation than in perfusion. Venous admixture occurs with disease processes that cause the alveoli to fill with water (cardiogenic edema, noncardiogenic edema), pus (pneumonia), blood (trauma, coagulopathy), or cells (neoplasia). Bronchospasm also produces venous admixture. Zero V/Q units, or true shunt, occurs when blood enters the left side of the heart without respiring with alveolar gas. Normally a small amount of blood bypasses the lung via the bronchial, pleural, and thebesian veins; this is referred to as *anatomic shunt*. Pathologic capillary shunt occurs when blood traverses the pulmonary capillaries but does not respire with alveolar gas. Capillary shunt occurs in regions of the lung that are atelectatic or completely consolidated.[5,6]

Any part of the tidal volume that does not participate in gas exchange is referred to as *dead space*. Anatomic dead space is the amount of air in the conducting airways. Physiologic dead space occurs when the blood flow to ventilated alveoli is reduced or absent. Causes of physiologic dead space include pulmonary vascular obstruction (pulmonary thromboembolism, heartworm disease, disease processes associated with damaged capillaries and intravascular coagulation such as sepsis, systemic inflammatory response syndrome), decreased pulmonary perfusion (hypovolemia, low cardiac output, pulmonary hypertension), and overdistention of alveoli caused by mechanical ventilation with high tidal volumes or pressures.

Diffusion impairment is an uncommon cause of lung failure. Diffusion of oxygen across the alveolar-capillary membrane is affected by the total surface area of the membrane, the thickness of the diffusion barrier, the diffusion coefficient of the gas, and the pressure gradient of the gas across the membrane. In the normal lung, the alveolar-capillary surface is extensive and very thin, supporting efficient gas exchange and providing a large reserve capacity for diffusion. Complete equilibration between the PO_2 in the pulmonary capillary blood and the alveolar gas usually occurs by the time a red blood cell has traveled only one third of the way along the capillary. Disease processes that decrease the surface area of the alveolar-capillary membrane (emphysema, lung lobectomy) or increase the thickness of the diffusion barrier (pulmonary edema, diffuse interstitial fibrosis, interstitial pneumonia) may adversely affect diffusion but must be severe to exhaust the large reserve capacity. Any hypoxemia caused by diffusion impairment can be readily corrected with oxygen administration. Increasing the inspired concentration of oxygen increases the alveolar PO_2 and therefore the pressure gradient driving the diffusion of oxygen across the abnormal diffusion barrier.[4]

15.4 HYPERCAPNIC RESPIRATORY FAILURE

The lung is ventilated by the respiratory pump. The pump consists of the respiratory controllers in the central nervous system, the pathways that connect the central controllers with the respiratory muscles (spinal cord, peripheral nerves, and neuromuscular junction), and the chest wall and associated respiratory muscles. Disorders of any of these pump components can result in the inability to sustain adequate ventilation and hypercapnic respiratory failure (see Box 15-1). Diseases of the airways can also adversely affect ventilation. Disorders such as asthma and laryngeal dysfunction cause a reduction in airway diameter, an increase in airway resistance, and a decreased flow of gas into the lungs.

In addition to disorders causing decreased central respiratory drive, impairment of neuromuscular transmission, mechanical defects in the ribcage, and a marked increase in airway resistance, hypercapnic ventilatory failure may occur secondary to respiratory muscle fatigue. Fatigue is defined as the inability of the respiratory muscles to continue to generate sufficient pressure to maintain alveolar ventilation and a normal $PaCO_2$.[3] Initiation of a spontaneous breath requires the inspiratory muscles to generate sufficient force to overcome the elastic (lung compliance) and inelastic (resistance) load of the lungs and chest wall. In health, the ventilatory capacity (the amount of mechanical work that the respiratory muscles can perform) greatly exceeds the demand (the load imposed on the respiratory muscles). Respiratory muscle fatigue occurs when the energy supply to the muscles is insufficient to meet energy demands (Figure 15-1).

Energy demands are determined by the work of breathing and the strength and efficiency of the inspiratory muscles. Respiratory diseases that cause hypoxemia are usually characterized by abnormal lung mechanics and an increased work of breathing. Decreased compliance is caused by diseases such as acute respiratory distress syndrome, pneumonia, pulmonary edema, and pulmonary fibrosis. Bronchoconstriction, increased airway secretions, and bronchial mucosal edema cause an increase in the resistance forces. Muscle efficiency, the ratio of work performed to energy consumed, is decreased in diseases associated with hyperinflation, such as asthma. With hyperinflation, both the diaphragm and intercostal muscles work at a short length, an inefficient part of their force-length relationship.[2,3]

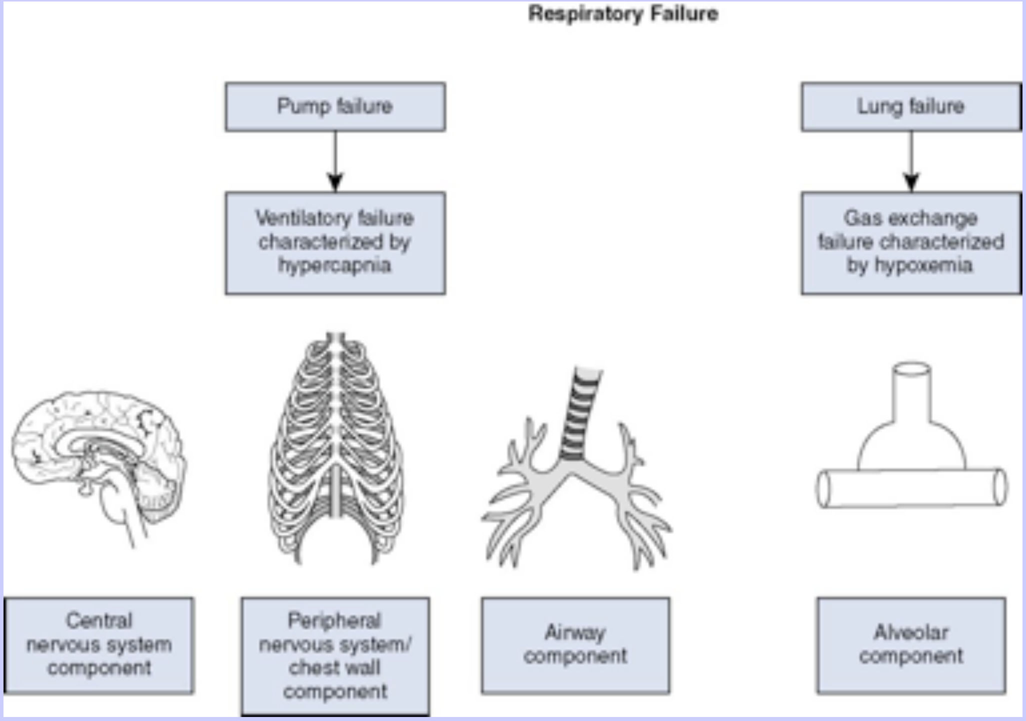
Concurrent with increased energy demands, patients with lung disease often have a decrease in respiratory muscle energy supply. Factors affecting the supply of energy to the respiratory muscles are blood flow to the muscles and the concentration of oxygen and other blood substrates (glucose, free fatty acids) in the blood. Arterial oxygen concentration is decreased with anemia, dysfunctional hemoglobin, and hypoxemia. In addition to adequate oxygen delivery, the muscles must be able to utilize the delivered oxygen. In sepsis and cyanide poisoning there is an inability of the cells to extract and use oxygen. Blood flow to muscles can be decreased in low cardiac output states. Blood flow to muscles is decreased during strenuous inspiratory efforts. Forceful muscle contractions cause compression of intramuscular vessels, limiting nutrient blood flow. Because blood flow occurs only during expiration, prolonged inspiration also causes decreased blood flow. Malnutrition and catabolic states can cause depletion of glycogen and other energy stores, predisposing to muscle fatigue.[2]

When respiratory muscle energy demand exceeds supply, fatigue develops. Decreased ability of the muscles to generate sufficient force for normal expansion of the thorax ensues, resulting in a decreased tidal volume, decreased alveolar ventilation, and hypercapnia. Evidence suggests that when fatiguing loads are imposed on the respiratory muscles, reflex changes in the central respiratory drive cause a rapid, shallow breathing pattern. The resultant smaller tidal volume reduces the energy demands per breath, a strategy that may save energy and avoid complete exhaustion at the expense of alveolar hypoventilation and hypercapnia.[2,3]

15.5 TREATMENT

All patients in respiratory distress should receive supplemental oxygen. Pulse oximetry and PaO_2, $PaCO_2$, and $PvCO_2$ monitoring can be used to further evaluate the patient's oxygenation and ventilatory status. Hypoxemia caused by hypoventilation, diffusion impairment, and low V/Q units (shunt effect) will improve with oxygen supplementation. Oxygen administration will not result in an increase in PaO_2 in true capillary shunt (zero V/Q) units. The blood passing through those units never interfaces with alveolar gas and therefore is not oxygenated. Because of the sigmoidal shape of the hemoglobin saturation curve, increasing the PO_2 to those alveoli that are well ventilated does not help improve the oxygenation of the blood leaving the lung. The hemoglobin molecules traversing these alveoli are already carrying their maximum capacity of oxygen, and increasing the amount of oxygen dissolved in the blood does not significantly increase the oxygen content.[4] Supplemental oxygen will reverse the hypoxemia caused by hypoventilation, but the hypercapnia will persist until the underlying cause of the hypoventilation is corrected.

Figure 15-1 Respiratory muscles fatigue if the energy demands exceed the energy supplied to the muscles.



Respiratory Failure
Pump failure
Lung failure
Ventilatory failure characterized by hypercapnia
Gas exchange failure characterized by hypoxemia
Central nervous system component
Peripheral nervous system/ chest wall component
Airway component
Alveolar component

If the cause of the respiratory failure cannot quickly be identified and reversed (e.g., evacuate the pneumothorax, reverse the narcotic sedative), the patient should be intubated and ventilated while the underlying cause is evaluated. Mechanical ventilation does not correct the underlying disorder. It only supports the respiratory system until the appropriate therapies can be applied. Returning the patient to health requires identification and treatment of the underlying pathology.

16 Chapter 16 Upper Airway Disease

Merilee F. Costello, DVM, DACVECC

16.1 KEY POINTS

- Upper airway disease is a common cause of respiratory distress in veterinary medicine.
- Rapid identification, intervention, and stabilization is essential to minimize complications.
- Diagnostic tests for evaluating patients with upper airway disease include radiography, laryngeal examination, flexible endoscopy, bronchoscopy, biopsy, endotracheal wash, and computed tomography.
- Emergency treatment for an animal with upper airway disease consists of minimizing stress, providing oxygen therapy, external cooling if necessary, and antiinflammatory therapy if indicated.
- Definitive management is variable depending on the underlying cause of the upper airway disease.
- Systemic sequelae to upper airway disease include aspiration pneumonia, noncardiogenic pulmonary edema, and heatstroke.
- The prognosis for animals with upper airway disease is variable depending on the underlying cause, the severity, and the other systems affected.

16.2 INTRODUCTION

Upper airway disease and obstruction is a common cause of morbidity in veterinary medicine, and this is particularly true in the emergency and critical care settings. There are numerous causes of upper airway disease, and the clinical signs are variable. It is important to remember that any abnormality of the upper airway will impair the natural defenses of the airway and may predispose the patient to pulmonary parenchymal diseases such as aspiration pneumonia and noncardiogenic pulmonary edema. Rapid identification, stabilization, diagnosis, and definitive therapy are imperative to minimize the morbidity and mortality that can be associated with upper airway disease.

16.3 CLINICAL SIGNS

The clinical signs in affected patients will vary based on species, underlying etiology, chronicity, comorbid conditions, and severity of the airway obstruction. Animals can exhibit variable degrees of dyspnea and respiratory distress. In mildly affected animals, clinical signs may include a change in voice, gagging or retching, stertor, stridor, or a dry, unproductive cough. Stertor is a low-pitched snoring sound that is generally associated with obstructive diseases affecting the nasal passages or nasopharynx. In contrast, stridor is a higher pitched respiratory noise that is generally heard during the inspiratory phase of respiration with extrathoracic obstruction and is associated with diseases affecting the larynx or trachea.[1,2] The upper airway noise in these patients often increases as the severity of the obstruction progresses. Open-mouth breathing will alleviate the airway obstruction if the disease is affecting only the nasal passages or nasopharynx. Although panting is common in dogs, open-mouth breathing in cats is never normal and should alert the clinician to the presence of respiratory disease.

Hyperthermia is a common clinical sign in dogs with upper airway disease. This occurs less frequently in feline patients, likely due to their more sedentary lifestyle. Panting is one of the primary mechanisms of thermoregulation in animals; the movement of fresh air through the upper airway effectively increases heat loss through evaporation.[3,4] In animals with upper airway disease, this air movement is compromised, predisposing them to hyperthermia. This hyperthermia can be extreme, and aggressive cooling may be necessary in severely affected patients (see Chapter 167, Heatstroke).[5]

Auscultation often reveals significant referred upper airway noise. The increased noise can be better localized by auscultating over the larynx and trachea, as well as the thorax. Inspiratory dyspnea with stertor or stridor typically results from extrathoracic obstructive diseases, and intrathoracic airway obstruction more commonly leads to expiratory dyspnea with adventitious sounds. Careful attention should be paid to thoracic auscultation to identify concurrent pulmonary parenchymal disease.

In animals with significant upper airway obstruction, severe respiratory distress and cyanosis can occur. These patients may show severe clinical signs such as an orthopneic stance when breathing, severe stridor, coughing, gasping, retching or vomiting, or collapse. In these cases, immediate anesthesia and intubation (or a tracheostomy) are imperative to minimize morbidity and mortality.

16.4 EMERGENCY STABILIZATION

Although treatment varies depending on the underlying disease process, the general emergency approach is similar in all patients with upper airway disease. As previously mentioned, these animals are fragile and can decompensate quickly, so any additional stress can be life threatening and will lead to an increase in oxygen requirements and therefore respiratory rate. This increased respiratory rate will only further exacerbate upper airway dysfunction. Early stabilization often relies on the administration of anxiolytics and sedatives (see Chapter 162, Sedation of the Critically Ill Patient). These agents should be given IM initially if the patient is not stable enough to undergo the stress of placing an IV catheter.

Acepromazine can be administered at a dosage of 0.005 to 0.05 mg/kg IV, IM, or SC. This is an excellent sedative, but it is important to remember that vasodilation and hypotension can occur, so it should be reserved for patients that are hemodynamically stable. Butorphanol is a sedative and antitussive, which can be used as a single agent or in combination with acepromazine. The dosage of butorphanol is 0.1 to 0.6 mg/kg IM, IV, or SC. In addition to sedation, patients should be placed in an oxygen-rich environment. Short-acting glucocorticoids have been recommended to reduce laryngeal and tracheal inflammation, edema, and swelling. Dexamethasone sodium phosphate at a dosage of 0.2 to 0.4 mg/kg can be administered IV, IM, or SC. In cases of suspected neoplasia, steroids should be avoided because this can complicate the diagnostic interpretation.

In patients with an elevated temperature, external cooling methods should be instituted. If sedation and oxygen therapy, with or without steroid therapy, fails to stabilize the patient, intubation is indicated. In the rare case in which intubation is not possible, an emergency tracheostomy should be performed to achieve a patent airway (see Chapter 18, Tracheostomy). When an emergency tracheostomy is not feasible, a small catheter may be passed into the trachea through the mouth or between tracheal rings and high-pressure jet ventilation or repetitive oxygen boluses from an anesthesia oxygen flow valve may be delivered until a tracheostomy is performed.

16.5 DIAGNOSTICS

Numerous disease processes can affect the upper respiratory tract. Differentiating the underlying cause in an individual patient can be challenging because the clinical signs are not pathognomonic for any single cause. Signalment, breed, history, and physical examination can often provide some information, but a detailed and thorough diagnostic approach is necessary to fully evaluate the anatomy and function of the upper airway. Even mild stress in animals with upper respiratory tract obstruction can be life threatening. In patients with mild clinical signs, less invasive testing may be possible with little or no sedation. In contrast, patients with moderate or severe airway compromise often require heavy sedation and intubation for diagnostic evaluation. In any case, the clinician should always be prepared to gain control of the airway, either via intubation or emergency tracheostomy, if necessary.

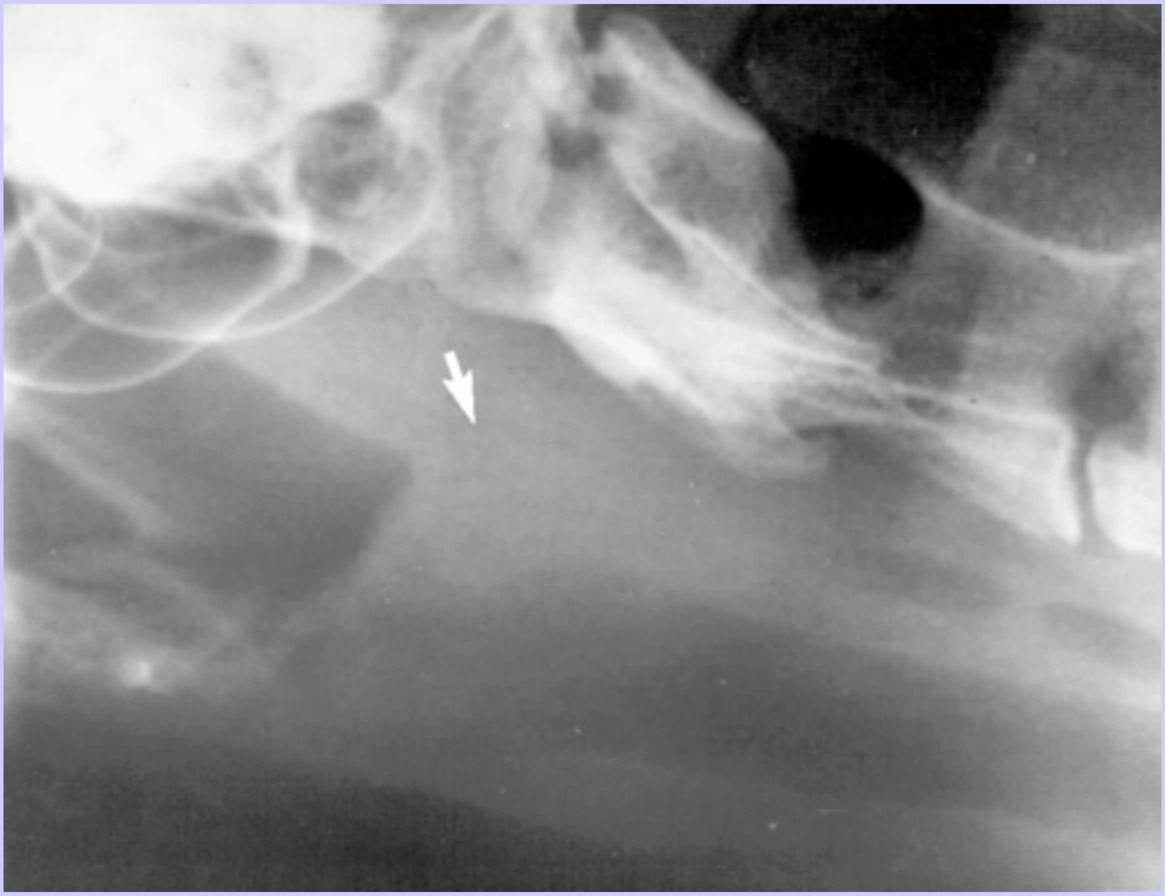
Although rarely diagnostic for a specific cause of upper airway disease, radiographs are important for evaluating both the upper and lower respiratory tracts. One ventrodorsal and two lateral views of the thorax should be taken to evaluate for metastatic disease, aspiration pneumonia, or noncardiogenic pulmonary edema. Thoracic radiographs are also used to evaluate the trachea and look for intrathoracic masses. Cervical radiographs may show evidence of laryngeal or pharyngeal neoplasia (Figure 16-1), radiodense foreign bodies, or extramural masses causing compression of the larynx or trachea. In patients with nasal or nasopharyngeal disease, skull radiographs (or computed tomography) may be indicated to evaluate the nasopharynx, the bullae, and the external canal and petrous temple bone. Unlike thoracic and cervical radiographs, patients undergoing skull radiography require general anesthesia for proper radiographic positioning.

Laryngeal examination is an essential part of the diagnostic evaluation in any patient with clinical signs attributable to upper airway disease. The laryngeal examination is used to evaluate the function and movement of the rima glottidis, including the vocal cords and arytenoid cartilages. The larynx is visualized to assess for thickening or irregularities, and the soft palate and laryngeal saccules should be identified and evaluated.

After evaluation of the upper respiratory tract, an endotracheal wash should be considered, particularly in any patient with signs of lower airway disease. The patient should be intubated with a sterile endotracheal tube and sterile saline aliquots (3 to 5 ml for cats; 5 to 7 ml for dogs) are injected into the endotracheal tube through a sterile red rubber catheter. The patient is given gentle coupage and the fluid suctioned via the red rubber catheter or a sterile suction catheter. The fluid obtained should be submitted to a diagnostic laboratory for fluid analysis and bacterial culture and sensitivity. Additional cultures may be indicated based on cytologic findings.

Endoscopy is required for evaluation of the upper airway caudal to the epiglottis. Endoscopy is used to identify nasopharyngeal stenosis, nasopharyngeal abscesses or masses, nasopharyngeal polyps, or extramural compression. 68
The endoscope can be retroflexed to evaluate the caudal nasal cavity. Finally, tracheoscopy is helpful in evaluating 69
for tracheal collapse, tracheal tumors, extramural compression, or tracheal foreign bodies.

Figure 16-1 Lateral cervical radiograph depicting a mass effect in the laryngeal region. From Costello MF, Keith D, Hendrick M, King L: Acute upper airway obstruction due to inflammatory laryngeal disease in 5 cats, *J Vet Emerg Crit Care* 11:205-210, 2001.



In cases with an irregularity, thickening, or mass effect associated with the larynx or pharynx identified on laryngeal examination, biopsy is always required for a definitive diagnosis because neoplasia and inflammatory disease are indistinguishable on gross examination.

Computed tomography of the skull can be an invaluable diagnostic test for nasal and nasopharyngeal disease. Although it cannot be used for functional abnormalities such as laryngeal paralysis, it is an excellent tool for evaluating the nasal and nasopharyngeal area for tumors or osteolysis, polyps, abscesses, stenosis, or collapse. As with skull radiographs, general anesthesia is required for adequate positioning and to avoid movement artifacts.

16.6 DISEASES OF THE UPPER AIRWAY

16.6.1 Laryngeal Paralysis

Laryngeal paralysis is a common cause of upper airway obstruction in dogs. Middle-aged to older, large to giant breed dogs are most often affected, and most studies have found that a higher number of male dogs are affected.[6-8] In normal dogs, innervation of the cricoarytenoideus dorsalis muscle by the recurrent laryngeal nerve allows the animal to abduct the arytenoid cartilage during inspiration. In animals with laryngeal paralysis, there is denervation of the recurrent laryngeal nerve resulting in cricoarytenoideus dorsalis muscle atrophy. This atrophy prevents the animal from abducting the arytenoid cartilage and results in narrowing of the glottic lumen and subsequent upper airway obstruction. In some breeds, such as Bouvier des Flandres, Siberian Husky, Dalmatian, Rottweiler, and Bull Terrier, this denervation may be congenital.[6-8] Other underlying causes include trauma; diffuse neuromuscular disease such as myasthenia gravis, polyneuropathy, or polymyopathy; neoplasia; and hypothyroidism. Unfortunately, however, in most cases an underlying cause is never identified. These cases are referred to as *idiopathic laryngeal paralysis*.

Clinical signs are consistent with upper airway disease and include inspiratory stridor, decreased activity and exercise intolerance, ptyalism, and voice change. Severely affected animals may show signs of upper airway obstruction including cyanosis, gagging, retching, and collapse.

In most cases, diagnosis is made by direct visualization of the arytenoid cartilages during laryngeal examination or via laryngoscopy. Laryngeal examination requires anesthesia, and this can sometimes confound evaluation of laryngeal function, which may be altered by many anesthetic drugs. In a study evaluating the effects of various anesthetic combinations on laryngeal function in normal dogs, IV thiopental given to effect had the least effect on laryngeal function. In addition, acepromazine combined with thiopental or propofol, and ketamine combined with diazepam, were not recommended because some of the normal dogs had no detectable arytenoid cartilage movement when anesthetized with these drugs.[9] Doxapram may facilitate the diagnosis of laryngeal paralysis in dogs that are not breathing well after induction.[10]

Transnasal laryngoscopy with a 2.5-mm flexible endoscope enabled researchers to differentiate normal laryngeal function in three dogs and abnormal laryngeal function in four dogs without anesthesia.[11] Two of the dogs required mechanical stimulation of the laryngeal mucosa for complete evaluation. Nevertheless, this may be a useful diagnostic technique.

Medical management of canine laryngeal paralysis consists of symptomatic management of the upper airway obstruction and avoidance of stress, excitement, and increased environmental temperatures in affected dogs. Treatment of concurrent disease processes, such as hypothyroidism or myasthenia gravis, is helpful in some patients.

Definitive treatment of laryngeal paralysis is surgical. Numerous surgical techniques have been described, including ventriculocordectomy, partial arytenoidectomy, unilateral or bilateral arytenoid lateralization (laryngeal tie-back), and modified castellated laryngofissure.[6,8] Of these techniques, unilateral arytenoid lateralization has been associated with the lowest complication rates, shortest surgical time, and best overall survival time.[7,8] Postoperative complications are common and range from 10% to 58%.[8] The most commonly reported complication is aspiration pneumonia. Others include continued respiratory distress, megaesophagus, failure of surgical repair, unresolved coughing or gagging, persistent exercise intolerance, vomiting, seroma formation at the surgical site, and acute respiratory distress syndrome.[7,8]

Unlike dogs, cats do not commonly suffer upper airway disease resulting from laryngeal paralysis. Clinical signs of laryngeal paralysis in cats are consistent with disease of the upper airway and include voice change, coughing, tachypnea or dyspnea, stridor, dysphagia, weight loss, and anorexia. As with dogs, the etiology of laryngeal paralysis in cats is largely unknown, although congenital and acquired forms seem to occur.[12] Potential causes include neoplasia, neuromuscular disease, and complications post thyroidectomy.[12,13] Medical management of unilateral laryngeal paralysis in cats is often effective, and it has been suggested that surgical repair should be reserved for those with bilateral disease. Although postoperative complications also occur in feline patients, the reported complications differ from those of dogs and include failure of the surgical repair, coughing, and laryngeal stenosis.[12,13] In contrast to dogs, aspiration pneumonia has not been reported as a complication in cats.

16.6.2 Brachycephalic Syndrome

Brachycephalic syndrome is a term used to describe a combi-nation of primary and secondary anatomic abnormalities found in brachycephalic breeds that leads to varying degrees of upper airway dysfunction and obstruction. The primary abnormalities include stenotic nares, enlarged tonsils, and an elongated soft palate. In affected animals, increased resistance to airflow through the nasal passages requires that the animal create a high negative pressure to achieve adequate tidal volumes. This increase in negative pressure distal to the nasal passages causes the tissue to become hyperplastic. As the pressure increases, it can actually pull the soft tissue into the lumen and even cause collapse of these structures. Secondary abnormalities associated with brachycephalic airway syndrome result from the increase in negative pressure and include everted lateral saccules and laryngeal and tracheal collapse.[14] As affected patients become more excited and tachypneic, the increased resistance and airway obstruction leads to increased inflammation, swelling, and edema. These changes can further impair the animal's airway and cause more severe airway obstruction.

Diagnosis of brachycephalic syndrome is based on visual examination of the nares and evaluation of the oropharynx under light anesthesia. Cervical and thoracic radiographs will confirm a hypoplastic trachea. Virtually all anesthetic drugs relax the muscles of the upper respiratory tract. This is a concern in brachycephalic breeds because the negative pressure generated by the diaphragm, combined with the impaired muscle tone in the upper respiratory tract, can lead to further collapse of the upper airway.[14] The patient should be preoxygenated and anesthesia induction should be rapid to minimize the risks. (See Chapters 162 and 163, Sedation of the Critically Ill Patient and Anesthesia of the Critical Care Patient, respectively.)

The treatment for brachycephalic airway syndrome is surgical. Widening of the stenotic nares is thought to be the most important therapy because the other changes may occur secondary to the stenotic nares. For this reason, some authors have recommended widening the nares of affected dogs as young as 3 to 4 months,[15] and in a review of airway obstruction surgery in the dog, 96% of dogs improved after the procedure.[16] Other surgical therapies include soft palate resection, resection of everted laryngeal saccules, and removal of the tonsils. Recommended treatment of laryngeal collapse is a permanent tracheostomy. This is based on the high mortality associated with partial laryngectomies.[14,16]

Brachycephalic syndrome is a rare clinical condition in cats. It has been described in brachycephalic cats, such as Persians, but little is known about the clinical progression or therapy.[1]

16.6.3 Neoplasia

Primary laryngeal neoplasia is rare in dogs and cats.[17,18] Tumor types in dogs include chondroma, osteosarcoma, melanoma, mast cell tumor, oncocytoma, lipoma, carcinoma, myxochondroma, anaplastic fibrosarcoma, fibropapilloma, thyroid carcinoma, rhabdomyosarcoma, and squamous cell carcinoma.[17,18] In cats, the most common laryngeal tumor types include lymphosarcoma and squamous cell carcinoma, although adenocarcinoma has also been seen.[1,17,18] Diagnosis requires histopathology examination because benign lesions are radiographically and grossly indistinguishable. The treatment and prognosis for laryngeal neoplasia vary depending on the extent, tumor type, and metastasis. The prognosis generally is considered poor due to the difficulty of surgical resection.[18]

Primary tracheal tumors are an uncommon cause of upper airway disease in dogs and cats.[17,19,20] Numerous tumor types have been described in dogs, including adenocarcinoma, carcinoma, mast cell tumor, leiomyoma, extramedullary plasmacytoma, osteosarcoma, chondroma, chondrosarcoma, osteochondroma, and ecchondroma.[17,19] The most common tumor type reported in dogs is osteochondroma. In cats, tumor types include lymphosarcoma, adenocarcinoma, seromucinous carcinoma, adenoma, carcinoma, squamous cell carcinoma, histiocytic lymphosarcoma, and lymphoblastic lymphosarcoma, with lymphosarcoma and adenocarcinoma being the most common.[17,19,20]

Diagnosis of tracheal tumors is done using radiography. The air in the trachea outlines and provides contrast outlining the mass. Both cervical and thoracic radiographs should be taken because intratracheal masses can occur anywhere along the length of the trachea. Tracheoscopy is also useful and allows direct visualization of the mass, and provides the opportunity for biopsy or brush cytology. Treatment options for tracheal tumors include surgical removal, radiation therapy, and chemotherapy. The modality of choice will vary depending on the tumor type, extent, and location. The prognosis for tracheal tumors is extremely variable depending on the tumor type, extent of disease, and comorbid disease processes. Young dogs with osteochondromas have a positive prognosis, but due to the paucity of long-term follow-up in these cases, the overall prognosis remains guarded.

16.6.4 Inflammatory Laryngeal Disease and Granulomatous Laryngitis

Inflammatory laryngeal disease and granulomatous laryngitis are unusual causes of upper airway obstruction in cats. Clinical signs will vary depending on the severity of the inflammation and subsequent obstruction, although airway obstruction requiring an emergency tracheostomy has been reported.[21] The etiology of inflammatory and granulomatous laryngitis is unknown, but proposed underlying causes of inflammation include viral or bacterial infection, trauma from endotracheal intubation, a complication of laryngeal surgery such as vocal fold resection, and eosinophilic granuloma complex.[21-23] In all reported cases, radiographs of the larynx showed a soft tissue opacity or a narrowing of the lumen.[21-23] Gross examination of the larynx often reveals severe thickening or erythema of the larynx, and polypoid or nodular lesions have been reported (Color Plate 16-1).[21-23] The clinical, radiographic, and gross lesions of inflammatory or granulomatous laryngeal disease are indistinguishable from those of neoplasia, so histopathology is necessary to differentiate the two diseases. The prognosis for both is variable and there are few reported cases in the veterinary literature, but an excellent long-term response to surgery, antibiotics, or glucocorticoids has been reported.[21-24]

16.6.5 Nasopharyngeal Polyps

Nasopharyngeal polyps are a common cause of upper airway disease and obstruction in the cat. They originate from the mucosa that lines the middle ear, auditory tube, and nasopharynx. The underlying etiology in these cats is not known, although infectious, inflammatory, and congenital origins have been suggested.[1] Although polyps may be associated with infection, either bacterial or viral, a causal relationship has not been established. Diagnosis is made by radiographs and oropharyngeal examination.[25,26] Treatment consists of surgical resection, and this may be combined with a bulla osteotomy.[25,26] The most common complication is temporary Horner syndrome in cats that undergo a bulla osteotomy.[25] Prognosis for affected cats treated surgically is excellent.

16.6.6 Nasopharyngeal Infection or Abscess

Infection of the middle ear can lead to upper airway obstruction due to inflammation or an abscess in the auditory tube. This can occur secondary to bacterial infections, foreign body migration, fungal infection (usually cryptococcal rhinitis), or aberrant migration of *Cuterebra*. [1,27] Diagnosis is made by sutures and/or caudal rhinoscopy, but in cases of granuloma formation secondary to fungal infection or parasite migration, definitive diagnosis requires histopathologic analysis.[1,27] Treatment consists of surgical debulking and appropriate systemic antimicrobial or antifungal therapy.

16.6.7 Tracheal Collapse

Tracheal collapse is a common cause of upper airway disease in dogs. Toy breed dogs are predominantly affected, 70 and 71 Yorkshire terriers are the most commonly affected breed.[28,29] Classically the tracheal rings collapse on the dorsoventral aspect in combination with laxity of the dorsotracheal membrane.[28] The exact etiology of tracheal collapse is not known, but there are likely many contributing factors. These factors, such as hypocellular tracheal cartilage, denervation of the dorsal tracheal membrane, chronic lower airway disease, congenital malformations, extratracheal masses, trauma, or compression of the trachea secondary to cardiomegaly, can occur individually or in combination.[29]

Diagnosis of tracheal collapse is made using lateral thoracic radiographs taken during inspiration and expiration. When radiographs alone are not diagnostic, fluoroscopy may be helpful because of the dynamic nature of the collapse. Tracheobronchoscopy has also been recommended to confirm the diagnosis, grade the severity, and facilitate a bronchoalveolar lavage. At the time of anesthesia, a complete laryngeal examination should be performed to identify any edema, laryngeal collapse, or laryngeal dysfunction, because this has been associated with a worse outcome.[29] Samples obtained from bronchoalveolar lavage should be submitted for cytologic analysis, culture, and sensitivity testing. The most commonly isolated bacteria from dogs with tracheal collapse include *Pseudomonas, Staphylococci, Pasteurella,* and *Escherichia coli*. [28-30]

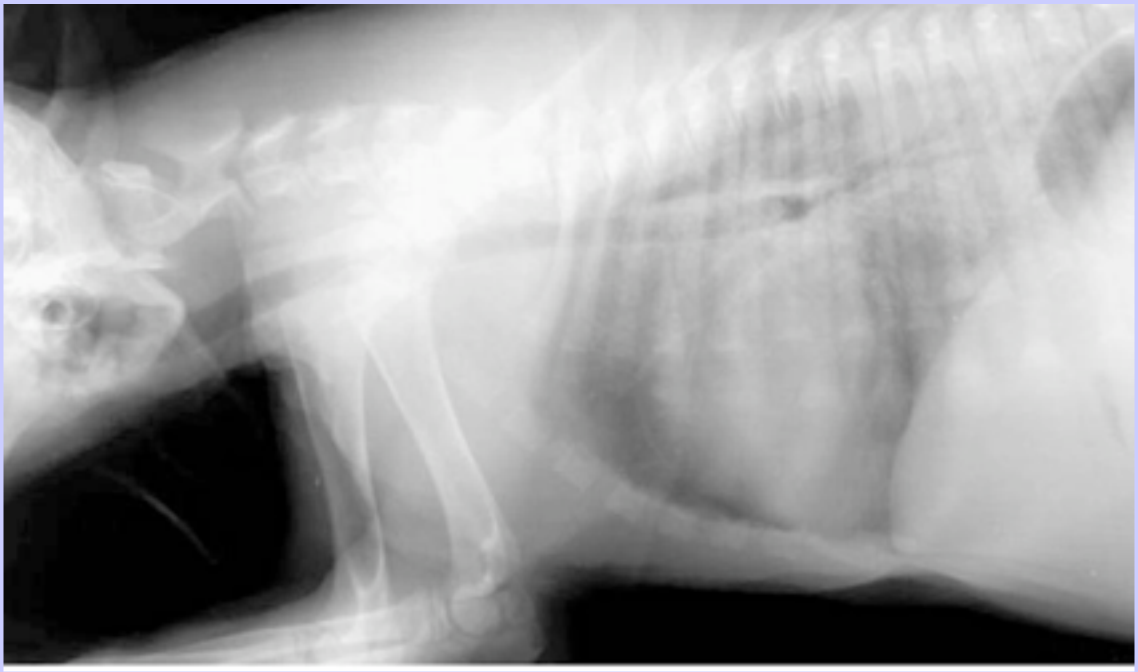
Treatment of tracheal collapse varies depending on the severity of the clinical signs, concurrent disease processes, and location and extent of the collapse. Medical treatment consists primarily of antitussive therapy and decreasing stressful stimuli. Other potential medical therapies include bronchodilators and intermittent steroid therapy. Overweight dogs should be put on a weight loss program, and a chest harness should be used instead of a neck lead. Patients should be treated for concurrent disease processes such as pneumonia or congestive heart failure.

In a study of 100 dogs with tracheal collapse, medical management provided long-term (greater than 12 months) resolution of clinical signs in 71% of patients.[31] When dogs fail to respond to medical treatment, surgical therapy is indicated. There are many surgical options, including tracheal ring chondrotomy, dorsal tracheal membrane plication, ventral placement of a synthetic tracheal ring prosthesis, tracheal resection and anastomosis, extraluminal polypropylene ring prosthesis, and intraluminal self-expanding wall stents.[28,29,31,32] For collapse affecting the thoracic trachea, extraluminal rings generally are not effective, and intraluminal self-expanding wall stents have been recommended (unless the mainstem bronchi also collapse). Complications from these implants include stent migration, granuloma formation, tracheal ulceration, tracheal necrosis, infection, and stent breakage. Commonly reported complications after surgery for tracheal collapse include coughing, continued dyspnea, and laryngeal paralysis secondary to damage to the recurrent laryngeal nerve. The overall prognosis for affected dogs is extremely variable and dependent on the severity, location, and extent of the collapse and comorbid disease processes.

16.6.8 Tracheal Stenosis

Tracheal stenosis is a rare cause of upper airway disease in dogs and cats. Clinical signs are consistent with upper airway disease, and the degree of respiratory distress will vary based on the extent and severity of the stenotic lesion. Causes include trauma, congenital malformation, aspiration of noxious substances, and tracheal injury secondary to endotracheal intubation.[33-36] Diagnosis is made with radiographs or tracheobronchoscopy. Surgical resection and anastomosis to remove the stenotic portion is recommended.

Figure 16-2 Noncardiogenic pulmonary edema in a dog. Note the alveolar disease located in the dorsocaudal lung fields.



16.7 SECONDARY COMPLICATIONS

Upper airway dysfunction and obstruction can lead to multiple, sometimes life-threatening sequelae. These complications include aspiration pneumonia (see Chapter 23, Aspiration Pneumonitis and Pneumonia), noncardiogenic pulmonary edema (Figure 16-2; see Chapter 21, Pulmonary Edema), and heat-induced illness (see Chapter 167, Heat Stroke). Radiographs often reveal a cranioventral interstitial to alveolar pattern in dogs affected with aspiration pneumonia. The radiographic pattern of noncardiogenic pulmonary edema is a mixed interstitial and alveolar pattern, primarily affecting the dorsocaudal lung fields (see Figure 16-2). The prognosis for patients affected by these complications is variable, depending on severity and comorbid disease processes. In a study of nine dogs with noncardiogenic pulmonary edema secondary to upper airway obstruction, the pulmonary edema resolved in all cases once the upper airway obstruction was treated.[36] No animal died from pulmonary edema.

17 Chapter 17 Endotracheal Intubation

Mack Fudge, DVM, MPVM, DACVECC

17.1 Key Points

- Careful airway assessment is an imperative first step in managing the critically ill and emergency patient.
- Prior planning and preparation are key and necessary steps to successful endotracheal intubation.
- Knowledge of and confidence in performing multiple techniques for airway access improve the odds for successful patient outcomes.
- Care must be taken to ensure effective patient oxygenation throughout the intubation process.

17.2 INTRODUCTION

Endotracheal intubation describes the procedure of inserting a tube into the trachea. The three main indications for tracheal intubation are: (1) provision of a patent airway in a patient with upper airway obstruction, (2) protection against aspiration in a patient without normal airway protection reflexes, and (3) administration of oxygen, gaseous anesthetics, or positive-pressure ventilation.[1-3] Intubation is a frequently performed and often lifesaving procedure in critically ill patients. Recognizing the need to intubate and understanding procedures to aid difficult intubation are essential skills for the critical care veterinarian.

17.3 AIRWAY ASSESSMENT

Airway assessment is the first priority in the evaluation of a critically ill or emergency patient. Both airway patency and protection must be ascertained. When upper airway disease is severe, rapid induction of anesthesia and tracheal intubation is indicated. If orotracheal intubation is unsuccessful, a temporary tracheostomy is required (see Chapter 18, Tracheostomy).

Any patient lacking an adequate gag reflex, as may occur with neurologic disease, sedative or anesthetic drug administration, or cardiopulmonary arrest, requires immediate intubation for airway protection, oxygen therapy, and positive-pressure ventilation as needed. The gag or swallow reflex can be assessed by inserting a tongue depressor into the pharynx.

17.4 ROUTINE INTUBATION

Intubation of animals with normal upper airway anatomy is commonly performed using laryngeal visualization and insertion of an appropriate sized, cuffed endotracheal tube. An adequate level of anesthesia is required. After correct placement is confirmed, the tube is secured by tying it around the maxilla or mandible, being sure that the tie lies caudal to both canine teeth. Alternatively, a tube can be tied around the back of the head. The tube usually is connected to an oxygen source such as a Bain circuit or an anesthetic machine circuit. Finally, the cuff is inflated until it gently occludes the airway exterior to the tube. To determine how much cuff inflation is required, a manual breath is delivered while simultaneously inflating the cuff and listening for resolution of the air leak around the endotracheal tube.[3]

17.4.1 Dogs

For routine intubation of the dog, a laryngoscope with a blade long enough to allow adequate visualization of the larynx is required. Intubation commonly is performed with the dog in sternal recumbency. An assistant holds the animal's upper jaw by grasping either side of the maxilla with one hand, keeping the head raised and extended. Either the assistant or the operator opens the mouth by pulling the tongue out and down, and the endotracheal tube is passed between the arytenoids.[3] Alternatively, many dogs can be intubated in lateral or dorsal recumbency without the aid of an assistant.

17.4.2 Cats

Routine intubation of cats is performed in a manner similar to that used for dogs, except application of lidocaine to the larynx is recommended before attempting intubation in an effort to prevent laryngospasm. Some operators favor the use of a stylet to stiffen the endotracheal tube for feline intubation.[3]

17.5 DIFFICULT INTUBATION

The possibility of a difficult intubation should be considered in animals with evidence of upper airway obstruction, trauma, or abnormal anatomy (e.g., brachycephalic breeds). Preplanning for intubation of cases such as these is essential to maximize the likelihood of success.

17.5.1 Preoxygenation

Any delay in intubation of a patient places the animal at risk of hypoxemia. When breathing room air, complete upper airway obstruction or apnea will lead to hypoxemia within approximately 3 minutes. Preoxygenation of a patient with 100% oxygen via a tight-fitting face mask can prevent hypoxemia for up to 10 minutes of airway obstruction or apnea. Although a study in human patients found preoxygenation not as effective as previously thought, it still is recommended before attempting intubation of any critically ill patient or any patient at risk of a difficult intubation or apnea.[4]

17.5.2 Equipment Setup

If a difficult intubation is anticipated, all equipment that may be required should be set up before the procedure. Endotracheal tubes of the size appropriate for the patient, in addition to several smaller sizes, should be selected. Stylets or a guide tube, such as a polyethylene urinary catheter, should also be available. Large-bore catheters for transtracheal gas insufflation and a surgical kit for an emergency tracheotomy in case intubation is unsuccessful should also be on hand.

17.5.3 Approach

Routine intubation should be attempted initially. Any fluid accumulation in the oropharynx should be removed by suction or with gauze swabs. If routine intubation is unsuccessful, intubation with a smaller size endotracheal tube may be possible. If an endotracheal tube cannot be passed, intubation with a guide tube is often possible. An endotracheal tube (routine size or smaller) with lubricant applied can then be passed over the stylet and introduced blindly into the trachea.[3] The stylet can then be removed.

17.6 ALTERNATIVE TECHNIQUES

17.6.1 Fiberoptic-Assisted Intubation

Fiberoptic-guided intubation via an oral route may be useful in some patients. The fiberoptic scope is introduced into the caudal oropharynx, permitting glottic visualization and endotracheal intubation. Various specialized fiberoptic laryngoscopes may be used for this technique.[1] Note that fiberoptic intubations, especially using the nasal route, may result in more severe pressor and tachycardiac responses than those observed with direct laryngoscopic intubations.[5]

17.6.2 Digital Palpation

In certain cases, digitally directed blind intubation may be a prudent and useful technique. Identifying key anatomic structures by palpation may facilitate a gentle insertion of the tip of the endotracheal tube into the airway. It is essential to always verify correct placement of the tube when using this technique.

17.6.3 Nasal Intubation

Intubation of a nasopharyngeal airway can be a useful adjunct in some patients. This technique is performed commonly in human patients in whom a larger nasal cavity may accommodate a tube large enough for a definitive airway. Nasal tubes used in veterinary patients usually do not permit an airtight seal of the trachea, but they do provide a good route for oxygen administration. This technique may be contraindicated in trauma patients with basilar skull fracture or disruption of the cribriform plate. In these cases, the airway tube may traverse the fractured cribriform plate and injure the brain.[1]

17.7 SURGICAL AIRWAY

In individual animals with prominent cricothyroid membranes, a cricothyroidotomy can be used to secure the airway for patients with severe facial trauma and for patients requiring an emergency tracheal intubation in which oral or nasal intubation was unsuccessful. Compared with a tracheotomy, cricothyroidotomy is probably less time consuming, easier to perform, associated with fewer complications, and more likely to result in a dependable airway. It may be later converted to a tracheostomy under more controlled conditions. Commercially available, prepackaged cricothyroidotomy kits may save time during resuscitation.[1] The potential problem with these kits is that they require the user to be familar with the contents, and equipment sizes may not be appropriate for a smaller veterinary patient.

17.8 OTHER OPTIONS

17.8.1 Retrograde Intubation

Retrograde intubation is another method for securing the airway in certain conditions. This technique requires retrograde placement of a guidewire or catheter via the cricothyroid membrane into the trachea and rostrally into the oropharynx. An endotracheal tube (or fiberoptic bronchoscope via the suction port, or a tube changer followed by an endotracheal tube) is then threaded over the guidewire and into the trachea.[1]

17.8.2 Transillumination

Transillumination of the soft tissues of the neck using a flexible lightwand device may be useful in select, especially light colored, patients. This may be a suitable technique for patients that are difficult to intubate but that are ventilating effectively and that have a trachea large enough to safely accommodate the lightwand. The lightwand is placed inside an endotracheal tube during intubation. As the tube is advanced through the glottic opening, a well-defined circumscribed glow is readily appreciated in the ventral neck just below the thyroid prominence. This light-guided technique may help to minimize cervical spine movement, especially useful in trauma, neurologic, or other patients with particularly difficult airways. It should be attempted only in animals with airways of sufficient size to accommodate the lightwand and still allow for some air movement around the wand.[1,6]

17.8.3 Cricoid Pressure

Cricoid pressure is a useful adjunct to tracheal intubation. Firm pressure, directed dorsally over the cricoid cartilage, collapses the esophagus and helps to prevent passively regurgitated gastric fluid from reaching the hypopharynx. This technique is used commonly in human patients with a high likelihood of vomition or regurgitation.[7]

17.9 NEEDLE CRICOTHYROIDOTOMY

If nasal or oral intubation is technically difficult and is not successful, an airway by another route or method may be indicated. Oxygen can be provided via a large-bore catheter inserted through the cricothyroid membrane or through the tracheal wall and attached directly to the gas outlet of an anesthesia machine. This technique is only a temporary adjunct that can buy time until a more permanent cricothyroidotomy or tracheotomy is performed. A high-frequency jet ventilator works well for this technique.[1] This percutaneous tracheotomy technique is a little quicker and easier to perform and may have less likelihood of postoperative infection than does a full tracheotomy.[8]

17.10 PLACEMENT VERIFICATION

Verification of correct placement of the endotracheal tube is a necessary and critical step. It is not uncommon, especially in hurried or difficult intubations, for the tube to be advanced inadvertently down the esophagus. The simplest and most obvious way to ensure correct placement is through direct visualization of the tube placement. Seeing the tube pass through the larynx and into the trachea should ensure correct placement. Measurement of exhaled carbon dioxide, either by a disposable colorimetric device or by an infrared carbon dioxide analyzer, can provide an additional level of assurance of correct tube placement. This technique is not recommended for intubations made during cardiac arrest. Other methods such as watching for fogging of the inside of the endotracheal tube during exhalation, vapor seen on shiny surfaces placed at the end of the tube, or fluttering of valves on connected anesthesia machines are often misleading and supportive at best.

17.11 COMPLICATIONS

Tracheal intubation can be associated with equipment-related or patient-related complications. Soft or particularly small endotracheal tubes can crimp because of the acute angle created as the tube passes from the oropharynx toward the larynx, reducing the airflow through the tube. This can lead to hypoventilation and subsequent hypercapnia and hypoxemia. Bending can also create additional pressure at the end of the tube that can damage the dorsal larynx or tracheal mucosa.

Pressure-induced tracheal necrosis is possible when the endotracheal tube cuff is over-inflated or the tube is too large for the patient. If the intubation is expected to be prolonged, take care to pad oral soft tissues that come into contact with the endotracheal tube. Prolonged contact of the tube with lips, gingiva, and tongue can cause multiple small areas of pressure necrosis. In rare cases of more extreme damage caused to the trachea by endotracheal tubes, subcutaneous emphysema or even pneumothorax are possible.

Endotracheal tubes may be unintentionally advanced too far and end in a mainstem bronchus, usually the right. This may lead to inadvertent overinflation of the intubated lung and impaired gas exchange. Premeasuring endotracheal tubes before placement and bilateral thoracic auscultation can help avoid inadvertant endobronchial intubation.

Endotracheal intubation can cause increased intracranial pressure and even increased intraocular pressure. It can also cause significant increases in blood pressure and heart rate.[9] Rapid, smooth intubation is important.

17.12 SUMMARY

Airway management is fundamental in the care of critically ill and emergency patients. Complications resulting from difficulties with airway management include brain injury, myocardial injury, increased intracranial and intraocular pressures, pulmonary aspiration of gastric contents, trauma to the airways, and death. Shock, respiratory distress, full stomach, airway trauma, cervical spine instability, and head injury may make emergency tracheal intubation a challenging procedure in the critically ill patient. Careful use of pharmacologic agents can greatly enhance the ability to safely secure the airway.

18 Chapter 18 Tracheostomy

Mack Fudge, DVM, MPVM, DACVECC

18.1 KEY POINTS

- Continuous patient monitoring and intensive nursing care are critical to successful tracheostomy tube management and patient comfort.
- Care must be taken to prevent damage to the left recurrent laryngeal nerve when a tracheotomy is performed.
- Long stay sutures placed around the cartilage rings adjacent to the tracheotomy incision allow routine tube replacement and may be lifesaving if the tube becomes occluded or dislodged.

18.2 INTRODUCTION

Temporary tracheostomy is indicated for life-threatening upper airway obstruction, oral or pharyngeal surgery when oral endotracheal intubation is undesirable, airway obstruction from edema and inflammation after pharyngeal or laryngeal surgery, long-term ventilator support for critically ill patients, and removal of tracheal foreign bodies.[1] Access to the trachea provided by the tracheostomy allows air to enter distal to obstructions and reduces damage to the oral cavity from prolonged intubation.[2,3]

18.3 TRACHEOSTOMY TUBE SELECTION

Numerous tracheostomy tubes are commercially available. They can be cuffed or uncuffed tubes and may or may not have an inner cannula. The requirement for a tube cuff will depend on individual patient factors. In most cases a cuff is not required, and the use of an uncuffed tube or keeping the tube cuff deflated may reduce the likelihood of tracheal injury. A cuff may be considered desirable in patients that require positive-pressure ventilation, although this mode may also be feasible with uncuffed tubes. A tube cuff may make it necessary to use a slightly smaller tracheostomy tube than would be possible without the cuff.

A removable inner cannula allows for easy and effective tube maintenance and is considered desirable. The inner cannula can be removed briefly for cleaning without disrupting the airway integrity. Unfortunately, smaller tubes cannot be made with an inner cannula. In the absence of an inner cannula, the entire tracheostomy tube should be replaced every 24 hours (more often if indicated) to prevent occlusion with accumulated secretions.

The size of the tracheostomy tube chosen is based on the diameter of the patient's airway. The largest tube that can be readily accommodated by the trachea is selected. Note that the size of tracheostomy tube does not correspond with the scale used to size endotracheal tubes. An estimate of the appropriate tracheostomy tube size usually can be made by evaluation of the inner lumen diameter of the trachea on a lateral cervical radiograph.

Tracheostomy tubes can also be fenestrated. The fenestration is an opening in the tube that allows air flow through to the upper airway if the external opening is occluded. In human patients this feature is used to enable speech. The utility of a fenestrated tube in veterinary patients is questionable. A fenestrated tube cannot be used if positive-pressure ventilation is required.

If a tracheostomy tube is not immediately available, an endotracheal tube can be shortened and used effectively in the interim.

18.4 SURGICAL TECHNIQUE

Temporary tracheostomy is best performed in a controlled manner with the patient under general anesthesia with an orotracheal tube in place. The animal is placed in dorsal recumbency with the neck carefully extended for exposure of the surgical site. The neck can be elevated from the table by placing it on a cushion. Routine surgical preparation of the ventral cervical region is performed.

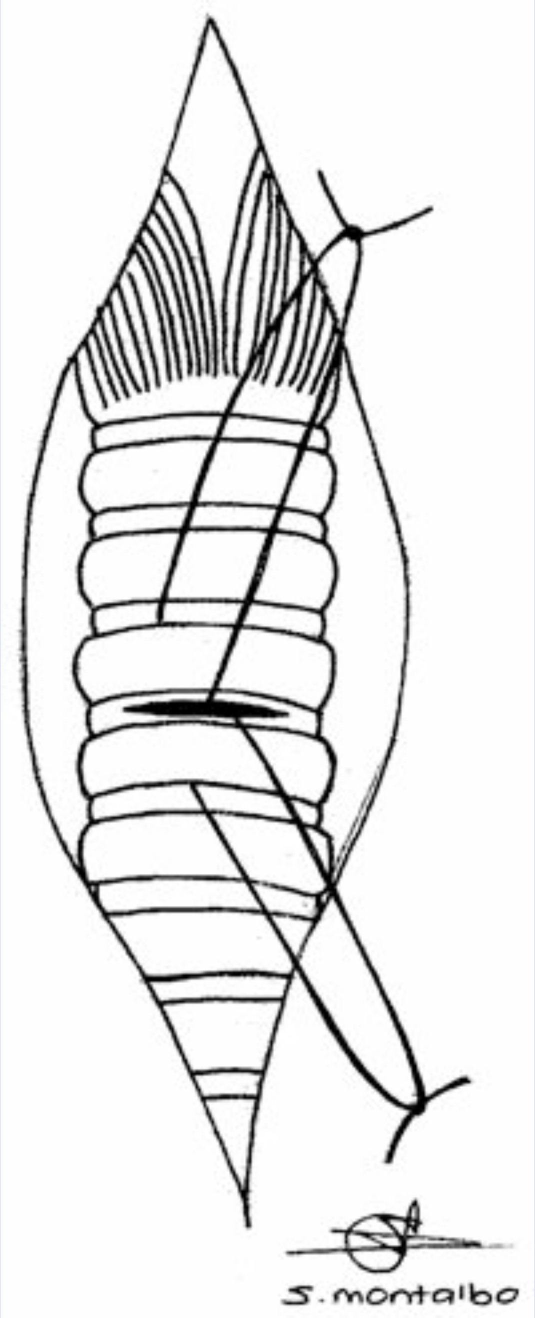
A 2- to 5-cm ventral cervical midline skin incision is made extending from the cricoid cartilage toward the sternum. The sternohyoid muscles are separated along their midline with blunt dissection and retracted laterally. The peritracheal connective tissue is removed from the region of the tracheotomy site. Throughout the procedure care must be taken to prevent dissection lateral to the trachea to prevent injury to the left recurrent laryngeal nerve or disruption of tracheal blood supply.

Various tracheal incisions have been proposed. Although most surgeons believe that a transverse approach is least likely to cause tracheal stenosis, studies suggest that the type of incision plays a minor role in the development of stenosis.[1,3-5] The two common surgical approaches for temporary tracheotomy are transverse and vertical incisions.

18.4.1 Transverse Incision

The annular ligament between the third and fourth or fourth and fifth tracheal rings is incised, taking care not to extend the incision longer than 50% of the tracheal circumference. Extreme care must be taken to avoid the left recurrent laryngeal nerve. A small ellipse of cartilage from each tracheal cartilage adjacent to the tracheotomy incision can be made to help reduce tracheal irritation and inflammation. Long loops of suture are placed around the tracheal rings adjacent to the incision to facilitate retraction of the trachea and future replacement of the tube after cleaning (Figure 18-1).[1,2]

Figure 18-1 Transverse incision tracheostomy.



75

76

18.4.2 Vertical Incision

A ventral midline vertical incision is made through two to four tracheal rings. Long stay sutures may be placed encircling the cartilage rings lateral to the incision to aid in continued manipulation of the trachea and future tube replacement (Figure 18-2). Segmental lateral tracheal collapse may be a long-term complication of this procedure.[1,2]

Following tube placement via either technique the muscles and skin can be closed routinely, but space should be left around the tracheostomy tube so that air can escape easily to prevent subcutaneous emphysema.

18.4.3 Securing the Tracheostomy Tube

The tracheostomy tube can be secured with sutures or with umbilical tape tied around the neck. Commercially made Velcro-fastening tracheostomy tube ties are also available. The author prefers to tie the tube in place to facilitate regular tube replacement and reduce patient discomfort. Tube ties need to be evaluated frequently to prevent inadvertent tube dislodgement.

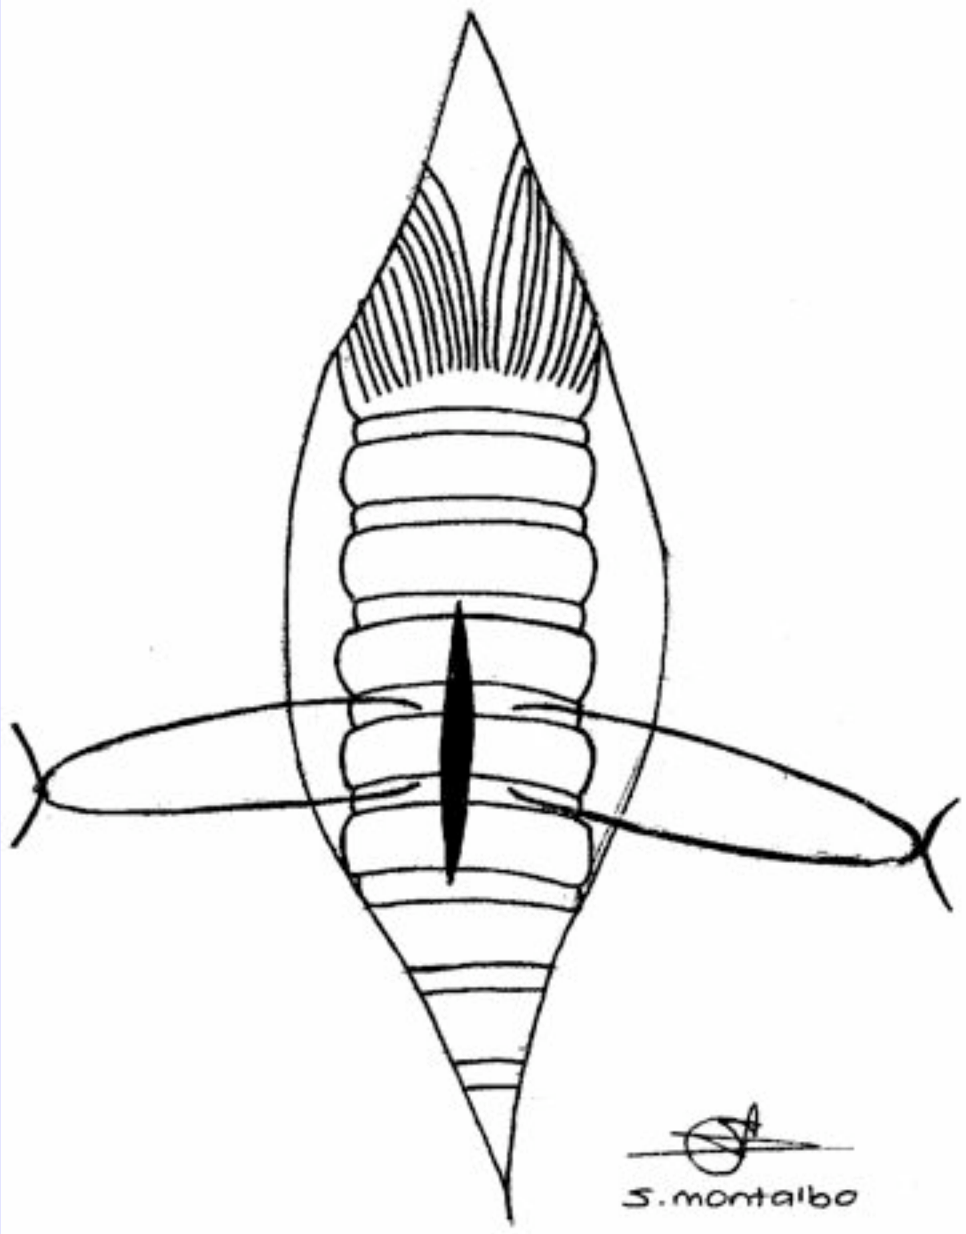
18.5 NEEDLE CRICOTHYROIDOTOMY

In cases of severe respiratory distress there may be insufficient time or inadequate preparation to perform a tracheostomy, and an airway by another route or method may be indicated. Using a needle cricothyroidotomy, oxygen can be provided via a large-gauge needle or catheter inserted through the cricothyroid membrane or through the tracheal wall. This technique is only a temporary adjunct used for minutes because ventilation will not be effective.[6] However, this technique can buy time until a better prepared, planned surgical procedure can be performed.

18.6 TRACHEOSTOMY TUBE MANAGEMENT

Tracheostomy tube management requires continuous intensive care monitoring.[1,3-5] When this level of care is unavailable, elective tracheostomy should not be done. When a tracheostomy is unavoidable, the patient should be transferred to a suitable facility for ongoing care as soon as possible.

Figure 18-2 Vertical incision tracheostomy.



The major aims of tracheostomy tube management are to prevent tube obstruction, to facilitate removal of airway secretions, and to minimize the risk of airway trauma or nosocomial pneumonia. It is important to recognize that tube occlusion or dislodgement can occur without warning despite ideal tube management, and staff should be prepared for rapid tube replacement (or inner cannula removal) should acute complications develop.[7,8] The placement of stay sutures around tracheal rings adjacent to the tracheotomy site at the time of surgery is essential to allow successful tube replacement. The author recommends that tape tabs be placed on the end of each stay suture and labeled *cranial* and *caudal* or *left* and *right* as appropriate. With the use of stay sutures most animals will tolerate tube replacement while awake, without sedation.

Patient positioning either in sternal recumbency with the neck extended or in dorsal recumbency with the neck extended is extremely important to facilitate this procedure. Gradual concretion of airway secretions within the lumen of the tracheostomy tube may occur despite regular suctioning. For this reason removal and cleaning of inner cannulas should be performed every 4 hours, and tubes without an inner cannula should be replaced every 24 hours routinely, even if there are no obvious problems.

18.6.1 Suctioning

Suctioning should be performed frequently to remove secretions from the airway and reduce the likelihood of tube occlusion. See Box 18-1 for a suggested protocol for tracheostomy tube management. Sterile technique should be used at all times. The suction catheter must be sterile as well as soft and flexible to minimize airway trauma. Human oxygen administration catheters work well for suctioning animal airways.

Sterile physiologic saline solution (1 to 2 ml) can be injected into the trachea through the tracheostomy tube to loosen exudates before suctioning. Respiratory distress or vagal stimulation (retching or vomiting) may occur during tracheal suctioning. The airway should be well humidified, and preoxygenation with 100% oxygen is recommended. The catheter is inserted down the airway, several centimeters beyond the length of the tube, and suction is applied as the catheter is withdrawn using a circular motion. The duration of suctioning should be brief (no more than 10 seconds) to minimize small airway collapse and 100% oxygen provided for at least 3 minutes immediately after each suctioning episode. Tracheostomy tube suctioning is performed routinely every 4 hours, although in some patients it may be necessary more frequently.

76
77

18.7 TUBE REMOVAL

The tracheostomy tube is removed when an adequate upper airway is established. Most small animals that have a tracheostomy for upper airway surgery can be extubated within 48 hours after surgery. Once the tube has been removed, the tracheostomy site is left open and allowed to heal by granulation and epithelialization.

18.8 COMPLICATIONS

Complications following temporary tracheostomy include tube occlusion or dislodgement, subcutaneous emphysema, pneumothorax, aspiration of fluid or foreign bodies, and pneumonia. Arrhythmias and vagally mediated bradycardia and collapse can occur during suctioning or tube manipulation. With careful management and appropriate monitoring, most complications can be prevented.

18.8.1 Box 18-1 Tracheostomy Tube Care Protocol

- Remove inner cannula (if present) for cleaning and replace with the temporary cannula for the duration of the procedure.
- Airway humidification is recommended for 20 minutes before suctioning patients that are not on a mechanical ventilator.
- Preoxygenate with 100% oxygen for at least 3 minutes before suctioning.

- When suctioning, use sterile technique, insert the sterile catheter to the level of the carina, and apply suction as the catheter is removed with a circular motion (taking no longer than 10 seconds).
- Administer 100% oxygen for at least 3 minutes after each suctioning episode.
- Perform suctioning 2 to 4 times; frequency is guided by the amount of exudate and how well the patient tolerates the procedure.
- Replace cleaned inner cannula.
- Clean incision site surrounding tracheostomy tube and check that the tube is still secured appropriately.

19 Chapter 19 Oxygen Therapy

Elisa M. Mazzaferro, MS, DVM, PhD, DACVECC

19.1 KEY POINTS

- Hypoxemia occurs in a variety of critical illnesses. Oxygen supplementation can improve oxygen delivery and decrease the incidence of lactic acidosis.
- Supplemental oxygen administration should be provided whenever a patient's partial pressure of arterial oxygen (PaO_2) is less than 70 mm Hg, oxygen saturation (SaO_2) is less than 93% on room air, and in cases of significant anemia or cardiovascular instability.
- Noninvasive means of oxygen supplementation, including flow-by, mask, hood, and oxygen cage, are a simple means of providing an oxygen-enriched environment to a critically ill patient.
- Nasal and nasopharyngeal oxygen supplementation require minimal equipment and are well tolerated by many hypoxemic patients.
- Tracheal oxygen supplementation provides a higher fraction of inspired oxygen (FiO_2) than nasal or noninvasive means of oxygen therapy, but it is technically more difficult and has higher inherent risks to the patient.

19.2 INTRODUCTION AND INDICATIONS FOR OXYGEN THERAPY

Hypoxemia is defined as a deficiency of oxygen in the arterial blood.[1,2] Hypoxemia can occur as a result of hypoventilation, ventilation-perfusion mismatch, diffusion impairment, decreased oxygen content of inspired air, and intrapulmonary or cardiac shunting. Global hypoxemia can occur in a variety of critical illnesses, including pulmonary parenchymal, neuromuscular, pleural cavity, chest wall, and cardiac disease. Hypoxemia results in inadequate delivery of oxygen to the tissues and subsequent cellular hypoxia. Systemic illnesses such as sepsis, systemic inflammatory response syndrome (SIRS), anemia, and acid-base imbalances such as a metabolic or respiratory alkalosis or acidosis can also contribute to inadequate tissue oxygen delivery.

Oxygen supplementation is one of the most important management tools for a variety of critical conditions, including cardiopulmonary disease, sepsis, SIRS, and head trauma. Delivery of oxygen to tissues is affected by the patient's arterial oxygen content (CaO_2) and cardiac output (Q). The formula to calculate arterial oxygen content is as follows:

$$\begin{aligned} CaO_2 = {} & [1.34(\text{ml } O_2 / \text{g}) \times SaO_2(\%) \times \text{hemoglobin}(\text{g}/\text{dl})] \\ & +[PaO_2(\text{mm Hg}) \times 0.003(\text{ml } O_2 / \text{dl} / \text{mm Hg})] \end{aligned}$$

where (SaO_2) is arterial oxygen saturation and (PaO_2) is partial pressure of arterial oxygen.

Arterial oxygen content depends on the concentration of hemoglobin as well as the binding affinity and the SaO_2 of the hemoglobin. Most of the arterial oxygen is carried to tissues while bound to hemoglobin. A small fraction is carried dissolved (or unbound [$0.003 \times PaO_2$]) in plasma and subsequently diffuses into the tissues. Providing supplemental oxygen to increase the fractional concentration of oxygen in inspired gas (FiO_2) above 21% is an effective means of increasing both bound and unbound oxygen in arterial blood, provided that a cardiac or pulmonary parenchymal shunt is not present.[1]

Supplemental oxygen should be provided whenever a patient's PaO_2 is less than 70 mm Hg or SaO_2 is less than 93% on room air.[1] Oxygen administration can be divided into noninvasive and invasive techniques. The method of supplementation is dependent on each patient's needs and tolerance, patient size, degree of hypoxemia, desired FiO_2, anticipated duration, clinical experience and skill, and the equipment and monitoring means available.[2]

19.3 HUMIDIFICATION

Oxygen supplementation can be accomplished in a number of ways. All methods require some kind of humidification if used for more than several hours. Otherwise the patient is likely to experience drying and dehydration of the nasal mucosa, respiratory epithelial degeneration, impaired mucociliary clearance, and an increased risk of infection.[2] A supplemental oxygen source can be humidified easily by bubbling the oxygen through a tube that is submerged in a bottle of sterile saline.[2] The humidified oxygen then accumulates above the surface of the solution. The gas that collects can then be delivered through a length of tubing to the patient's oxygen delivery device, whether it is a mask or tube into some component of the respiratory tract.

19.4 NONINVASIVE METHODS OF OXYGEN SUPPLEMENTATION

19.4.1 Flow-By Oxygen

Flow-by oxygen supplementation is one of the simplest techniques to use in an emergency setting. A length of oxygen tubing connected to an oxygen source is held adjacent to or within 2 cm of a patient's nostril or mouth. An oxygen flow rate of 2 to 3 L/min generally provides an FiO_2 of 25% to 40%.[3] This technique is well tolerated by most patients and can be used during the initial triage and patient assessment. Because this technique also delivers a large quantity of oxygen to the surrounding environment, it is wasteful and not appropriate or economical for long-term use.

19.4.2 Face Mask

Short-term oxygen supplementation can be accomplished by placing a face mask over a patient's muzzle, then delivering oxygen (humidified if oxygen administration of more than a few hours is required) or tank oxygen in a circle rebreathing or a nonrebreathing circuit. With a tight-fitting face mask, flow rates of 8 to 12 L/min can provide an FiO_2 of up to 50% to 60%.[3] With loose-fitting face masks, higher flow rates of 2 to 5 L/min are recommended, depending on the size of the patient and degree of hypoxemia. With a tight-fitting face mask, rebreathing of carbon dioxide can occur, as well as dangerous increases in temperature and humidity. The face mask should be vented periodically, or changed to a looser face mask or other means of oxygen supplementation as soon as possible.

Awake and coherent patients may not tolerate oxygen delivered by face mask for long periods. An attendant must be present to ensure that the mask does not become detached and that the patient does not struggle or damage its eyes with the edge of the mask.[4] Advantages of this technique are that minimal equipment is required and that the patient can be simultaneously treated and evaluated in emergency situations.

19.4.3 Oxygen Hood

Several varieties of oxygen hood are available from commercial manufacturers, or they can be made easily in the hospital with clear plastic wrap such as Saran Wrap, tape, and a rigid Elizabethan collar (or recycled x-ray film of appropriate size). To create an oxygen hood, the front of a rigid Elizabethan collar is covered with lengths of clear plastic wrap taped in place. A small portion of the front is left open to room air to allow the hood to vent. The collar is then placed around the patient's neck and secured snugly. A length of oxygen tubing is inserted through the back of the collar and taped to the inside of the collar so that it will not be dislodged with patient movement. Once the hood has been flooded with oxygen (1 to 2 L/min), flow rates of 0.5 to 1 L/min typically will deliver an FiO_2 of 30% to 40%,[5] depending on the size of the patient and how tightly the collar fits. With extremely small patients, such as toy breeds or neonates, the entire patient can be placed in the collar for a homemade oxygen tent or minicage. Some patients will not tolerate the collar and can become hyperthermic. If the hood is left unvented, carbon dioxide and moisture can accumulate within the hood and contribute to patient distress. Overall, an oxygen hood is an economical and practical means of supplemental oxygen administration and is well tolerated by most patients.

19.4.4 Oxygen Cage

Supplemental oxygen can be delivered into a Plexiglas box to administer higher FiO_2 concentrations than are possible with nasal, hood, or flow-by methods.[4] Oxygen cages that control oxygen concentration, humidity, and temperature are available from commercial sources. The cages are vented to decrease buildup of expired carbon dioxide. Oxygen cages can be made from human pediatric incubator units into which humidified oxygen is supplied through a length of tubing. The FiO_2 can reach up to 60%, depending on the size of cage and patient and oxygen flow rate, but it typically is maintained at 40% to 50%.[2,4] Oxygen cages are very useful, but they are an expensive means, because oxygen is released from within the cage into the external environment whenever the cage is opened. In some patients, hyperthermia can develop if the temperature within the cage is not monitored and maintained at 70° F (22° C).[4] Ice packs can be placed in an oxygen cage to decrease ambient temperature, but they should not be placed in contact with the patient because peripheral vasoconstriction can exacerbate hyperthermia.

Although many authors describe lack of direct patient access as a disadvantage of this technique, continuous observation and continuous assessment of pulse oximetry, blood pressure, and ECG allow patient monitoring through the Plexiglas cage doors.[4] Precaution must be taken when placing animals with upper airway obstruction in the oxygen cage, because the observer's ability to hear stertor or stridor through the cage door is diminished.

19.5 INVASIVE METHODS OF OXYGEN SUPPLEMENTATION

19.5.1 Nasal and Nasopharyngeal Oxygen

If supplemental oxygen will be required for more than 24 hours and an oxygen cage is not readily available or feasible, a nasal or nasopharyngeal oxygen catheter should be considered in dogs. Nasal oxygen catheters are fairly simple to place, require minimal equipment, and are well tolerated by most patients.[6] Oxygen insufflation catheters can be placed in the nasal cavity or directly into the nasopharyngeal region by a similar technique.

To place a nasal oxygen catheter, the patient's nasal passage should be anesthetized first with topical 2% lidocaine or proparacaine. Next, a 5 to 10 Fr red rubber or polypropylene catheter should be held along the side of the nose, the tip placed at the lateral canthus of the eye, and a mark made on the tube with a permanent marker at the nostril level (Color Plate 19-1). The tip of the tube is lubricated and the tube gently inserted into the ventral nasal meatus to the level of the mark on the tube. The tube can be secured adjacent to the nostril with suture or staples. The external tubing can then be secured to the lateral maxilla or between the patient's eyes with suture or staples. To help prevent patient intolerance of the tube, be sure to avoid securing the tube to the patient's whiskers.

Oxygen should be provided from a humidified source to avoid drying and irritation of the nasal mucosa. Nasal catheters can provide a wide range of FiO_2, depending on the size of the animal, respiratory rate, and panting or mouth breathing.[4,7] Flow rates of 50 to 150 ml/kg/min can provide 30% to 70% FiO_2.[2,8,9] Higher flow rates can be irritating to the patient and cause sneezing. Sneezing and patient intolerance can be alleviated in most cases by reapplying the topical anesthetic or advancing the nasal catheter into the nasopharyngeal region.

Nasopharyngeal catheter placement is almost identical, inserting it into the nasal meatus, with the exception of the anatomic landmark for measuring the tube. After the topical anesthetic has been applied, the catheter is held along the side of the face with the tip placed at the ramus of the mandible; the catheter is marked at the level of the nostril. The lubricated tube is then inserted ventromedially into the nasal meatus. To facilitate passage of the tube ventrally and medially to the turbinates, the lateral aspect of the nostril should be pushed medially, and the patient's nasal philtrum pushed dorsally, as the tube is passed. Once the tube has been passed to the level of the mark, it can be secured to the patient's face in a manner identical to that used with the nasal oxygen catheter. Overzealous pressure as either tube is placed can cause epistaxis.

Following insertion of a nasal or nasopharyngeal catheter, an Elizabethan collar should be placed to help prevent 79
80
tube dislodgement by the patient. A length of oxygen tubing can be attached to the proximal end of the tube with a cut 1-ml syringe or Christmas tree adapter and then attached to a humidified oxygen source. Alternatively, nasal prongs can be placed in the nares of larger animals. These are very simple to use and well tolerated by dogs but require close observation because they can easily be dislodged by the patient.

19.5.2 Transtracheal Oxygen

Tracheal catheter placement is an effective means of administering supplemental oxygen to patients that are intolerant of nasal or hood oxygen or are panting or open-mouth breathing or have an upper airway obstruction. Although this technique is more labor intensive and requires a higher degree of skill than placement of a nasal catheter, higher FiO_2 with a degree of continuous airway pressure is provided[10] and can be beneficial for patients that require a higher degree of supplemental oxygen than that provided with a nasal catheter, but that do not require assisted ventilation.

Two methods of transtracheal oxygen supplementation have been described. The first method utilizes a through-the-needle large-bore catheter placed percutaneously through the skin and underlying tissues directly into the trachea.[4] The patient's ventrocervical region should be clipped from just caudal to the larynx to the thoracic inlet and laterally off of midline. To avoid iatrogenic introduction of bacteria and debris into the tracheal lumen, aseptic technique must be followed at all times. The clipped area should be aseptically scrubbed. A small bleb of

2% lidocaine should be placed at the level of the third to fifth tracheal ring, infiltrating the subcutaneous tissues and skin as the needle is backed out. The area is aseptically scrubbed again.

Wearing sterile gloves, the operator gently palpates and then grasps the patient's trachea with the fingers for stabilization. A small nick incision can be made through the skin with a No. 11 scalpel blade to decrease tissue drag as the catheter is inserted. The needle of the catheter is then inserted through the skin, through the subcutaneous tissue and sternohyoideus muscle, between tracheal rings, and into the trachea. A pop will be felt as the needle enters the trachea. Once in place, the catheter with stylette is inserted through the needle into the tracheal lumen. The needle is then removed from the trachea once the catheter has been inserted to its hub. Depending on the size of the animal, the distal end of the catheter may reach the carina.

The catheter can be connected to a humidified oxygen source with a cut 1-ml syringe and oxygen run at a flow rate of 50 to 150 ml/kg/min.[10] The catheter should be secured to the neck with lengths of white tape. Caution must be exercised to monitor the patient carefully, because ventral flexion of the neck or excessive skin folds can cause catheter kinking and occlusion. Excessive skin folds can be pulled dorsally and secured on the dorsal cervical midline with several horizontal mattress sutures until the catheter is no longer required.

The second method of transtracheal oxygen supplementation is more invasive and requires heavy sedation or a short-acting anesthetic agent. The choice of sedative/anesthetic drug should be made in light of the patient's clinical state. The ventrocervical region should be clipped and aseptically scrubbed in a manner identical to that described previously. The area should be aseptically draped with sterile towels and infiltrated with a local anesthetic (2% lidocaine 1 to 2 mg/kg). A midline skin incision should be made over the third to fifth tracheal rings. The subcutaneous tissues and sternohyoid muscle should be bluntly dissected with a curved hemostat or tips of a Metzenbaum scissors until the trachea is visible.

A small incision is then made between the fourth and fifth tracheal rings with a No. 11 scalpel blade, taking care to avoid cutting more than 50% of the circumference of the trachea. A curved hemostat is used to open the hole between tracheal rings, and a grooved director (from a spay pack) inserted into the tracheal lumen. A large-bore fenestrated catheter with a styletlte (Global Product) is then inserted into the tracheal lumen along the grooved director (Color Plate 19-2). Once the catheter is inserted, the grooved director and catheter stylet can be removed and the catheter secured. A sterile 4 × 4 gauze square with antimicrobial ointment should be placed over the incision and the catheter secured with lengths of white tape.

The cranial and caudal edges of large skin incisions should be sutured with nonabsorbable suture. The benefits of this technique are that larger catheters can be inserted and continuous airway pressure can be administered at higher oxygen flow rates than is possible with other methods of supplementation. Oxygen flow rates of 50 ml/kg/min are required to achieve 40% to 60% FiO_2.[10] This technique is well tolerated by many patients and is economical, but has the inherent risks associated with sedation, general anesthesia, and introduction of bacteria directly into the tracheal lumen. Jet lesions and damage to the trachea can occur with this technique.[4]

19.6 HYPERBARIC OXYGEN

A hyperbaric chamber provides 100% oxygen under supraatmospheric pressures (>760 mm Hg) to increase the percentage of dissolved oxygen in the patient's bloodstream by 10% to 20%.[1,9,11] Dissolved oxygen can diffuse readily into tissues that are damaged and may not have adequate circulation. Hyperbaric oxygen has been recommended for the treatment of severe soft tissue lesions including burns, shearing injuries, infection, and osteomyelitis. Ruptured tympanum and pneumothorax have been associated with hyperbaric oxygen therapy.

Hyperbaric oxygen is rarely used in veterinary medicine, given the expense of the equipment and space required for a specialized "dive chamber" in which to place the patient during treatment. An additional disadvantage is that once the dive chamber has been pressurized to supraatmospheric levels, it cannot be opened to gain patient access should complications occur.

19.7 COMPLICATIONS OF OXYGEN THERAPY AND OXYGEN TOXICITY

Supplemental oxygen is not an innocuous therapy. Hypercapnia is the primary stimulus for respiration in normal patients. In patients with chronic respiratory disease and hypercapnia, however, hypercapnic respiratory drive is diminished or lost, and the patient becomes largely dependent on hypoxemia as a respiratory stimulant. The administration of supplemental oxygen to a chronically hypercapnic patient depresses the hypoxic respiratory drive and can result in severe hypoventilation and respiratory failure. Mechanical ventilation may be necessary to treat the severe hypercapnia and hypoxemia that develop.[1]

Oxygen can be directly toxic to the pulmonary epithelium. The severity and timing of injury are dependent on the FiO_2 and duration of therapy. Pulmonary oxygen toxicity can be divided into five distinct phases. During the *initiation* phase, oxygen-derived free radical species such as superoxide anion, peroxide, and hydroxyl radicals cause direct damage to pulmonary epithelial cells as cellular antioxidant stores become depleted.[1,9] The initiation phase occurs within 24 to 72 hours of exposure to 100% oxygen.[1] Next, destruction of the pulmonary epithelial lining causes airway inflammation and the recruitment of activated inflammatory cells to the site. During this *inflammatory* phase, massive release of inflammatory mediators results in increased tissue permeability, and pulmonary edema develops. Severe local destruction occurs and is associated with high patient mortality rates. If the patient survives the *destruction* phase, type II pneumocytes and monocytes increase during a stage of *proliferation*. Finally, collagen deposition and interstitial fibrosis occur and can result in permanent damage to the lungs. An FiO_2 of over 60% should not be administered for longer than 24 to 72 hours, to avoid pulmonary oxygen toxicity.[9] Fortunately, without mechanical ventilation or an oxygen cage, an FiO_2 greater than 60% is difficult to obtain, making the risk of pulmonary oxygen toxicity minimal with most methods of oxygen supplementation.

20 Chapter 20 Allergic Airway Disease In Dogs And Cats And Feline Bronchopulmonary Disease

Carrie J. Miller, DVM, DACVIM

20.1 KEY POINTS

- Allergic airway disease in dogs and cats encompasses a broad spectrum of diseases that are somewhat poorly defined, but the clinical signs and pathologic appearances are similar for all causes.
- Diseases commonly included in this category include parasitic allergic airway disease, allergic bronchitis (eosinophilic bronchopneumopathy), feline asthma, and pulmonary infiltrates with eosinophils.
- Lower airway inflammation in response to either an extrinsic noxious stimuli or intrinsic hypersensitivity to antigenic stimulation is a known factor in the development of allergic respiratory disease in small animals. The airway inflammation causes mucosal edema, airway smooth muscle hypertrophy and constriction, and excessive production of airway secretions.
- Although the causes of both canine and feline allergic airway disease are numerous, the medical management is similar because it is often difficult to remove the inciting cause (unless infectious in nature). The clinician must therefore attempt to control and dampen symptoms.
- Steroids, bronchodilators, and oxygen therapy are the mainstays of emergency therapy for animals with allergic airway disease.

20.2 Definition of Allergic Airway Disease

Allergic airway disease in dogs and cats encompasses a broad spectrum of diseases that are somewhat poorly defined, but the clinical signs and pathologic appearances are similar regardless of causes. Diseases commonly included in this category are parasitic allergic airway disease, allergic bronchitis (eosinophilic bronchopneumopathy), feline asthma, and pulmonary infiltrates with eosinophils (PIEs). These diseases typically are characterized by bronchial or alveolar inflammatory changes including submucosal wall edema, increased bronchial secretions, smooth muscle hypertrophy, and smooth muscle constriction of the bronchioles and small bronchi. Histologically, there is typically a predominance of eosinophils within the airways and submucosa of the bronchial tree. Clinical signs include labored breathing, rapid shallow breathing, increased expiratory effort, and cough. Studies have shown variable degrees of inherent hypersensitivity in the bronchiolar smooth muscle in small animals with lower airway disease.[1,2] Animals may have an acute onset of respiratory signs with completely reversible changes or may develop chronic disease (defined as more than 2 months duration) that is associated with irreversible bronchial wall alterations.[3] The pathogenesis of these diseases has not been as thoroughly investigated as has human asthma. One should avoid terming small animal allergic airway disease as *asthma* because the pathogenesis and definition are much less clear than they are in humans.[4]

20.3 HUMAN ASTHMA

Human asthma is defined as a disease of the lower airways that makes affected individuals prone to inappropriate airway narrowing in response to a wide variety of provoking stimuli. The ease with which these airways narrow is termed *hyperreactivity*. [5] Human asthmatic patients will develop large numbers of immunoglobulin E (IgE) antibodies in response to various inhaled allergens. These IgE antibodies then crosslink to mast cells in the submucosa of the bronchi and bronchioles of the lung, causing mast cell degranulation. Degranulation leads to the release of several inflammatory mediators (i.e., histamine, leukotrienes, eosinophilic chemotactic factor, bradykinin) that cause immediate airway constriction, as well as a late-phase inflammatory response that takes place several hours after initial release secondary to the effects of the leukotrienes.[5–7] These mediators are responsible for pulmonary mucosal edema, smooth muscle hypertrophy of the bronchi and bronchioles, accumulation of pulmonary secretions, and airway narrowing.[6] Because expiratory resistance and function is the primary breathing phase affected, there is air trapping within the lungs that leads to an increase in functional residual capacity (FRC) and appears radiographically as hyperinflation of the lungs.[6,8]

20.4 PATHOGENESIS OF SMALL ANIMAL ALLERGIC RESPIRATORY DISEASE

The pathophysiology of small animal allergic airway disease is less well understood than human asthma, but it is clear that these diseases in small animals are characterized clinically by a cough, typically a prominent increase in expiratory effort with or without appreciable wheezes, and a predictable response to glucocorticoids.[2,4,9] Allergic airway disease in small animals commonly causes an increase in the numbers of eosinophils within the airways, hyperinflation of the lungs, and thickening of the bronchi and bronchioles. Lower airway inflammation, in response to either an extrinsic noxious stimulus or intrinsic hypersensitivity to antigenic stimulation, is a known component in animals with allergic respiratory disease. The airway inflammation causes mucosal edema, airway smooth muscle hypertrophy and constriction, and excessive production of airway secretions.[3,9] Although similar in clinical picture and treatment, diseases such as feline and canine bronchitis should not be termed *allergic* in nature because they do not fit all of the above criteria (particularly overabundance of eosinophils in the airways). Diseases that should be included in small animal allergic airway disease include canine allergic bronchitis (also termed *eosinophilic bronchopneumopathy*), parasitic larval migration, PIE, and feline asthma.[10] Although the clinical picture and treatment of feline bronchopulmonary disease and feline asthma are similar, it is important to remember that they may have separate causes, because the cytopathologic features differ.

20.5 PARASITIC ALLERGIC AIRWAY DISEASE

Intestinal parasite migration as well as primary pulmonary parasitism can cause a parenchymal or lower airway allergic inflammatory response. The most common migratory parasite to cause an allergic response in the canine lungs is *Toxocara canis*. An inflammatory "allergic" reaction can take place in the lower airways and parenchyma of young dogs when this parasite migrates through the lungs as part of its normal development. Because of antigenic stimulation and the eosinophilic infiltrate induced by the larvae, these dogs may develop signs of respiratory disease that can vary in intensity.[11]

Other, less common parasites known to migrate through the lungs include *Ancylostoma caninum* (dogs only) and *Strongyloides stercoralis* (dogs or cats). Primary lung parasites include *Paragonimus kellicotti, Aelurostrongylus abstrusus, Capillaria aerophila,* and *Filaroides hirthi* (Table 20-1). *Dirofilaria immitis* (heartworm infection) can also cause an allergic inflammatory response when large numbers of antimicrofilarial antibodies entrap microfilariae within the pulmonary capillaries.[12] All of these parasites elicit predominantly a type I hypersensitivity reaction in the lungs that leads to bronchoconstriction and inflammation within the airways and lung parenchyma.[11]

Clinical signs associated with larval migration or primary pulmonary parasitic infection vary markedly from asymptomatic to severe coughing, wheezing, and respiratory distress. A complete blood count may show eosinophilia or basophilia, however this finding is not always present in animals suffering from parasitic allergic airway disease. Chest radiographs can show a variety of changes, including interstitial infiltrates, bronchial thickening, and even alveolar consolidation. *Ancylostoma caninum* and *Toxocara canis* can be seen using routine fecal flotation techniques. [10] *Strongyloides stercoralis* is more reliably found with the Baermann technique. However, negative fecal examination results do not rule out the possibility of migrating larval airway disease. Ova are often difficult to find on fecal examination because larvae typically begin to migrate through the lungs before shedding ova into the intestinal tract.[13]

Initially, a course of an appropriate antihelminthic medication (ivermectin or fenbendazole) can be used for treatment, particularly in mild to moderate clinical cases (see Table 20-1). Appropriate treatment for infection with *D. immitis* is discussed elsewhere.[14] In situations in which the clinical signs are severe, or fail to resolve completely, an antiinflammatory dosage of prednisone (0.5 to 1 mg/kg q24h) may be used to help control the disease manifestations.[10,11]

20.6 CANINE ALLERGIC BRONCHITIS OR EOSINOPHILIC BRONCHOPNEUMOPATHY

Canine allergic bronchitis (eosinophilic bronchopneumopathy) is characterized by pulmonary hypersensitivity with eosinophilic infiltration of lung and bronchial mucosa. The signalment of dogs with this disease tends to be different from that of either PIE or canine chronic bronchitis; these dogs tend to be younger (mean ± SD = 3.3 ± 2 years) and Siberian Huskies and Alaskan Malamutes are overrepresented. These dogs usually are in good physical condition, but show clinical signs such as coughing, labored breathing, or nasal discharge that is mucopurulent or yellow-green in appearance.[12,15]

Table 20-1 Parasitic Diseases That May Cause an Inflammatory Pulmonary Reaction*

Parasite	Species	Location	Diagnosis	Management
Aelurostrongylus abstrusus	Cats	Southern United States and worldwide	Larvae in tracheal wash or fecal Baermann technique	Fenbendazole or ivermectin if clinical
Capillaria aerophila	Dogs and cats	Worldwide	Eggs in tracheal wash or fecal flotation	Fenbendazole or levamisole (dogs)
Filaroides hirthi	Dogs	North America, Japan, Europe	Zinc sulfate flotation or Baermann technique or larvae in tracheal wash	Albendazole or fenbendazole
Crenosoma vulpis	Dogs	Worldwide	Larvae in tracheal wash or fecal Baermann technique	Fenbendazole or levamisole
Paragonimus kellicotti	Dogs and cats	Great Lakes, Midwest, southern United States	Eggs in tracheal wash or fecal sedimentation	Praziquantel or fenbendazole
Intestinal parasite migration*: ~*Toxocara canis*	Dogs	Worldwide	Ova on fecal flotation	Pyrantel pamoate; for larval migration use either fenbendazole or ivermectin

The most common radiographic finding in dogs with canine allergic bronchitis (eosinophilic bronchopneumopathy) is a diffuse, prominent, bronchointerstitial pattern. Forty percent of dogs have alveolar infiltrates (due to secondary pneumonia in some cases), and 26% have radiographic signs of bronchiectasis. A peripheral eosinophilia is present in about 60% of cases. Bronchoscopy typically reveals abundant yellow-green mucus or mucopurulent material, thickening with irregularities or polypoid changes to the mucosa, and exaggerated closure of the airways during expiration. Cytologic findings in fluid obtained from a bronchoalveolar lavage (BAL) or endotracheal wash (ETW) include more than 50% eosinophils in 87% of dogs and between 20% and 50% eosinophils in 13% of dogs.[15]

The mainstay of treatment for animals with this disease is glucocorticoids, with an induction dosage of prednisone of approximately 1 mg/kg q12h, although larger dogs often require lower dosages. Most dogs will relapse within months of discontinuing the steroids, but some dogs may remain disease free for years. A maintenance dosage of prednisone (0.25 to 0.5 mg/kg q48h) is suggested in an attempt to maintain remission. Other immunosuppressive drugs and inhaled medications have not been evaluated objectively for their efficacy in treating animals with this disease. Culture and sensitivity testing should be performed on the BAL or ETW fluid in order to rule out a secondary pneumonia. It is important to stress to the owner that this disease requires life-long management and there may be unwanted side effects from the long-term use of steroids.[12,15]

* Clinical signs may include cough, respiratory distress, and often a peripheral eosinophilia. Other intestinal parasites to consider in animals with allergic lung disease include *Ancylostoma caninum* and *Strongyloides stercoralis*.

20.7 PULMONARY INFILTRATES WITH EOSINOPHILS

PIE describes a spectrum of diseases that involve a type I hypersensitivity reaction occurring in the pulmonary parenchyma in response to various stimuli. PIE should be considered more of an “umbrella term” that encompasses several pulmonary diseases, all of which cause eosinophilic airway inflammation. The stimuli for this eosinophilic inflammation can include pulmonary or migrating parasites, heartworms, drugs, or inhaled allergens. One study showed that 65% of cases of PIE were caused by heartworm disease; however this predominance may vary depending on the animal's geographic location.[16] The disease tends to occur in adult dogs, with no known sex or breed predilection.

Although PIE appears to be allergic in nature based on the high numbers of eosinophils in the airways, it leads primarily to pulmonary parenchymal disease rather than airway disease. Affected dogs have classic symptoms of parenchymal disease, including respiratory distress with rapid, shallow breathing, coughing, and possibly cyanosis. Radiographically, a diffuse interstitial, bronchial, or alveolar pattern is apparent, and many dogs also have hilar lymphadenopathy. Bronchoscopy and BAL or ETW reveal a predominance of eosinophils within the airways. A peripheral eosinophilia is common, but its presence is dependent on the cause of the pulmonary eosinophilic inflammation. The morbidity and mortality in animals with PIE depends primarily on the underlying cause of PIE and whether the cause can be treated or removed. Given the heterogeneity of diseases represented by the term *PIE,* one should avoid this classification as an ultimate diagnosis and strive to uncover an underlying cause.[11,16]

20.8 FELINE BRONCHOPULMONARY DISEASE

Much like PIE, feline bronchopulmonary disease is a broad term that encompasses several disease processes. Although some cats may be truly allergic and asthmatic in nature, others may have chronic changes (chronic bronchitis) from prolonged and persistent irritation and inflammation to the lower airways related to nonallergenic stimuli.[2] Because these groups of cats will look very similar clinically and the etiology of feline bronchopulmonary disease is unknown, both diseases are presented here in detail. One should keep in mind, however, that most clinical cases of feline bronchopulmonary disease do not fit the true definition of allergic airway disease.

20.8.1 Pathogenesis

The pathogenesis of the feline bronchopulmonary inflammatory response appears variable. The response is difficult to predict because it has been reported that up to 30% eosinophils may be seen in the BAL or ETW fluid of healthy cats.[17] The cellular inflammatory response is only partially responsible for feline bronchopulmonary disease. Another important factor is lower airway hyperreactivity, which is defined as the ease with which airways narrow in response to a nonspecific stimulus. Although some cats may have inherently reactive airways to truly allergic stimuli, others may have a degree of airway responsiveness to extrinsic noxious stimuli. Feline patients have been reported to have exacerbations of signs associated with exposure to scented hair sprays, clay-based litters, scented air fresheners, or cigarette smoke. In some cases, simply removing the noxious stimulus from the environment may noticeably improve a cat's symptoms.[2]

20.8.2 Clinical Signs

Respiratory distress, with increased expiratory effort and rapid, shallow breathing, is a common manifestation of feline bronchopulmonary disease. Cats often display open-mouth breathing, and excessive coughing with severe tracheal sensitivity is common. Although the inflammation within the airways is typically a chronic problem, the episode of respiratory distress may appear acute and severe in nature. Airway narrowing caused by inflammation and bronchoconstriction in the lower airways frequently causes wheezes and a forced abdominal push during exhalation.[1,18]

Feline bronchopulmonary disease appears to be the most common cause of coughing in cats, although 16% of cases had no coughing in the history or during physical examination.[2,12] Seventy-five percent of cats in one study coughed during examination, and many also exhibited wheezing or sneezing. The Siamese breed is overrepresented in cats with lower airway disease. There is no known sex or age predilection.[2,3]

20.8.3 Laboratory Diagnostic Tests

Once the cat is stabilized, a complete blood count, biochemical analysis, and urinalysis should be performed to help rule out systemic diseases that could be causing respiratory distress (see Chapter 2, Patient Triage). These test results are typically normal in cats with feline bronchopulmonary disease, and it is a common misconception that they have a peripheral eosinophilia. In one study of cats with peripheral eosinophilia, only 9% were diagnosed with feline allergic airway disease.[2,3,19] A diagnosis of allergic airway disease in a cat with a peripheral eosinophilia should not be made without cytologic evidence demonstrating concurrent airway eosinophilia. A fecal examination will help rule in or rule out pulmonary parasites. A heartworm test is also important for any cat with labored breathing and evidence of bronchointerstitial disease. A bronchointerstitial pattern is the most persistent and chronic radiographic finding in feline heartworm disease, even without changes seen in the pulmonary vasculature.[12,20] Both feline antibody and antigen heartworm tests should be performed, because the amount of antigen can be extremely low or the antigen may be absent in some cats.[14]

20.8.4 Radiology

Thoracic radiographs are essential in a cat in respiratory distress. The cat should first be stabilized with oxygen, and other medications, if indicated. The radiographic appearance of feline bronchopulmonary disease can vary. The classic radiographic findings include an increase in bronchial densities, often described as *doughnuts, tram lines,* or *train tracks*. These terms describe the thickened bronchial walls viewed end-on or from the side. Other radiographic findings can include an increase in interstitial markings, an alveolar pattern, or hyperinflation of the lung fields with flattening of the diaphragm.[10-12] Alveolar infiltration and consolidation of the right middle lung lobe have been reported in 11% of cats with bronchopulmonary disease.[3] This radiographic appearance should not be mistaken for bronchopneumonia.

The severity of radiographic changes in cats with allergic airway disease varies, ranging from mild to severe, and does not necessarily correlate with the severity of symptoms or diagnostic test results.[23] A prognosis should therefore not be made based solely on radiographic changes.

20.8.5 Bronchoscopy

Bronchoscopy allows direct visualization of the trachea and bronchial tree. Cats with feline bronchopulmonary disease will often have thick mucus secretions in their lower airways, as well as hyperemic and edematous mucosa.[2,3] During bronchoscopy, a BAL should be performed. A BAL is preferred over a transtracheal wash because the BAL yields a cell population that is more representative of the lower airways and pulmonary interstitium. A BAL has also been shown to be more accurate than a transtracheal wash for the diagnosis of bacterial and mycotic infections of the lower airways.[21]

Fluid culture should be performed to rule out infectious causes of airway inflammation. A quantitative culture should be performed, with significant bacterial numbers indicating true bacterial infection. The bronchi of healthy cats are not considered sterile; thus a bacterial culture is generally considered significant only if the growth is greater than 2000 colony-forming units (cfus)/ml in cats. One study has shown that cats with feline bronchopulmonary disease have a significantly higher rate of mycoplasma colonization than that seen in cats with healthy airways.[2,3,17] The most predominant cell types found in bronchial washings of cats affected with bronchopulmonary disease are neutrophils and eosinophils. Dye and colleagues reported that moderately and severely affected cats had statistically significantly higher percentages of eosinophils, neutrophils, and combined neutrophils and eosinophils than did healthy cats. Mast cells, however, were found infrequently and represented up to 8% of all the cell types.[2] Moise and coworkers found that the predominant cell types in affected cats were eosinophils (24% of cats), neutrophils (33% of cats), macrophages (22% of cats), or a mixed cell population (21% of cats).[3] Clearly, cats with feline bronchopulmonary disease have variable cytologic findings, thus demonstrating why this disease is not routinely considered to be allergic in nature.

20.9 TREATMENT OF ALLERGIC AIRWAY DISEASE

20.9.1 Glucocorticoids

Although the causes of both canine and feline allergic airway disease are numerous, the medical treatment is similar because it is often difficult to remove the inciting cause (unless infectious in nature). The clinician must therefore attempt to control and dampen the clinical manifestations, which includes advising clients to remove inhalant irritants from the animal's environment, including such things as dusty litter, perfumes, aerosols, and cigarette smoke. Both drug therapy and irritant avoidance are necessary in most animals with allergic airway disease. Several options exist for medical treatment of these patients. Steroids, bronchodilators, and oxygen therapy are the mainstay of emergency therapy.[22] Steroids are used in emergent patients and for long-term therapy to decrease inflammation and resistance in the lower airways (Table 20-2).[23] Although steroids are generally very effective in decreasing airway resistance and inflammation, the common and often severe side effects of this class of drugs limit their practical use for long-term control of allergic airway disease.[24] Some inhalant steroids (e.g., fluticasone and flunisolide) are now being used in the clinical setting to control airway inflammation without the systemic side effects.[25] The efficacy of these medications has not been thoroughly evaluated (see Chapter 192, Aerosolized Medications).

Table 20-2 Commonly Used Medications and Dosages for the Treatment of Allergic Airway Disease in the Dog and Cat

Drug	Class and Mechanism	Indication	Dosage Recommended
Dexamethasone sodium phosphate	Glucocorticoid: long-acting	Parenteral steroid for emergency use	0.2 to 1 mg/kg IV or IM
Prednisone or prednisolone	Glucocorticoid: short-acting	Appropriate for maintenance use and alternate-day therapy	1 to 2 mg/kg PO q12h for 2 weeks, then taper over 2 to 3 months
Methylprednisolone acetate	Glucocorticoid: long-acting	Appropriate only for cases with problems in compliance	20 mg per cat IM q4-6wk
Aminophylline	Bronchodilator: methylxanthine	Not recommended orally because of the short half-life in dogs and cats	5 to 10 mg/kg PO q8h or 5 to 10 mg/kg IV q6-8h
Theophylline extended release (Inwood brand)	Bronchodilator: methylxanthine	Maintenance therapy	Cats: 15 mg/kg (tablets) or 19 mg/kg (capsules) PO q24 h/ Dogs: 10 mg/kg PO q12h
Terbutaline	Bronchodilator β_2-agonist	Parenteral or oral bronchodilator	0.01 mg/kg SC or IM q4h Cats: 1.25 mg PO q12h Dogs: 2.5 mg PO q8h

IM, intramuscular; *IV,* intravenous; *PO,* per os; *SC,* subcutaneous.

20.9.2 Bronchodilators

Two classes of bronchodilators can be used to manage allergic airway disease in veterinary patients. These include methylxanthines (theophylline, aminophylline) and selective β_2-receptor agonists (terbutaline or albuterol). Parenterally administered terbutaline has a rapid onset of action and is most commonly given to animals in acute, severe respiratory distress. Because β-agonist drugs may cause tachycardia or tachyarrhythmias in some animals, the clinician should attempt to rule out cardiac disease before administering these medications.[26] Inhaled β-agonist therapy is also an option for inpatient or outpatient therapy of allergic airway disease and may carry fewer side effects (see Chapter 192, Aerosolized Medications). Methylxanthine drugs may be preferable for long-term bronchodilation because tolerance to the β-agonist drugs may occur and subsequently decrease their efficacy in emergency situations. The Inwood brand of theophylline results in the most reliable and appropriate pharmacokinetics in dogs.[27]

Antihelminthic medications are recommended routinely for animals with allergic airway disease. Although bronchoscopy and BAL washings offer the best chance of diagnosing parasitic allergic airway disease, migrating larvae and primary pulmonary parasites can be missed with these diagnostic tools.[11] Deworming protocols are generally very safe and can effectively cure animals with parasitic allergic airway disease.

20.9.3 Miscellaneous Drugs and Other Therapies

Because of the potent side effects of many steroids, other drugs have been used empirically for the treatment of allergic airway disease. There are no controlled, in vivo studies that demonstrate the efficacy of these medications; however, they are sometimes prescribed when other medications appear unsuccessful. Cyclosporine is an immunosuppressant that specifically inhibits the T-helper cells of the immune system. There is evidence that the T-helper cells are a primary component of the allergic immune response.[24] Cyclosporine has been shown to block inflammatory changes associated with experimental asthma in cats; however, it has not been evaluated in 85
naturally occurring cases of allergic airway disease and its side effects may preclude its use in routine treatment.[28] 86
Many human asthmatics are now treated with therapies such as leukotriene receptor blockers (montelukast and zafirlukast) or inhibitors of the enzyme 5-lipoxygenase (zileuton), which is responsible for the formation of leukotrienes themselves.[29] Cysteinyl leukotrienes do not appear to be important mediators of bronchoconstriction in cats, and the one veterinary study evaluating these medications did not show efficacy using a lipoxygenase blocker in a model of experimentally induced feline allergic airway disease.[30]

Cyproheptadine has also been suggested for use in cats with allergic airway disease. It is a serotonin receptor antagonist that inhibits feline airway smooth muscle contraction in vitro. Oral administration (2 mg q12h) was associated with a reduction in airway hyperreactivity in a subpopulation of cats with experimentally induced asthma, although there is some evidence to suggest that higher dosages (i.e., 8 mg q8-12h) may be more appropriate.[30] It has yet to be determined whether cyproheptadine will work in vivo in cats with airway disease. Serotonin does not appear to play a role in smooth muscle contraction in human or equine species.[31]

20.10 PROGNOSIS

The prognosis for small animals with allergic airway disease is variable and depends on the cause, chronicity, and continued exposure to irritants. The overall clinical picture can be exacerbated by concurrent underlying cardiac or other respiratory disease. Feline bronchopulmonary disease in cats is often a chronic disorder, one that will manifest with either persistent signs or episodic flare-ups. Patient morbidity is high in affected cats because of the chronicity of the disease.

21 Chapter 21 Pulmonary Edema

Sophie Adamantos, BVSc, CertVA, DACVECC, MRCVS

Dez Hughes, BVSc, DACVECC, MRCVS

21.1 Key Points

- Pulmonary edema is a common cause of dyspnea in dogs and cats.
- Two main pathophysiologic forms exist: high-pressure edema and increased permeability edema.
- Hydrostatic pressure is an important pathologic mechanism in both forms of edema.
- Cardiogenic edema and fluid overload are the most common forms of high-pressure edema.
- Decreased colloid osmotic pressure (COP) within the intravascular space is rarely a sole cause of pulmonary edema.
- Pulmonary capillary pressure modification is important in management of both pathophysiologic forms.
- Fluid therapy should be administered with caution in all patients with pulmonary edema.
- The prognosis for animals with pulmonary edema varies depending upon the underlying cause.

21.2 INTRODUCTION

Pulmonary edema is the accumulation of extravascular fluid within the pulmonary parenchyma or alveoli. The two main pathophysiologic forms are high-pressure edema (due to increased pulmonary capillary hydrostatic pressure) and increased permeability edema (due to damage of the microvascular barrier and alveolar epithelium in more severe cases). Pulmonary edema is a relatively common disease process in veterinary patients that can be rapidly life threatening.

21.3 PATHOPHYSIOLOGY

In normal tissues, transvascular fluid fluxes are determined by Starling forces. The amount of flow is dependent on a number of variables: the capillary hydrostatic pressure, interstitial hydrostatic pressure, capillary colloid osmotic pressure (COP), interstitial COP, and the reflection and filtration coefficients for the tissues.[1] 87

The filtration coefficient is a measure of fluid efflux from the vasculature of specific tissues and is dependent on the capillary surface area and hydraulic conductivity. The reflection coefficient indicates the relative permeability of the membrane to protein. Tissue safety factors protect tissues against the deleterious effects of edema. In normal tissues, extravasation of low-protein fluid results in a fall in interstitial COP, which results in preservation of the COP gradient, thereby protecting against further fluid extravasation.[2] Other safety factors in nondistensible tissues include increased interstitial hydrostatic pressure and increased driving pressure for lymphatic flow (which can increase up to 10 times normal).

The pulmonary capillary endothelium is relatively permeable to protein compared with other tissues, so the effective COP gradient that can be generated between the intravascular space and pulmonary interstitium is lower than in other tissues. Consequently, increased lymphatic flow is largely responsible for protecting against edema in the lung,[3] and hypoproteinemia causing a decrease in COP rarely results in pulmonary edema. Pulmonary edema occurs when the rate of interstitial fluid formation overwhelms the protective fluid clearance mechanisms. Due to the lower COP gradient, hydrostatic pressure is the main determinant of fluid extravasation and edema formation in the lungs,[4] hence the rationale for using hydrostatic pressure modulators in the treatment of all forms of pulmonary edema. The pulmonary ultrastructure is designed to protect gaseous diffusion. Most interstitial fluid flow is on the side of the capillary opposite to that where gas exchange occurs, and the distensibility of the lung tissue increases toward the peribronchovascular region. This results in initial fluid accumulation in areas not used for gas exchange.[5]

High-pressure edema forms as a result of increasing pulmonary capillary pressures, leading to fluid extravasation that eventually overwhelms the lymphatic removal capacity. Fluid flows initially toward the peribronchovascular interstitium, then distends all parts of the pulmonary interstitium, and eventually spills into the airspaces at the junction of the alveolar and airway epithelia.[4] In many animals with cardiogenic edema, the increase in pressure occurs gradually, and overt edema may develop over a period of months; however, if there are acute increases in hydrostatic pressure (e.g., chordae tendineae rupture), then edema will form rapidly.

Increased permeability edema occurs secondary to injury to the microvascular barrier and alveolar epithelium, resulting in extravasation of fluid with a high protein content.[4] The protective fall in COP is thereby diminished, so the hydrostatic pressure becomes the main determinant of edema formation. Interstitial fluid accumulation can then occur at even lower hydrostatic pressures, and relatively small rises in pressure can result in greater edema formation. In more severe cases in which the alveolar epithelium is also damaged, a direct conduit may form in the intravascular space, and interstitial edema progresses to alveolar flooding. This occurs rapidly and explains the greater severity and fulminant course of increased-permeability edema compared with hydrostatic edema.

Although the lymphatic system plays a major role in limiting interstitial fluid accumulation, it has only a minor role in the clearance of pulmonary edema. Most fluid is mobilized to the bronchial circulation, probably because most fluid tends to accumulate in the peribronchovascular areas.[6] The rate of resolution depends on the fluid type, with pure water being reabsorbed much more rapidly than fluid containing macromolecules and cells.

21.4 CLINICAL PRESENTATION

Pulmonary edema results in reduced oxygenation, usually as a result of ventilation-perfusion mismatching; therefore most animals have symptoms of respiratory distress. Some of these patients are extremely fragile, so a risk-benefit assessment should be considered before even performing a physical examination. Oxygen should be given to all patients with respiratory distress, and the benefits of giving a patient time to recover in a quiet, oxygen-enriched environment cannot be overstressed (see Chapter 19, Oxygen Therapy). Initial diagnostic evaluation should be directed toward identifying the severity of the respiratory disease and the underlying cause. Historical information can be useful in some cases, such as smoke inhalation, choking, or a previous diagnosis of congestive heart failure. Neurogenic pulmonary edema may be suspected in animals that have dyspnea after head trauma, upper respiratory tract obstruction, or electric shock.

As with many conditions, the severity is often inversely proportional to the duration of clinical signs. Although typically associated with pulmonary edema, crackles are not heard in all cases; however, most patients will have either loud lung sounds or crackles. Crackles are particularly difficult to hear in patients with rapid respiratory rates and low tidal volumes. Careful auscultation may allow the abnormal lung sounds to be localized to one region and this may aid in the diagnosis, such as a cranioventral distribution with aspiration pneumonia and occasionally a perihilar distribution with cardiogenic pulmonary edema (primarily in the dog).

21.4.1 High-Pressure Edema

21.4.1.1 Cardiogenic Edema

Cardiogenic pulmonary edema is the most common form of high-pressure edema.[7] It occurs as a result of left-sided congestive heart failure. Cardiac disease is often chronic, and in dogs there is usually a history of clinical signs consistent with heart disease: cough, exercise intolerance, and usually a heart murmur. Acute onset of signs may be seen, particularly if there has been a precipitating event such as stress. Cats often have no premonitory clinical signs. Due to the chronic progression of heart disease, compensatory mechanisms result in fluid retention to maintain cardiac output and, although beneficial in the short term, this eventually leads to signs of congestion which in its most life-threatening form is pulmonary edema.

As a result of chronic increases in blood volume, the capillary pressure at which edema forms is higher than in the normal dog or cat. In severe cases blood vessel rupture may occur, leading to a serosanguineous appearance of secretions, as evidenced by pink frothy sputum. Fortunately only a few common diseases cause cardiogenic pulmonary edema, and signalment can be extremely useful in forming a differential diagnosis list. Middle-aged, large breed dogs tend to have dilated cardiomyopathy, whereas the smaller breeds tend to have mitral valve disease. Cats are more prone to the myocardial diseases, with hypertrophic, thyrotoxic, and restrictive cardiomyopathies seen most commonly.[7]

87

88

21.4.1.2 Fluid Therapy

Fluid therapy is an uncommon cause of pulmonary edema without preexisting heart or lung disease, due to the effective safety mechanisms within the lung. However, fluid therapy may cause rapid increases in hydrostatic pressure in animals with preexisting (although asymptomatic) heart disease, leading to pulmonary edema. Experimental studies have demonstrated that dogs are able to cope with large volumes: dosages of 360 ml/kg of crystalloid over 1 hour were given before severe fluid overload was seen.[8] Cats are less able to cope with large volumes, especially those with renal failure, cardiac insufficiency, or lung disease. Synthetic or natural colloid products and hemoglobin-based oxygen-carrying solutions cause much more volume expansion than crystalloids. Approximately 5 times the amount of colloid is retained within the intravascular space, so appropriate reductions in fluid administration rates and dosages should be made, especially in cats. When there are other risk factors such as systemic inflammation, pulmonary parenchymal disease, or hypoalbuminemia, fluid therapy may readily lead to pulmonary edema.

21.4.2 Increased-Permeability Edema

An increase in permeability is caused by direct injury to the microvascular barrier or alveolar epithelium by chemical damage and inflammatory mediators. Patients with systemic inflammatory response syndrome (SIRS) and diseases associated with systemic vasculitis are at increased risk of developing an increased-permeability edema. Infectious diseases that cause parenchymal inflammation can also cause increased-permeability edema. Acute respiratory distress syndrome (ARDS) is the most severe form of increased-permeability edema and is extremely difficult to manage. Clinical experience suggests that survival rate is low, although no studies have been performed to confirm this. Both SIRS and ARDS occur secondary to other disease processes, which may be primarily in the lung or in another organ system, for example, sepsis, pancreatitis, pneumonia, severe tissue trauma, immune-mediated disease, and metastatic neoplasia (see Chapters 11 and 24, Systemic Inflammatory Response Syndrome and Acute Lung Injury and Acute Respiratory Distress Syndrome, respectively).[9] Because these conditions often are difficult to manage, the clinician should be aware of the differential diagnoses for dyspnea in affected patients and act rapidly and aggressively if dyspnea occurs.

Other causes of increased-permeability edema include pulmonary thromboembolism (see Chapter 27, Pulmonary Thromboembolism), ventilator-associated lung injury (see Chapter 26, Ventilator-Associated Lung Injury), toxic lung injury such as volatile hydrocarbons and cisplatin in cats, and smoke inhalation (see Chapter 28, Smoke Inhalation). A number of chemical irritants in smoke can directly injure the respiratory tract and inactivate surfactant, causing a combination of atelectasis and increased-permeability edema.

21.4.3 Mixed Cause Edema

There are a number of other causes of pulmonary edema in which the pathophysiology is incompletely understood and that are probably due to a combination of hydrostatic and increased-permeability edema. Neurogenic edema is typically seen after head or neck trauma, submersion injuries, seizures, electrocution, and upper respiratory tract obstruction. Most affected dogs are young (<1 year) and the initiating cause may be trivial, such as a pull on a choke chain. Older dogs tend to have a more serious underlying disease, such as laryngeal paralysis or seizures. Signs of respiratory distress are seen immediately after the incident, and the prognosis for the resolution of edema depends on the inciting cause but is typically good, especially in younger dogs. Reexpansion edema has been reported in dogs and cats after acute reexpansion of chronically collapsed lung lobes.[10] Suggested mechanisms include decreased surfactant levels in collapsed lung tissue, negative interstitial pressure, and oxygen free radical formation and reperfusion injury.

21.5 DIAGNOSTIC TESTS

Thoracic radiographs are the most useful initial test to identify the cause of dyspnea; however, they can be highly stressful and should be avoided in the most severely dyspneic patient until initial stabilization with empiric therapy has been attempted. Most dogs will tolerate a quick lateral radiograph. Cats should not be placed in lateral recumbency because most find this extremely stressful. Most cats will tolerate sitting in sternal recumbency.

Equipment should be made ready in advance and oxygen supplementation should be available before attempting to radiograph these patients. The distribution of the alveolar pattern can be helpful in discriminating between cardiogenic (Figure 21-1, *A*) and noncardiogenic (see Figure 16-2) edema, but nearly all causes of edema can cause a diffuse alveolar pattern. Cardiogenic edema in dogs is typically seen in the perihilar region. In cats, however, there can also be a patchy, almost nodular, diffuse alveolar pattern (Figure 21-2). Pulmonary veins that are more distended than the pulmonary arteries may also be seen in some cases. A dorsocaudal alveolar pattern suggests neurogenic edema, whereas a cranioventral pattern is suggestive of aspiration pneumonia. A brief echocardiogram may reveal an enlarged left atrium, which raises the likelihood of congestive heart failure. In dyspneic patients, positioning may be challenging, and dyspneic animals should not be stressed excessively to obtain an echocardiogram.

Arterial blood gas analysis or pulse oximetry may be used to provide objective evidence of hypoxemia; however, they are not essential for stabilization and cause too much stress to perform in cats or very small dogs (see Chapter 208, Blood Gas and Oximetry Monitoring). Pulse oximeters are often unreliable, especially in conscious patients that are moving or have darkly pigmented skin. Pulse oximetry measurements are accurate only when a reliable pulse waveform is seen. Arterial blood gas analyzers are becoming increasingly available and, with practice, arterial blood sampling is a relatively easy technique to master. Sampling from the dorsal metatarsal artery is less stressful than from the femoral artery and can be performed even in standing dogs. Arterial blood gas analysis also allows calculation of the alveolar-arterial gradient, which typically is increased in all cases of pulmonary edema, except in the very early stages.

21.6 TREATMENT

21.6.1 Oxygen Therapy

Treatment of pulmonary edema depends on the underlying cause. No therapy is uniformly effective. Oxygen 88 89 supplementation should be provided by the least stressful means, as with all dyspneic patients, to increase arterial oxygen content and tissue oxygen delivery. Patients should be subjected to minimal stress, and movement should be limited to prevent increases in oxygen demand. Dyspneic animals should never be forcibly restrained. An oxygen cage is ideal following initial evaluation (if available), but mask, flow-by, or nasal cannula is also effective (see Chapter 19, Oxygen Therapy). Positive-pressure ventilation (PPV) may be indicated in patients that cannot maintain a hemoglobin saturation above 90% or a partial pressure of arterial oxygen (PaO_2) over 60 mm Hg with noninvasive methods of oxygen supplementation or those with evidence of hypoventilation ($PaCO_2$ >55 to 60 mm Hg) (see Chapter 213, Basic Mechanical Ventilation). If impending respiratory fatigue is a concern, PPV should be considered before there is significant deterioration (see Chapter 19, Oxygen Therapy). There is contradictory evidence in the literature regarding the effects of PPV on the resolution of pulmonary edema; PPV may help to resolve pulmonary edema in some situations, but slow it in others.[11,12] There can be significant morbidity associated with PPV, so careful case-by-case consideration should be made before commencing ventilation.

Figure 21-1 **A,** Lateral radiograph of a dog (Doberman Pinscher) showing marked perihilar alveolar infiltrates, an enlarged cardiac silhouette, and left atrial enlargement. This dog had severe congestive heart failure secondary to dilated cardiomyopathy. **B,** Lateral radiograph of the same dog 3 days later after intensive diuretic, positive inotropic, and vasodilator therapy (furosemide, dobutamine, pimobendan, and nitroprusside). There is marked improvement in the alveolar pattern, although mild perihilar infiltrates are still present.

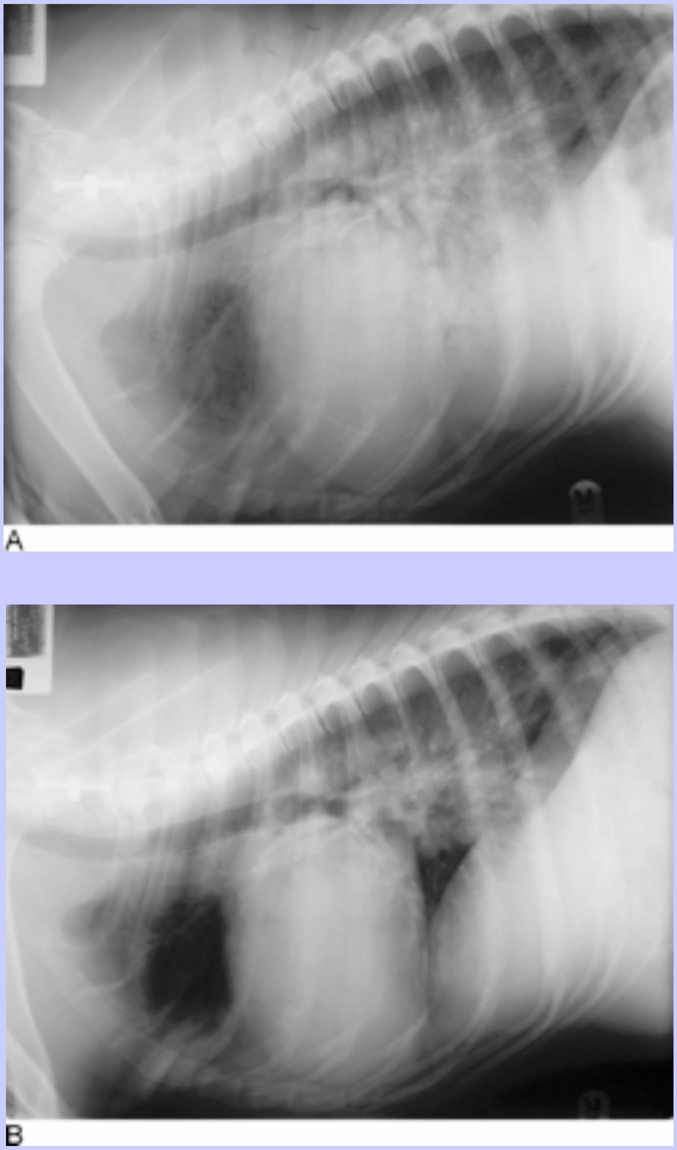

Figure 21-2 Lateral radiograph of a cat with congestive heart failure. Note the enlarged cardiac silhouette and widespread patchy alveolar infiltrates.

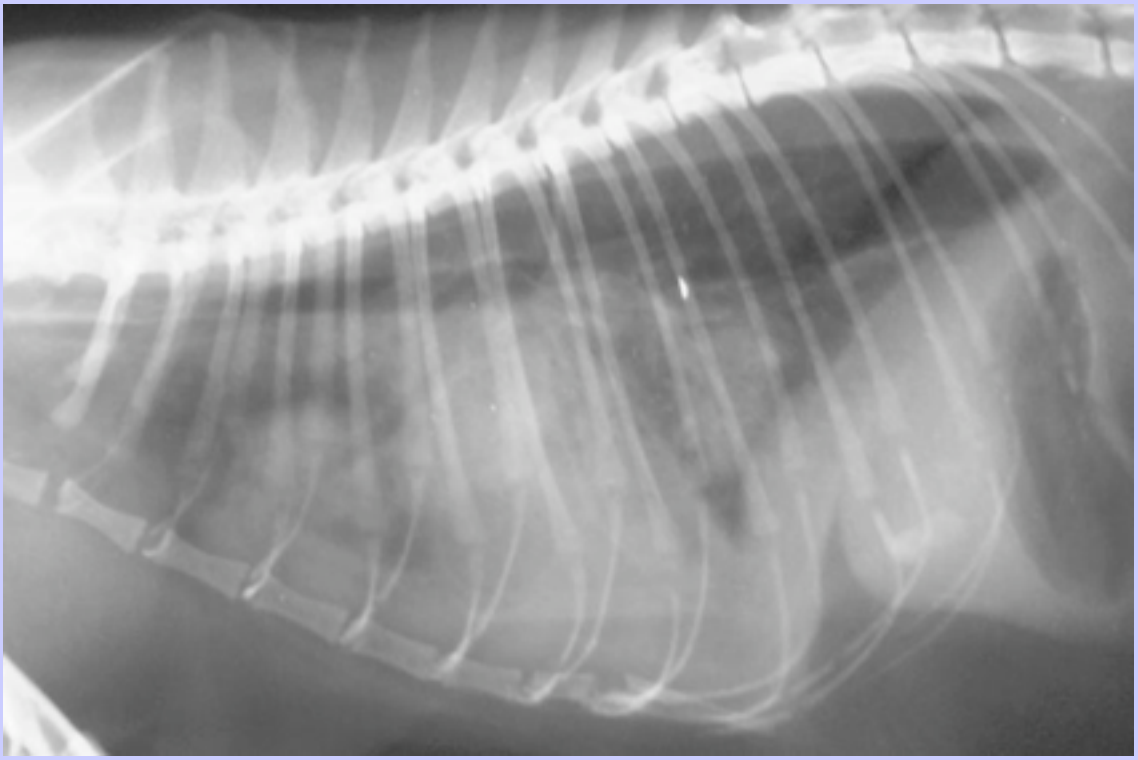

Body position can also be important. Sternal recumbency aids with gas exchange, probably by reducing atelectasis. In animals with unilateral disease it is preferable initially to place the patient with the affected lung lobe down if the animal will not tolerate sternal recumbency. In some patients placing the more severely affected lung uppermost can precipitate severe hypoxemia.

21.6.2 Medical Therapy

The key to managing cardiogenic pulmonary edema is the reduction of pulmonary capillary pressures by reducing preload. Promotion of forward flow is also important in patients with large regurgitant fractions. The drugs used can be split into two groups, diuretics and vasodilators. Furosemide is the most frequently used diuretic and is particularly useful because of its rapid onset of action (see Chapter 180, Diuretics). Excessive use can cause hypovolemia as a result of an excessive reduction in preload. Typically furosemide is used to effect at dosages of 1 to 4 mg/kg IV or IM (up to 8 mg/kg in the dog) as needed (up to every 30 to 60 minutes) until the respiratory status is stabilized and evidence of pulmonary congestion is improved. The frequency and dosage are subsequently reduced. In very severe cases this may be hourly initially, although in most cases every 3 to 4 hours is adequate.

There is evidence that furosemide acts as a pulmonary vasodilator and bronchodilator, and causes an increase in COP secondary to hemoconcentration. These changes, in combination with the resultant reduction in pulmonary hydrostatic capillary pressure, may assist with alveolar fluid reabsorption.[13-15] Concerns have been expressed about reduced mucociliary clearance due to excessive dehydration of secretions, but in life-threatening situations this is not an immediate concern. Constant rate infusions (CRIs) are more effective in promoting fluid excretion than intermittent boluses in humans with congestive heart failure,[16] and experimental studies in healthy greyhounds have shown better diuresis with a CRI than with bolus injection.[17] Nevertheless, patients with severe pulmonary edema need a more rapid effect; bolus therapy is recommended.

Vasodilators are less commonly used but can prove beneficial in many cases. A number of drugs are available, but in acute situations the most useful group are the nitric oxide donors, which include nitroprusside and glycerol trinitrate (nitroglycerin). These drugs act rapidly to cause vasodilation, thereby reducing preload and afterload (see Chapters 178 and 179, Antihypertensives and Nitroglycerin, respectively). Nitroprusside is a balanced vasodilator that may cause hypotension due to arteriolar dilation. It has a short half-life and is therefore administered intraveneously as a CRI. Nitroprusside should be used with extreme caution in hypotensive patients because the general goal with therapy is to reduce the mean arterial pressure (or systolic blood pressure) by 10 to 15 mm Hg from the baseline pressure. In hypotensive patients, nitroprusside should not be used without a positive inotrope; however, there is evidence to suggest that even in patients with severe left ventricular dysfunction, nitroprusside is associated with beneficial cardiopulmonary effects.[18] Animals should be monitored carefully for clinical signs of hypotension, ideally with invasive blood pressure monitoring, although this may not be possible in all cases. In addition to its hypotensive effects, nitroprusside may cause a reduction in hypoxic pulmonary vasoconstriction, thereby increasing ventilation-perfusion mismatch. A reflex tachycardia is also commonly seen. Because nitroglycerin is mainly a venodilator, minimal hypotension or tachycardia is seen with this drug, so it is safe in most cases. Nitroglycerin is available as a paste, which is applied to hairless areas such as the axilla or ear flap. Empiric doses of ¼ inch in cats and ¼ to 2 inches per dog are recommended and can be repeated every 6 to 8 hours. Tachyphylaxis occurs rapidly and the drug may have reduced efficacy after as little as 24 hours. Care should be taken with application: gloves should be worn and the ointment should be rubbed in well. Headaches are a common side effect in people.

Other drugs that have been of benefit in experimental models include β_2-agonists, such as terbutaline.[19,20] These act via cyclic adenosine monophosphate (cAMP)[19] to increase fluid reabsorption from the alveolar space. Caution should be exercised when using β_2-agonists in cats with pulmonary edema, however, because these drugs may worsen cardiac function in patients with hypertrophic, restrictive, or hyperthyroid-induced cardiomyopathy. Phosphodiesterase inhibitors such as pimobendan also increase cAMP levels and these drugs may also prove useful in the management of pulmonary edema, although scientific data are lacking. Their cardiovascular effects, vasodilation and positive inotropy, may prove beneficial for the treatment of cardiogenic pulmonary edema.

Because hydrostatic pressure influences both increased hydrostatic pressure and increased permeability edema, pressure modification is indicated in all cases of pulmonary edema. Most patients with noncardiogenic edema do not respond as well as those with cardiogenic edema to medical interventions to decrease hydrostatic pressure (Figure 21-1, *B*). However, some improvement may be seen, and in most cases these drugs are safe when used with caution. Large-scale clinical studies are lacking, however, and most experimental data point toward therapeutics that modulate hydrostatic pressure for the management of noncardiogenic edema.

21.6.3 Fluid Therapy

Because the hydrostatic pressure gradient is so important in the pathogenesis of pulmonary edema, it seems prudent to restrict fluid administration to these patients. In all cases, the decision to restrict intravenous fluid administration should be balanced against the risks of compromised renal function and multiple organ failure. The pulmonary, microvascular barrier is relatively permeable to protein[21] and therefore natural or synthetic colloids such as albumin or hetastarch, respectively, may equilibrate rapidly across the endothelial space. If there is increased permeability such that most of these molecules may extravasate, colloid therapy may lead to worsening of the pulmonary edema, which will resolve slowly due to slow clearance of macromolecules from the alveolar space. Because there is no way of clinically determining the permeability, one has to rely on response to therapy. A trial dose of colloid may be administered cautiously in animals suspected of having increased vascular permeability.

21.7 PROGNOSIS

Due to the diversity of causes of pulmonary edema, general statements about prognosis cannot be made. Usually when there is no serious underlying disease, the prognosis for resolution is good. However, when there is evidence of multisystemic disease and severe increased permeability edema, the prognosis is guarded at best. The prognosis for cardiogenic edema is related to the severity of the underlying disease; some dogs with mitral valve disease may survive for years after diagnosis of failure, whereas the prognosis for dogs with dilated cardiomyopathy may be poor. In cats, the prognosis with congestive heart failure is less favorable and few of these animals live beyond 1 to 1½ years from the time of diagnosis. Those that respond well to initial treatment with furosemide and vasodilators seem to have a slightly better prognosis than those whose disease is difficult to control.

The outcome in animals that require PPV is generally poor, although financial concerns are often involved in many of these decisions. Nevertheless, survival rates are low.[22,23]

22 Chapter 22 Pneumonia

Etienne Côté, DVM, DACVIM (Cardiology)

Deborah C. Silverstein, DVM, DACVECC

22.1 KEY POINTS

- Pneumonia is an inflammation of the lung parenchyma that is often secondary to an underlying disorder in dogs and cats.
- Complete blood count results are neither sensitive nor specific, and the white blood cell count cannot be used reliably to confirm or rule out pneumonia.
- Many patients with bacterial pneumonia (dogs: 53%; cats: 74%) are afebrile. Coughing is usually absent in cats with pneumonia (92% of cases do not cough), but dyspnea is common (49%).
- Obtaining three-view thoracic radiographs, avoiding overexposure or underexposure, and carefully examining all lung fields on all thoracic radiographs are important measures for detecting pneumonia radiographically.
- An endotracheal or transtracheal wash with culture and sensitivity testing is often useful for determining the etiologic agent(s).
- Long-term antibiotic therapy is indicated for infectious pneumonia.
- Appropriate treatment and supportive care will maximize success. Severe sepsis and multiple organ dysfunction are poor prognostic indicators.

22.2 INTRODUCTION

Pneumonia is an inflammation of the lung parenchyma.[1,2] It occurs chiefly in response to inhalation of infectious agents (bacteria, viruses, fungi, protozoa, parasites) either as a primary disorder or secondary to a predisposing disturbance in the lungs. Less common causes of pneumonia include idiopathic eosinophilic pneumonia, secondary to inhaled allergens or a hematogenous infection, and endogenous lipid infiltration.[1] Pneumonia that occurs as a result of inhalation of foreign substances or materials is described in Chapter 23, Aspiration Pneumonitis and Pneumonia. The focus of this chapter is infectious pneumonia.

22.3 CLINICAL PRESENTATION

22.3.1 Initial Evaluation

Critically ill animals with pneumonia require rapid identification and treatment. A soft cough, mild dyspnea, and nonspecific signs of lethargy and inappetence may be noted as the earliest manifestations in some dogs and cats. However, many patients with pneumonia show no respiratory signs (e.g., 36% of cats).[3] The spectrum of clinical signs ranges from none (the diagnosis is made incidentally on thoracic radiographs) to life-threatening dyspnea and impending cardiorespiratory arrest. Therefore pneumonia may be suspected at one of several points in the evolution of a case: when clinical signs are noted, when predisposing causes are identified, or when characteristic findings are apparent on thoracic radiographs.

22.3.2 History

Elements of a patient's history that should raise the clinician's index of suspicion for pneumonia are numerous. Broadly, historical clues include respiratory signs (cough, increased respiratory effort, purulent nasal discharge), systemic signs including lethargy and inappetence, and signs associated with predisposing or underlying causes (Table 22-1). Approximately 36% to 57% of dogs with pneumonia are found to have a concurrent predisposing disorder.[4,5] Geographic location and travel history may reveal important details to consider in cases suspected of having fungal or parasitic disease.

22.3.3 Physical Examination

Physical abnormalities in patients with pneumonia often are nonspecific beyond respiratory signs.[1,5] Demeanor may be normal, with some patients showing a bright and alert disposition despite having pneumonia, or abnormal, with lethargy and depression predominating. Inappetence, weight loss, and signs attributable to an underlying disorder are common. Respiratory signs are rarely sensitive or specific. For example, dyspnea occurs with moderate or severe pneumonia, but is absent in mild cases. The cough of a patient with pneumonia may be moist or dry, and tracheal pressure may elicit a cough in some pneumonia patients and not in others. Most dogs with pneumonia (>90%) do have abnormally loud breath sounds, crackles, or wheezes on pulmonary auscultation[6]; however, these findings are nonspecific and do not allow differentiation from other causes of dyspnea (pulmonary edema, pulmonary hemorrhage). In contrast to dogs (47%),[6] cats with infectious pneumonia rarely cough (8%).[3] Mucopurulent nasal discharge may or may not be present in either species. Fever is a highly inconsistent finding in both species, and pneumonia can be neither confirmed nor ruled out on the basis of body temperature. Animals with fungal, viral, parasitic, or protozoal pneumonia may have multisystem involvement (e.g., bone, intestinal tract, lymph nodes). Overall, pneumonia is suspected in an animal when one or more compatible signs are noted in the history and physical examination, especially in a patient with a predisposing condition (see Table 22-1).

22.4 DIAGNOSTIC TESTING

Evaluation of patients suspected of having pneumonia is centered on diagnostic imaging and sampling respiratory

secretions. Thoracic radiography remains the routine imaging test of choice. The characteristic finding is alveolar opacification. Air bronchograms, silhouetting of lung(s) with the heart, and consolidation, with or without interstitial patterns, are typically present with an asymmetric distribution (Figure 22-1). The alveolar pattern of pneumonia often is visualized more clearly in one radiographic view than in another. For example, a left lateral thoracic radiograph will allow optimal visualization of the right lung fields. Therefore, three-view thoracic radiography (a dorsoventral or ventrodorsal projection and both lateral projections) is recommended in all pneumonia suspects, in order to minimize false-negative results and underdiagnosis. Computed tomography may also be beneficial in animals with complicated pulmonary disease or with those suspected of having foreign body–associated pneumonia, to assist in the approach to exploratory thoracostomy or lung biopsy.

Table 22-1 Factors Predisposing to or Associated With Pneumonia in Dogs and Cats

Factor	Comment
Impaired patient mobility	
Unconsciousness (natural, or via general anesthesia)*	Attenuation, loss of reflexes (gag, cough)
Mechanical ventilation	Natural defense mechanisms of the upper airway bypassed by intubation and mechanical ventilation; normal movement and coughing prevented Regurgitation or aspiration of oropharyngeal bacteria may contribute
Weakness, paresis, paralysis*	—
Upper airway disorders	
Laryngeal mass or foreign body*	Successful laryngeal examination possible using only a bright light source (Finnoff transilluminator) and without sedation in patients with laryngeal disorders, especially laryngeal paralysis
Laryngeal paralysis*	
Laryngeal or pharyngeal surgery*	Aspiration pneumonia (without overt clinical signs)—a common postoperative complication in animals with laryngeal paralysis (see Chapter 23, Aspiration Pneumonitis and Pneumonia)
Regurgitation syndromes	
Esophageal motility disorder*	Dynamic esophagram (barium swallow) required for diagnosis Important if other tests do not identify an underlying cause for pneumonia
Esophageal obstruction*	Foreign body sometimes visible on thoracic radiographs Caution necessary with barium swallow procedures (barium aspiration risk)
Megaesophagus*	Often identifiable concurrently on thoracic radiographs
Other factors	
Bronchoesophageal fistula	Usually acquired via trauma (e.g., perforating esophageal foreign body)
Cleft palate	Congenital abnormality that may cause ingesta to enter nasal cavity with subsequent aspiration
Crowded or unclean housing	Persistence and concentration of infectious organisms in environment contributors to risk
Forceful bottle feeding*	Aspiration possible when care provider squeezes the nursing bottle during suckling, or if hole in nipple is too large
Gastric intubation*	—
Immune compromise	Specific conditions: anticancer or immunosuppressive chemotherapy; concurrent illness including feline leukemia, feline infectious peritonitis, diabetes mellitus, or hyperadrenocorticism; primary ciliary dyskinesia; immunoglobulin or leukocyte defects or deficiencies

Inadequate vaccination	Viral, bacterial, or parasitic infection with secondary opportunistic bacterial pneumonia
Induced vomiting*	—
Seizures*	Must differentiate pneumonia radiographically from noncardiogenic pulmonary edema
Tracheostomy*	—

Ancillary testing including a complete blood count (CBC), serum biochemistry profile, and urinalysis is important in all pneumonia suspects, but rarely contributes directly to the diagnosis. Although many animals with pneumonia have unremarkable CBC results, some of the most common CBC findings include leukocytosis characterized by neutrophilia, left shift, and monocytosis.[6] Animals that are severely affected may be leukopenic, and dogs with idiopathic eosinophilic pneumonia may have a peripheral eosinophilia. Nonspecific biochemical abnormalities may be present, most commonly hypoalbuminemia secondary to inflammation or vascular leak syndromes.

A coagulation profile often is helpful in assessing critically ill patients that may have a bleeding disorder or pulmonary hemorrhage. Additional testing for hypercoagulability (thromboelastography, D-dimer, fibrin degradation product, and antithrombin III levels) may be indicated in some patients, particularly if pulmonary thromboembolism is suspected.

Figure 22-1 **A,** Thoracic radiograph of a dog with pneumonia, dorsoventral projection. Alveolar infiltrates are seen most clearly in the central region of the right lung: the right middle lung lobe and adjacent regions of the right caudal lung lobe. **B,** Thoracic radiograph of the same dog, right lateral recumbent projection. The infiltrated lung is in the dependent region and not clearly visible; pneumonia could be falsely ruled out if this projection was the only one taken of this dog. Some gas is present in the esophagus *(asterisk)* and a prominent skin fold *(arrows)* should not be mistaken for a pleural fissure line. **C,** Thoracic radiograph of the same dog, left lateral recumbent projection. The infiltrates within the right middle lung lobe are clearly seen (note prominent air bronchograms), as is marked gaseous and soft tissue and fluid distention of the esophagus. Diagnosis: evidence of pneumonia and concurrent megaesophagus, suggesting aspiration as the inciting mechanism.

Confirmation of bacterial lung infection requires demonstration of inflammation and infection in the lower respiratory tract. This information usually is obtained using transtracheal wash (TTW) or endotracheal wash (ETW), both of which can yield specimens for cytologic evaluation and bacterial or fungal culture and sensitivity. These tests are highly recommended when possible. In all cases, a complete evaluation first must be made to identify other conditions, such as pulmonary hemorrhage (typically caused by anticoagulant ingestion) or cardiogenic pulmonary edema, that would contraindicate such testing but could otherwise mimic pneumonia clinically.

Transcutaneous fine-needle aspiration of lung tissue in suspected cases of infectious pneumonia may be a low-yield, high-risk procedure, especially in dogs with diffuse pulmonary disease; a lower risk is expected if the patient is kept in lateral recumbency, aspirated side down, for 30 to 60 minutes post procedure (15 to 20 minutes if anesthetized).[9] In cats with unexplained pulmonary parenchymal disease, fine-needle aspiration may have better yield than from ETW.[7]

Additional diagnostic tests that may be indicated include fungal titers, serology for heartworm disease and toxoplasmosis, viral testing, and fecal examination (flotation, Baermann, and sedimentation) as dictated by each case.

Blood gas evaluation (and pulse oximetry) can be valuable in patients with pneumonia causing dyspnea or respiratory distress, especially at baseline and for subsequent monitoring.[1] An arterial blood sample is necessary for accurately measuring partial pressure of oxygen (PaO_2) and oxygen saturation (normal ≥80 mm Hg and ≥95%, respectively, when breathing room air at sea level). If hypoxemia is present, oxygen supplementation should be considered[1] (see Chapters 19 and 208, Oxygen Therapy and Blood Gas and Oximetry Monitoring, respectively). Abnormalities in dogs with pneumonia include hypoxemia, decreased oxygen saturation, and increased alveolar-arterial oxygen gradient. Typically, hypercapnia is not present.[8]

* Indicates predisposition to aspiration pneumonia.

22.5 PATHOPHYSIOLOGY

22.5.1 Mechanism

Infectious pneumonia represents an imbalance between natural defenses (upper airway mechanisms, airway barriers, humoral and cell-mediated immunity) and infectious agents. Pneumonia is characterized by bronchioalveolar inflammation. The bronchioalveolar junction is a major site of small particle (0.5 to 3 μm) deposition and is especially vulnerable to damage. Although large particles are cleared by the mucociliary apparatus, coughing, and the nasopharynx, particles smaller than 3 μm are deposited in the alveoli and bypass the upper respiratory tract defenses.[1] When large numbers of organisms or those with high virulence enter the lower airways, surfactant and alveolar macrophages are overwhelmed. An inflammatory response must ensue to effectively remove the offending organisms. Complex interactions between the cell-mediated and humoral immune systems, in conjunction with cytokines and chemokines, take place in an attempt to clear the offending agents.

Organisms and inflammatory exudates within the airways may lead to hypoxemia through several mechanisms. These include ventilation-perfusion mismatch, intrapulmonary shunting, and impaired diffusion. Severe or chronic pneumonia can lead to destruction of the alveolar walls, damage to type II pneumocytes, and increases in pulmonary vascular permeability, all of which contribute to acute lung injury and acute respiratory distress syndrome (see Chapter 24, Acute Lung Injury and Acute Respiratory Distress Syndrome). If the infection and inflammation are not restricted to the lungs, a systemic inflammatory response syndrome, sepsis, and multiple organ dysfunction can occur (see Chapters 11 and 106, Systemic Inflammatory Response Syndrome and Sepsis, respectively). Animals with pneumonia may also develop bronchiectasis, pyothorax, polyarthritis, or glomerulonephritis secondary to antigen-antibody complex deposition.

22.5.2 Causes

Predisposing factors and disorders associated with pneumonia are listed in Table 22-1. Organisms commonly isolated via TTW from dogs with bacterial pneumonia include the gram-negative bacilli *Pasteurella* spp (22% to 28% of dogs with bacterial pneumonia) and Enterobacteriaceae such as *E. coli* (17% to 46%), and gram-positive cocci such as *Staphylococcus* spp (10% to 16%) and *Streptococcus* spp (14% to 21%).[4,5,8] Anaerobic bacteria are isolated in 10% to 21% of cases,[4,8] and their presence warrants suspicion for pulmonary abscess formation. *Mycoplasma* spp commonly are detected, either as sole organisms (8%) or as coinfections with other bacteria in a large proportion of dogs with bacterial pneumonia (62%).[5,9] Often, bacterial cultures from patients with pneumonia reveal multiple species of bacteria (e.g., 43%,[4] 47%,[8] and 74% [including *Mycoplasma*][5] of dogs and 38% of cats[3]). Fungal, viral, parasitic, and protozoal pneumonia may also occur secondary to predisposing factors as listed in Table 22-1.

22.6 TREATMENT

Animals that are breathing comfortably and have mild pneumonia as an incidental finding should be treated with appropriate long-term oral therapy and supportive care, including management of underlying or predisposing factors. Immunocompromised animals should be monitored frequently for worsening of clinical signs.

Oxygen supplementation should be provided to dyspneic and hypoxemic animals. Possible methods include flow-by delivery, intranasal cannula, oxygen cages, oxygen hoods, and oxygen tents, based on facilities and patient characteristics (see Chapter 19, Oxygen Therapy). The oxygen should be humidified and a sensor used for monitoring the inspired oxygen concentration. The approach to oxygen supplementation must be balanced against two important potential drawbacks: hyperthermia, especially for large breed or thick-coated dogs in an oxygen cage (even with air cooling settings) and reduced monitoring and handling due to the apparatus (oxygen cage, Elizabethan [E] collar). Intranasal oxygen should be delivered at a flow rate of 50 to 100 ml/kg/min. The lowest concentration of inspired oxygen that alleviates respiratory distress should be used. Long-term oxygen supplementation (>24 to 48 hours) should not exceed a concentration of 60% in order to reduce the risk of oxygen toxicity, which increases capillary permeability and denudes the alveolar epithelium.

Endotracheal intubation and positive-pressure ventilation (see Chapter 213, Basic Mechanical Ventilation) are indicated if severe dyspnea leads to impending respiratory fatigue, if severe hypoxemia (partial pressure of arterial oxygen [PaO_2] <60 mm Hg) is present, or if ventilatory failure (partial pressure of carbon dioxide ($PaCO_2$) >60 mm Hg) occurs. Fentanyl, pentobarbital, or propofol is typically chosen to immobilize a patient during ventilation (Table 22-2).

Empiric antibiotic therapy is often necessary initially, given the multiday turnaround time for bacterial culturing, yet misuse of antibacterial drugs may be detrimental. Samples that can be used for bacterial culture (ETW or TTW fluid, sputum, blood, urine) should be obtained as soon as possible. Antibiotic therapy should be initiated pending culture and sensitivity results (see Table 22-2). Empiric coverage should initially address gram-positive, gram-negative, and anaerobic bacteria. Animals with moderate to severe pneumonia should receive parenteral therapy.

For all these reasons, a common first choice approach is parenteral ampicillin and enrofloxacin, continued orally if bacterial culture results are positive and show susceptibility to these drugs. Preventive use of antibiotics (e.g., patient hit by a car, has pulmonary contusions; antibiotics given to prevent infection of contusions) is unsupported, helps to select resistant bacteria, confers an unjustified sense of therapeutic effect, and is not recommended. Overall, antibiotics that penetrate lung tissue are preferable (such as chloramphenicol, doxycycline, enrofloxacin, trimethoprim-sulfa, and clindamycin), although pulmonary inflammation may allow additional antibiotics to 94
penetrate during disease states. Long-term oral therapy (6 weeks to 6 months) may be necessary following 95
stabilization of the patient and marked improvement in oxygenating ability and radiographic infiltrates, but the exact duration depends on many elements, including underlying cause, local immunity, nature of pathogenic organisms, and client factors.

Table 22-2 Common Medications Used for Pneumonia

Drug	Effect or Spectrum	Dosage	Formulation
Antibacterial Agents: Injectable			
Amikacin (Amiglyde-V)	G–	15 mg/kg IV q24h provided renal function and hydration are sufficient	50 mg/ml
Ampicillin (many names)	G+, some G– (certain *E. coli* and *Klebsiella* strains), some anaerobes *(Clostridia)*	22 mg/kg IV q6-8h	1, 3, 6 mg vials
Cefoxitin (Mefoxin)	Some G+, some G–, some anaerobes	30 mg/kg IV q6-8h	1, 2, 10 g vials
Cephalothin, cefazolin (many)	G+	22 mg/kg IV q6-8h	1, 5, 10, 20 g vials
Enrofloxacin (Baytril)	G–, *Mycoplasma*	5 to 10 mg/kg, dilute 1:1 in saline and give IV q12h or 10 to 20 mg/kg IV q24h (dog) or as maximum 5 mg/kg q24h (cat)	22.7 mg/ml IV use is off-label
Gentamicin (Gentisin)	G–	6 to 8 mg/kg IV q24h provided hydration and renal function are sufficient	50 mg/ml
Metronidazole (Flagyl)	Anaerobes	10 to 15 mg/kg slow IV infusion q12h	500 mg/100 ml
Ticarcillin-clavulanate (Timentin)	G+, G–, anaerobes	40 to 50 mg/kg slow IV infusion q6h	3 g vial
Antibacterial Agents: Oral			
Azithromycin (Zithromax)	G+, G–, *Mycoplasma*	5 to 10 mg/kg IV or PO q24h	250, 600 mg tablets; 20 or 40 mg/ml oral solution
Clindamycin (Antirobe)	G+, *Mycoplasma, Toxoplasma,* anaerobes	5 to 10 mg/kg PO q8-12h	25, 75, 150 mg capsules; 25 mg/ml oral solution
Metronidazole (Flagyl)	Anaerobes	10 to 15 mg/kg PO q12h	250 mg tablets
Trimethoprim-sulfa (Ditrim, Tribrissen)	Some G+, some G–	15 mg/kg IV or PO q12h	30, 120, 480, 960 mg tablets
Sedatives and Anesthetics			
Fentanyl	For positive-pressure ventilation	5 µg/kg IV boluses to effect (maximum 50 µg/kg), then 5 to 7 µg/kg/hr IV (can add diazepam)	50 µg/ml (= 0.05 mg/ml)

Pentobarbital	For positive-pressure ventilation	2 mg/kg IV boluses to effect (up to 12 mg/kg) q4-6h or as needed to maintain sedation; 0.1 to 1 mg/kg/hr IV	50 mg/ml
Propofol (Diprivan, Rapinovet)	For positive-pressure ventilation	2 to 8 mg/mg IV bolus to effect, then 0.1 to 0.4 mg/kg/min IV	10 mg/ml
Diazepam	For use with anesthetics for positive-pressure ventilation	0.25 to 0.5 mg/kg IV, then 0.1 to 1.0 mg/kg/hr	5 mg/ml
Additional Therapeutic Agents			
Aminophylline	Bronchodilator and respiratory stimulant	5 mg/kg IV q8h (dilute and give over ≥30 minutes; up to 10 mg/kg in dog)	25 mg/ml
Caffeine	Bronchodilator, respiratory stimulant	5 to 10 mg/kg IV q6-8h (dilute and give over ≥30 minutes)	121 mg/ml
N-Acetylcysteine	Mucolytic	70 mg/kg IV q6h (dilute and give over ≥30 minutes)	20% solution
Terbutaline	Bronchodilator	0.01 mg/kg SC/IM/IV q4-6h	1 mg/ml

G+, Gram positive; *G−,* gram negative; *IM,* intramuscular; *IV,* intravenous; *PO,* per os; *SC,* subcutaneous.

Animals diagnosed with idiopathic eosinophilic pneumonia or sterile inflammatory pneumonia should be treated with glucocorticoids and removal of potential allergens.

The use of bronchodilators in animals with pneumonia is controversial, but may be helpful in select cases by 95
increasing airflow and mucokinetics via improving ciliary activity and increasing the serous nature of respiratory 96
secretions. However, their use may suppress the cough reflex, worsen ventilation-perfusion mismatch, and allow exudates within the affected lung to spread to unaffected portions of the lung. β_2-Agonists may also have a direct antiinflammatory effect by decreasing mucosal edema and downregulating cytokine release. Methylxanthine bronchodilators may also increase mucociliary transport speed, inhibit degranulation of mast cells, and decrease microvascular permeability and leak. Aminophylline is a respiratory stimulant that helps to increase the strength of diaphragmatic contractility to assist animals with ventilatory fatigue. Intravenous caffeine has been used in place of aminophylline, although its benefit in veterinary medicine remains unproven.

Mucolytic therapy is used commonly in veterinary patients, but scientific proof of its benefit is lacking. N-acetylcysteine (NAC) leads to a breakdown of the disulfide bonds in thick airway mucus and is also a precursor to glutathione, a free radical scavenger. Aerosolized NAC may irritate the airways and cause a reflex bronchoconstriction, so it is not recommended. Dilute intravenous NAC therapy has been used in small animals, but caution must be exercised.

Nebulization using 0.9% sodium chloride is an effective means of increasing particulate saline droplets in the inhaled air stream, to liquify thick lower airway secretions in order to hydrate the mucociliary system and enhance productive clearing. Vaporizers and humidifiers are not effective because the particle size generated with these methods is greater than 3 μm.

Coupage of the chest refers to a rapid series of sharp percussions of the patient's chest using cupped hands and closed fingers. Compression of air between the cupped hand and the chest wall creates vibrational energy that is transmitted to the underlying lungs to loosen deep secretions and consolidated areas of the lung and stimulate the cough reflex. Although its efficacy is contested in human medicine (see Chapter 23, Aspiration Pneumonitis and Pneumonia), coupage should be performed for several minutes over affected areas of the lung in small animal patients. Nebulization with or without coupage are performed every 4 to 6 hours. Coupage is unnecessary in animals that are coughing spontaneously and frequently, and may be contraindicated in animals that have a coagulopathy, have pain in the chest region, or are fractious.

Because atelectasis can exacerbate respiratory insufficiency, recumbent patients with pneumonia should be turned every 1 to 2 hours and supported in an upright position at least twice daily. Short walks should be encouraged as well.

22.7 ADDITIONAL MANAGEMENT CONSIDERATIONS

22.7.1 Contagion and Zoonosis

In most cases pneumonia-causing bacteria, as secondary invaders, are not contagious. However, contagion of the underlying process is possible by aerosol in dogs (canine distemper in the mucosal phase but not neurologic phase, infectious tracheobronchitis) and cats (feline herpesvirus, possibly calicivirus). Systemic mycoses are not contagious by aerosol from one animal to another. Zoonotic concerns are minimal if the human is not immunocompromised, although *Mycobacteria* spp in dogs and cats, and the agents of plague *(Yersinia pestis)* and tularemia *(Francisella tularensis)* in cats, have zoonotic potential for immunocompetent human hosts.

22.8 MONITORING

The cornerstones of monitoring are observation and diagnostic testing. The two must occur jointly, and in the busy critical care environment it is essential to avoid managing and monitoring the patient's results rather than the actual patient.

An attentive clinician can identify subtle changes in alertness, demeanor, appetite, respiratory effort, and other parameters that are not easily quantified but are highly valuable in identifying change, be it response to treatment or deterioration. More obvious changes in respiratory rate and effort, nasal flaring, cheek puffing, and orthopnea should be addressed immediately.

The interval between measurements of arterial blood gases and of pulse oximetry varies from hours to days, depending on initial severity and clinical progression. Serial pulse oximetry measurements performed every 1 to 6 hours may reveal overall trends in arterial oxygen saturation that forewarn of deterioration or improvement. However, single measurements should be interpreted with caution because erroneous readings may occur (see Chapter 208, Blood Gas and Oximetry Monitoring).

Thoracic radiographs may be used for monitoring progression of pulmonary disease, but for patients that are stable or improving, radiographic findings are unlikely to change during the first few days of treatment. Therefore retaking thoracic radiographs of a patient with pneumonia is not indicated during the first 3 to 5 days, except in a patient whose condition is deteriorating or in which unexpected new clinical signs emerge. It is normal for patients with severe pneumonia, especially puppies with *Bordetella* pneumonia, to look clinically and radiographically worse during the first few days of treatment.

22.9 PROGNOSIS AND OUTCOME

Antibiotic response is observed in most dogs (69% to 88%) when the pneumonia is managed appropriately.[5,6] Long-term outcome depends on the ability to resolve the inciting or associated cause, with cure expected when reversal of the trigger is possible (e.g., surgical foreign body removal) versus long-term management and frequent relapses expected when the predisposing cause lingers (e.g., idiopathic megaesophagus). Recurrent bouts of bacterial pneumonia should prompt the clinician to rule out bronchiectasis, an abscess or foreign body, structural changes, or inappropriate antibiotic therapy (e.g., discontinuing therapy prematurely or antibiotic resistance) that may allow a nidus of infection to persist within the lungs. Anecdotal reports and observations suggest that certain bacteria, certain underlying disorders, and empiric antibiotic treatment (instead of management based on culture and sensitivity) are associated with a worse prognosis.[5,6] Subjectively, initial severity of clinical signs and response during intensive treatment also offer prognostic information. However, a comprehensive assessment of specific, evidence-based prognostic parameters is lacking for small animal bacterial pneumonia. Fungal, viral, parasitic, and protozoal pneumonias vary in their response to management, often depending on pathogenicity of the offending organism, degree of systemic involvement, and underlying risk factors. 96 97

23 Chapter 23 Aspiration Pneumonitis and Pneumonia

Robert Goggs, BVSc, MRCVS

Amanda K. Boag, VetMB, DACVIM, DACVECC, MRCVS

23.1 KEY POINTS

- Aspiration pneumonitis has a biphasic pathogenesis. Initial events are caused by direct chemical injury. This is followed by localized inflammatory mediator cascades producing neutrophil chemotaxis, sequestration, and subsequent increased permeability edema.
- Aspiration pneumonia is an infectious process caused by either aspiration of contaminated material or by bacterial colonization of damaged lungs subsequent to a sterile aspiration episode. Acid-induced lung injury enhances bacterial adherence to and reduces bacterial clearance from the lungs.
- Diagnosis is typically based on history, physical examination, and radiography. The severity of respiratory compromise is best monitored by arterial blood gas analysis.
- Management is principally supportive, consisting of airway management, cardiovascular support, oxygen therapy, and respiratory physiotherapy.
- Antimicrobial drug therapy should be directed by cytologic testing, Gram stain, and bacterial culture and sensitivity on samples collected by tracheal wash (TW) or bronchoalveolar lavage (BAL).
- The incidence of aspiration pneumonia can be reduced by recognizing the risk factors and attempting to control or minimize them.

23.2 INTRODUCTION

Aspiration pneumonitis and pneumonia frequently coexist in veterinary patients and may cause significant morbidity and mortality. The pathophysiology of both conditions shares some common features, namely the initiation of a localized inflammatory cascade with resultant impairment of respiratory function. Both conditions may incite development of acute respiratory distress syndrome (ARDS) or the systemic inflammatory response syndrome (SIRS).[1] A number of risk factors exist for aspiration of gastric contents (Box 23-1). Emergency clinicians should be aware of these risk factors and have an understanding of the subsequent pathogenesis of pulmonary damage to aid in prevention and early recognition in order to enable optimal patient monitoring and treatment.

23.3 ASPIRATION PNEUMONITIS

23.3.1 Etiology

Aspiration pneumonitis is defined as acute lung injury due to inhalation of chemical irritants such as acidic stomach contents, hydrocarbons, or water (saltwater or fresh water near-drowning). The most common cause of aspiration pneumonitis is inhalation of gastric contents, and this will be the focus of the ensuing discussion.

Inhalation of small quantities of oropharyngeal material contaminated by bacteria likely occurs in normal animals, but bacterial colonization of the airway mucosa is prevented by rapid removal of this material by mucociliary clearance. In human patients with decreased levels of consciousness secondary to head trauma, seizures, sedation, or anesthesia the incidence of aspiration is greatly increased.[2] A landmark study in 1946 reported acute respiratory failure in 66 women due to aspiration of stomach contents during anesthesia for obstetric procedures and suggested causal mechanisms for the associated pulmonary injury.[3] The study also investigated the effects of a variety of solutions on the lungs of rabbits and concluded that aspirate acidity was the key factor in determining the severity of injury.

23.3.1.1

Box 23-1 Disorders and Conditions Predisposing to Aspiration of Gastric Contents

23.3.1.1.1

Large Volumes of Intragastric Food or Fluid

Delayed gastric emptying

Gastric outflow obstruction

Pain medication or opioid administration

Gastrointestinal motility disorders

Ileus

Pregnancy

Obesity

Recent meal

Overfeeding by the enteral route

23.3.1.1.2

Esophageal Disorders

Esophageal obstruction

Esophageal dysmotility

Megaesophagus

Myasthenia gravis

Esophageal reflux

Lower esophageal sphincter impairment

Drug administration

Nasogastric tube placement

23.3.1.1.3 Impaired Consciousness

Sedation, general anesthesia

Head trauma

Seizures

Encephalopathy

Coma

23.3.1.1.4 Impaired Airway Function

Laryngeal or pharyngeal dysfunction or surgery

Airway trauma

23.3.1.1.5 Other

Tracheostomy

Gastric intubation

Cleft palate

Weakness, paresis, paralysis

Factors affecting severity have since been further described. The magnitude of lung injury depends on the pH, volume, osmolality, and presence of nonsterile particulate matter in the aspirate.[4,5] Severe histologic damage is caused by aspirates more acidic than pH 1.5, but little or no damage is caused by those with pH greater than 2.4.[6] Particulate matter causes pulmonary injury by airway obstruction, prolongation of the inflammatory response, and by acting as a source of and nidus for bacterial infection.[6,7] Aspiration of gastric contents containing particulate matter may cause severe pulmonary injury even if the pH is above 2.5.[8,9]

23.4 ASPIRATION PNEUMONIA

23.4.1 Etiology

Aspiration pneumonia refers to a pulmonary bacterial infection that develops following aspiration, but the distinction between pneumonitis and pneumonia is poorly defined in veterinary species. Aspiration pneumonia can result from bacterial colonization of lungs injured by acid aspiration or from aspiration of contaminated material. Because oropharyngeal colonization with pathogenic bacteria such as *Pasteurella* spp is extremely common in dogs and cats, both mechanisms likely occur. Aspiration of saltwater, oils, and liquid hydrocarbons may be included in the definition of aspiration pneumonia even though concurrent bacterial infection may not be present.

23.5 ASPIRATION PNEUMONITIS AND PNEUMONIA

23.5.1 Pathophysiology

The accepted biphasic model for acute lung injury following acid aspiration was developed following murine experiments in which lung permeability changes following direct tracheal instillation of hydrochloric acid were evaluated and the chronology of the histologic changes described.[10]

The first phase of lung injury, which begins immediately following aspiration, results from direct effects of the acidic aspirate. This is initially a chemical burn that damages the bronchial and alveolar epithelium and the pulmonary capillary endothelium.[11] Pulmonary capillary permeability increases following acid stimulation of sensory neurons in the tracheobronchial smooth muscle. These sensory (substance P–immunoreactive) nerves are involved in the control of bronchial smooth muscle tone and vascular permeability. Stimulation of these nerves induces release of multiple tachykinin neuropeptides such as substance P and neurokinin A.[12] Neurogenic inflammation, bronchoconstriction, bronchial mucus secretion, cough, vasodilation, and increased vascular permeability result. Permeability changes are maximal 1 to 2 hours after aspiration. Histologically, first phase damage consists of epithelial and endothelial degeneration, necrosis of type I alveolar cells, and intraalveolar hemorrhage.

The second phase of acid-induced lung injury starts 4 to 6 hours after aspiration and may continue for up to 2 days. It is characterized by additional, larger increases in pulmonary capillary permeability and protein extravasation than during the first phase, leading to extensive pulmonary edema formation, further compromising gas exchange and depleting intravascular volume.[10] Neutrophils initially are attracted to the lungs by chemotactic mediators such as interleukin-8, tumor necrosis factor-α, and macrophage inflammatory protein-2 released by alveolar macrophages following the initial aspiration episode.[13-15] The second phase involves the generation of a localized proinflammatory state by activation of sequestered neutrophils. Interleukin-8 is the main stimulus for neutrophil chemotaxis and also upregulates neutrophil β_2-integrin endothelium receptors, mediates transendothelial neutrophil migration, and primes neutrophils for activation.[13] Combination acid-particulate aspirates induce larger and longer lasting tumor necrosis factor-α expression than aspiration of acid alone.[16] Neutrophils damage tissue by production and release of oxygen free radicals and proteolytic enzymes. High levels of serine proteases released by the sequestered, activated neutrophils seem to play a more important role in causing tissue damage than leukocyte-derived reactive oxygen species.[17]

The contralateral lung may be affected even if aspiration is unilateral. Complement activation resulting from mast cell degranulation stimulated by tachykinins mediates this response.[18,19] In guinea pig models, tachykinin 98 release in the lungs occurs following esophageal stimulation by gastric acid due to the presence of 99 nonadrenergic, noncholinergic neural networks between the esophagus and the trachea.[20]

Aspiration pneumonia may develop concomitantly with pneumonitis if the aspirated contents are contaminated with oropharyngeal bacteria. Alternatively, aspiration pneumonia may develop from pneumonitis by subsequent bacterial colonization of the respiratory tract. Likely bacteria include commensals such as *Staphylococcus* spp, coliforms such as *E. coli* and *Klebsiella* spp, oropharyngeal *Mycoplasma* spp, and primary respiratory pathogens including *Pasteurella* spp, *Pseudomonas* spp, *Bordetella* spp, and *Streptococcus* spp.[21-24] Gastric acid aspiration enhances bacterial adherence to the respiratory epithelium and reduces pulmonary clearance of bacteria. Acid injury may also facilitate bacterial adherence by upregulating expression of certain receptors providing de novo binding sites or by damaging epithelial cells, allowing respiratory pathogens to bind preferentially.[25] Bacterial adherence may be mediated by pili, which access the cell surface following acid injury.[26,27]

Ultimately, the vascular permeability changes lead to pulmonary edema formation, focal atelectasis, and collapse of alveoli, resulting in hypoventilation and shunting. The inflammatory response to bacterial infection exacerbates this and hypoxia may develop as a consequence of ventilation-perfusion (V/Q) mismatch and reduced lung compliance.

23.5.2 Diagnosis

23.5.2.1 History

A full clinical history from the primary caregiver is essential in making a diagnosis of aspiration pneumonia. Aspiration episodes may be witnessed, but frequently go unnoticed and unreported. Hospitalized patients perceived as at risk (see Box 23-1) should be monitored closely and suspicion of aspiration aroused if respiratory distress develops acutely.

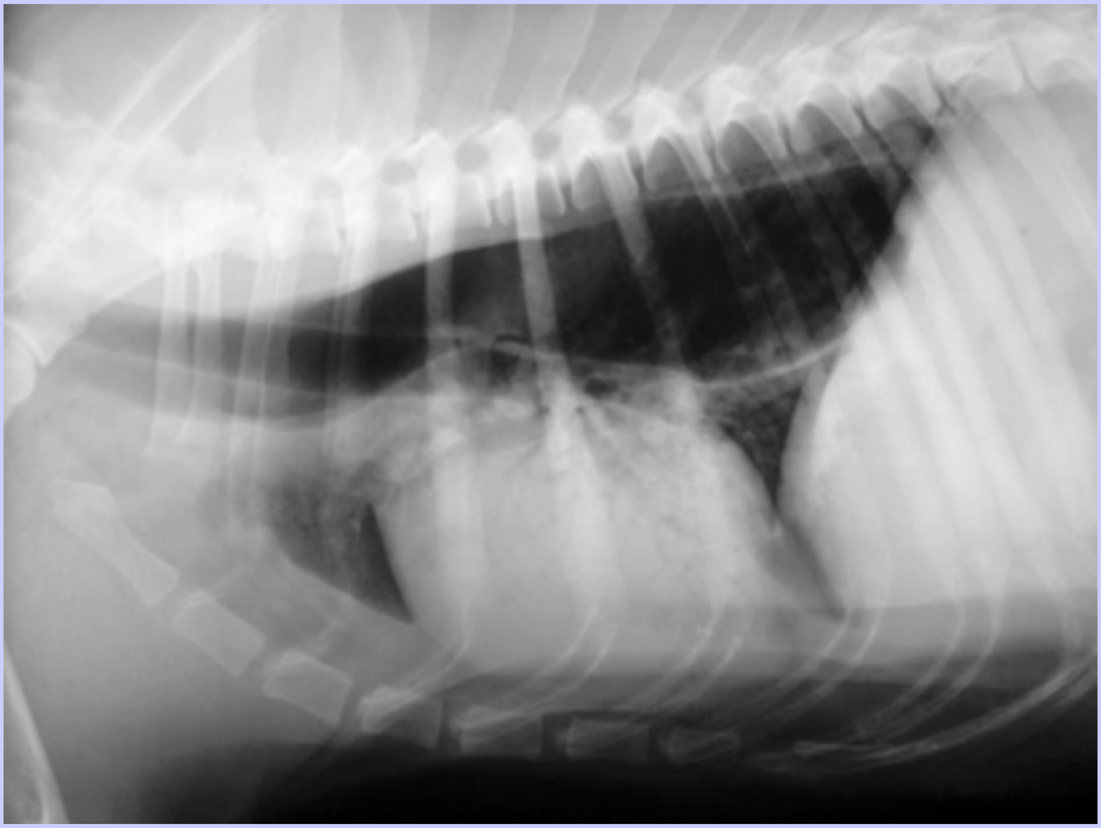
23.5.2.2 Physical Examination

The clinical signs of aspiration pneumonia and pneumonitis include acute-onset respiratory distress, potentially accompanied by cyanosis, cough, collapse, pyrexia, or a mucopurulent nasal discharge. Respiratory pattern, rate, rhythm, effort, and depth should be observed. Patients with aspiration pneumonia frequently have abnormal lung sounds unless auscultated soon after a small-volume aspiration. It is important to consider whether the sounds heard are appropriate for the patient's respiratory rate and effort. Lung sounds in patients with aspiration pneumonia are often louder than normal. Fine crackles may be heard during inspiration, especially in the cranioventral areas. Rarely, lung sounds may be significantly decreased if a large bronchus becomes filled with exudates and cellular debris such that air can no longer pass through. Auscultation of the lung fields, subdivided into smaller areas, can aid in lesion localization and improve detection rates (Color Plate 23-1). Thoracic percussion is occasionally used to determine the relative densities of portions of the lung fields. Areas of decreased sound are suggestive of lung lobe consolidation.

23.5.2.3 Radiography

Thoracic radiography is the mainstay for the diagnosis of aspiration pneumonia. Patients typically develop an alveolar lung pattern as a result of displacement of air from alveoli by fluid accumulation and cellular infiltration. In the dog and cat, aspiration pneumonia typically affects the right middle lung lobe and ventral parts of the other lobes (Figure 23-1). Lesion distribution may be affected by patient position at the time of aspiration. History, clinical suspicion, and radiographic lesions are often sufficient to diagnose aspiration pneumonia. Other radiologic differential diagnoses include infectious bronchopneumonia, pulmonary hemorrhage, neoplasia, and lobar collapse or torsion. Radiographic signs of aspiration pneumonia may change markedly over time, typically lag hours behind the onset of respiratory distress, and may persist for several days despite clinical improvement. In humans the degree of alveolar infiltration visible radiographically correlates poorly with arterial hypoxemia, degree of dyspnea, or prognosis.

Figure 23-1 A right lateral thoracic radiograph of a dog with aspiration pneumonia secondary to megaesophagus. There is an alveolar pattern in the area of the right middle lung lobe and overlying the cardiac silhouette. Several air bronchograms can be seen.



Radiography may be useful in assessing factors that predispose to aspiration pneumonia. Megaesophagus may be identified on plain thoracic radiographs. Contrast studies may be necessary to investigate and identify pharyngeal or esophageal motility disorders. However, contrast media may be aspirated by these patients (Figure 23-2), so it should be used with caution, especially in patients with megaesophagus.

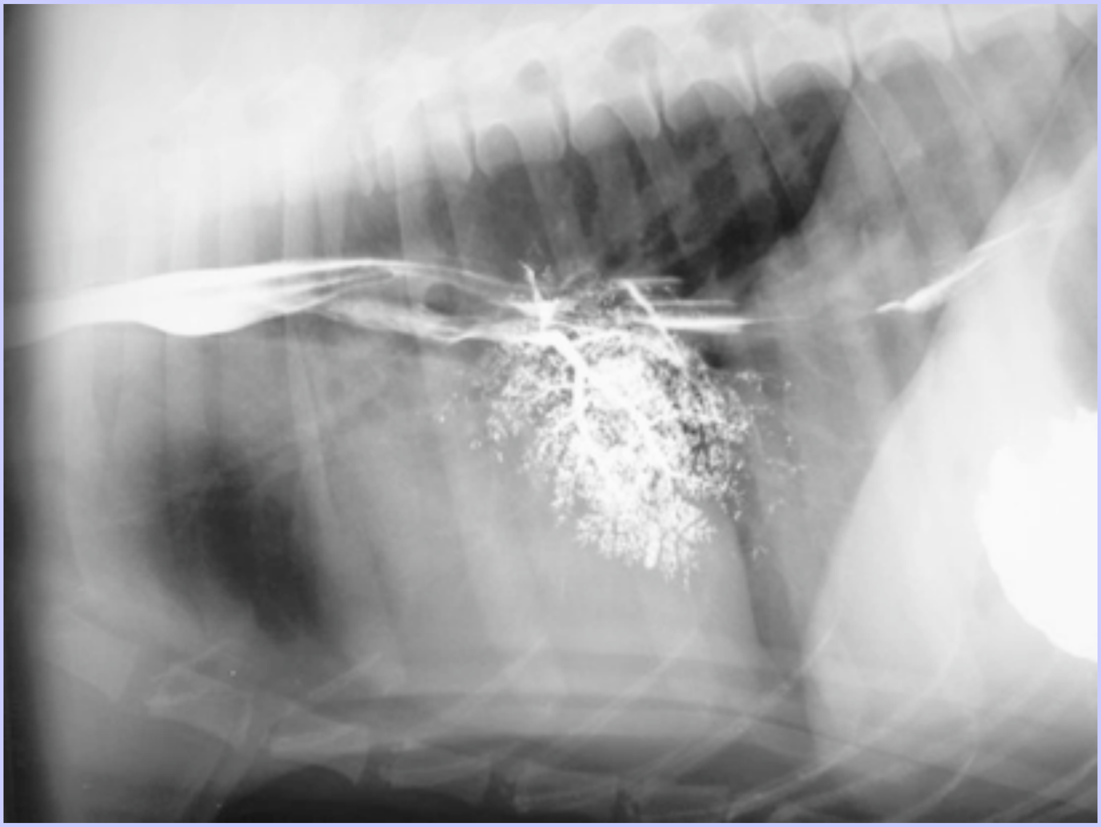
23.5.2.4 Tracheal Wash

Tracheal wash (TW) is a minimally invasive diagnostic test used in both dogs and cats to obtain airway samples for cytologic analysis and bacterial culture. TW can be performed by the transtracheal (TTW) or endotracheal (ETW) routes, depending on the size and stability of the patient. Both techniques are suitable for investigation of suspected aspiration pneumonia. One experimental study in dogs with *Streptococcus pneumoniae* infection found that TTW was as sensitive as transbronchial biopsy, lung aspirates, and bronchoalveolar lavage (BAL).[28] TTW had poorer specificity, however, and produced fewer pure cultures than did other techniques. Sensitivities of between 45% and 57% have been reported for diagnosis of bacterial pneumonia by TTW.[22,29,30]

23.5.2.5 Bronchoscopy and Bronchoalveolar Lavage

Bronchoscopy allows visualization of the luminal surface of the respiratory tract typically to the tertiary bronchi level, assessment of airway injury, and collection of lavage samples. The procedure is not without risk in patients suffering from aspiration pneumonia that have respiratory compromise, hypoxemia, or hypercapnia. BAL performed at the time of bronchoscopy is a more invasive diagnostic sampling technique than TW. BAL may cause transient but potentially significant decreases in lung function that may not be well tolerated in patients with preexisting compromise. BAL retrieves larger volumes of fluid directly from visibly affected areas than TW, potentially providing greater sensitivity, specificity, and increased diagnostic yield. Compared with TW, BAL may have superior diagnostic yield for investigation of lower airway, alveolar, and interstitial disease.

Figure 23-2 A right lateral thoracic radiograph of a dog with an esophageal motility disorder, showing contrast material within the esophagus, trachea, and the right middle lung lobe.



23.5.2.6 Complete Blood Count and Serum Biochemistry

Blood samples for complete blood count (CBC) and serum biochemistry values are indicated in all patients suspected of having aspirated gastric contents. Common hematologic abnormalities include a neutrophilia or neutropenia with a left shift and lymphopenia. Although these changes are nonspecific, they may reflect the degree of inflammatory response. These CBC changes may take up to 24 hours to develop following an aspiration event. Both CBC and serum biochemistry analysis are useful in identifying and investigating comorbidities.

23.5.2.7 Arterial Blood Gas Analysis

Changes in arterial blood gas values have minimal lag time following aspiration. They provide an objective assessment of respiratory functional impairment, which can be measured serially to chart the course of the disorder as well as to guide and monitor therapeutic interventions. Typical changes include hypoxemia and hypocapnia, although patients may become hypercapnic when the respiratory muscles become fatigued or severe pulmonary parenchymal disease is present.

23.5.3 Treatment

23.5.3.1 Airway Management

Following a witnessed aspiration event, airway patency should be established. Endotracheal intubation may be necessary, and solid foreign material obstructing the airway should be removed immediately. Aspirated liquid material will disperse quickly, but suctioning of the pharynx may reduce further fluid entering the trachea and may be necessary to allow intubation. Suctioning of the airway may not always be successful in removing fluid; however, it may stimulate coughing, which is protective. Although therapeutic bronchoscopy for lavage of the affected areas has been suggested, it is of unproven benefit in veterinary patients and, given the pathogenesis of acid-induced lung injury and the risks of anesthesia, is not routinely recommended.

23.5.3.2 Oxygen Therapy

Aspiration typically results in severe hypoxemia due to V/Q mismatch, intrapulmonary shunting, and hypoventilation. Oxygen therapy is indicated in cases of aspiration pneumonia that exhibit hypoxemia or inadequate hemoglobin saturation documented by arterial blood gas analysis or pulse oximetry. Numerous minimally invasive techniques are described, including nasal flow-by, masks, insufflation via nasopharyngeal catheters, oxygen hoods, and oxygen cages (see Chapter 19, Oxygen Therapy). Oxygen administration should be sufficient to alleviate respiratory distress and ensure adequate arterial partial pressure of oxygen (PaO_2). Oxygen toxicity has not been reported in the clinical veterinary literature but experimental studies suggest prolonged high inspired oxygen concentrations may have detrimental effects, including increased lung permeability, protein extravasation, and impaired compliance. Oversupplementation should be avoided.[31,32]

23.5.3.3 Mechanical Ventilation

Ventilatory support may be required in patients with progressive ventilatory failure (hypercarbia) or failure of pulmonary oxygen delivery or exchange (hypoxemia) where less invasive methods of oxygen support are unsuccessful (see Chapter 213, Basic Mechanical Ventilation). The decision to put an animal on mechanical ventilation typically is made on the basis of serial arterial blood gas analyses and repeated patient examinations. Patients with aspiration pneumonia generally are considered to have a poor prognosis if mechanical ventilation is required, although ventilation may be lifesaving. Patients with pulmonary parenchymal disease causing severe hypoxemia have a much higher risk of alveolar rupture and pneumothorax, capillary endothelial damage, impairment of venous return, and ventilator-associated pneumonia, compared with patients with hypercapnia and ventilatory failure.[33]

23.5.3.4 Bronchodilators

Drugs such as salbutamol, terbutaline, and aminophylline may be useful in acute aspiration pneumonitis, because bronchoconstriction is part of the physiologic response to acid injury. The use of bronchodilators in animals with pneumonia is controversial, but they may be helpful in select cases by increasing airflow and mucokinetics via improving ciliary activity and increasing the serous nature of respiratory secretions. Their use may suppress the cough reflex, worsen V/Q mismatch, and allow exudates within the affected lung to spread to unaffected portions of the lung. Aminophylline may also act by decreasing inflammation and reducing the oxygen demands of breathing (see Chapter 22, Pneumonia).

23.5.3.5 Cardiovascular Support

Fluid therapy should be used judiciously in patients with aspiration pneumonitis or pneumonia, because any increase in pulmonary capillary hydrostatic pressure will tend to exacerbate fluid extravasation into the alveoli. The patient's intravascular volume and hydration status should be assessed frequently and fluid therapy tailored to individual patient requirements, with due consideration for the degree of cardiovascular and respiratory compromise.

23.5.3.6 Nebulization and Coupage

Nebulization and coupage are a form of respiratory physiotherapy that aims to humidify bronchial secretions and encourage their removal from the airways. Two human clinical studies evaluating physiotherapy in patients with bacterial pneumonia concluded that chest physiotherapy did not reduce duration of hospital stay or improve lung function.[34,35] In the second study, patients with pneumonia who received chest physiotherapy had a longer duration of pyrexia than those not receiving treatment.[35] There have been no studies of respiratory physiotherapy in veterinary patients (see Chapter 22, Pneumonia).

23.5.3.7 Antibiotics

Antimicrobial therapy is not indicated in the early stages of aspiration pneumonitis. Antibiotics are appropriate for aspiration pneumonia, and selection should be based on culture and sensitivity results from samples obtained by TW or BAL. This will not be possible in all cases and results will not be immediately available. Cytologic analysis of airway washes, including Gram stain, can be used to guide antimicrobial choices while culture results are pending. In general, broad spectrum antimicrobial agents should be chosen with consideration of local resistance profiles. Anaerobic coverage is unlikely to be necessary.[36] Antimicrobial therapy should be reevaluated frequently on the basis of clinical response and culture results. The pharmacokinetics of antimicrobial agents should also be considered. Polar drugs such as the cephalosporins and penicillins penetrate poorly, although they may achieve higher levels in inflamed tissues. Lipophilic molecules such as the fluoroquinolones penetrate natural body barriers readily and will reach therapeutic levels in bronchial secretions (see Chapter 22, Pneumonia).

23.5.3.8 Glucocorticoids

Glucocorticoids could theoretically be beneficial in suppressing the proinflammatory state that occurs in aspiration pneumonitis. However, these agents suppress the immune system by decreasing levels of T-lymphocytes, inhibiting leukocyte chemotaxis and phagocytosis and antagonizing complement. They also increase the risk for gastrointestinal ulceration. Thus glucocorticoids likely negate the protective immune response to acid aspiration and may increase the risk of bacterial pneumonia.[37] Their use is not recommended.

23.5.4 Prevention

Arguably, the best method for managing aspiration pneumonia is to prevent its occurrence. This will not be possible in all patients, especially those with pathologic impairment of their protective airway reflexes or with diseases that predispose them to vomiting or regurgitation. When medical or surgical interventions place patients at risk, techniques should be employed to minimize the risk, including fasting and the use of prokinetic agents, antiemetic medications, and gastric alkalinization.

Evacuation of the stomach using a nasogastric tube or via suction in anesthetized patients may decrease the frequency and volume of vomitus. Fasting for 6 hours prior to anesthesia is common practice to minimize residual gastric volume. In humans this consistently reduces the amount of food in the stomach, but the effect on gastric pH is variable.[38] In dogs, fasting reliably increases gastric pH to a median 24-hour intragastric pH of 4.4.[39] Gastric alkalinization to a pH higher than 2.5 may be appropriate to minimize the risk of acid-induced lung injury in patients considered to be at risk for aspiration. Famotidine, pantoprazole, or omeprazole, but not ranitidine, would be suitable to achieve this in canine patients that have not fasted.[39]

There is some evidence in human medicine suggesting that gastric alkalinization promotes bacterial colonization within the stomach and thus increases the potential for aspiration pneumonia. This subject is still a matter of controversy. Several recent human studies found no increase in the rate of ventilator-associated pneumonia in patients receiving gastroprotective drugs, suggesting that any increased risk is minimal and is independent of the drug used.[40,41] Unfortunately, similar studies in the veterinary field are not available, thus firm recommendations cannot be made (see Chapter 181, Gastrointestinal Protectants).

Prokinetic drugs such as metoclopramide enhance gastric emptying by increasing gastric contraction and small intestinal peristalsis. Metoclopramide is also an antidopaminergic antiemetic which, in combination with a histamine-2 (H_2) receptor antagonist given 12 hours before and on the day of anesthesia, reliably reduces the risk of aspiration in humans. The intravenous administration of metoclopramide and an H_2 receptor antagonist may be useful for emergency anesthesia in veterinary patients that have not been fasted.

Enteral feeding, whether it is esophageal, gastric, or postpyloric, predisposes patients to aspiration pneumonia.[42,43] Bacterial colonization of enteral feeding tubes occurs within 4 days of intensive care unit admission in human patients receiving gastric alkalinizing drugs.[44] Systemic antibiotics will neither prevent nor manage this colonization. Because nutritional support of critical patients is important for recovery, the aspiration risk should be minimized using safe feeding protocols. Patients should not be fed enterally while recumbent, and the residual gastric volume should be ascertained prior to administration of food. Feeding should be stopped at any sign of patient discomfort or resistance and the tube position checked.

24 Chapter 24 Acute Lung Injury and Acute Respiratory Distress Syndrome

Elizabeth A. Rozanski, DVM, DACVIM, DACVECC

Daniel L. Chan, DVM, DACVECC, DACVN, MRCVS

24.1 KEY POINTS

- Acute lung injury (ALI) is a severe complication of critical illness or injury. Acute respiratory distress syndrome (ARDS) is a more severe form of ALI.
- Inflammation and alterations in the alveolar-capillary membrane lead to the influx of inflammatory cells and proteinaceous fluid, causing alveolar flooding and resulting in severe hypoxemia.
- ALI and ARDS are clinical diagnoses.
- The relative clinical importance of ALI in animals is likely growing, but uncertain.

24.2 INTRODUCTION

Acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) represent life-threatening complications of critical illness in people. These complications reflect the advances in critical care that have occurred in human medicine during the last 40 years. As a result of these advances most patients now survive beyond the initial injury and illness, but they are at risk of developing complications such as multiple organ failure, ALI, and ARDS.

Early pathologic and clinical reports from World War I describe findings consistent with the modern definitions of ALI, although it was not recognized as a clinical entity.[1] During the 1960s it was recognized that although previously healthy, young soldiers injured in combat could be resuscitated in the field, they would often die days to weeks later from progressive multiple organ failure. Ashbaugh and colleagues are credited with the first modern description of adult respiratory distress syndrome in 1967.[2] Since its recognition, ARDS has remained a devastating complication of critical illness, with survival rates now only slightly better than they were 40 years ago. Adult respiratory distress syndrome was reclassified as acute respiratory distress syndrome in 1994 to include pediatric patients.[3]

24.3 HUMAN PERSPECTIVE

Acute lung injury–acute respiratory distress syndrome (ALI-ARDS) has been defined by the American-European Consensus Conference of 1994 as severe respiratory failure following a catastrophic event.[3] The catastrophic event may be pulmonary (e.g., aspiration pneumonia or pulmonary contusion) or extrapulmonary (e.g., abdominal sepsis).

More recently, other inciting events have been recognized to result in a specific form of ALI. For example blood transfusions can be associated with pulmonary injury, a syndrome that is termed *transfusion-related acute lung injury (TRALI)*. ALI-ARDS is further defined by a low oxygenation index (PaO_2-to-FiO_2 ratio). Patients with ALI have an oxygenation index of less than 300, and those with the more severe category of ARDS have an index of less than 200.[3] Additional diagnostic criteria include bilateral pulmonary infiltrates on thoracic radiographs, exclusion of cardiogenic pulmonary edema, and decreased lung compliance.

The most consistent histologic pattern appreciated with ARDS is diffuse alveolar damage.[4,5] However, this pattern is considered rather nonspecific and may be associated with a variety of clinical syndromes in addition to ARDS, including other pulmonary conditions such as acute interstitial pneumonia, inhalation of toxic substances, or prior treatment with amiodarone.[6-8]

In cases of suspected ARDS, stages of lung injury include exudative, proliferative, and, ultimately, fibrotic phases. During the initial insult, hemorrhage and protein-rich pulmonary edema accumulate in the alveoli. The initial exudative phase (days 0 to 6) is characterized by protein-rich edema, the influx of neutrophils, and eosinophilic hyaline membranes in the walls of the alveolar ducts. This is followed by the proliferative phase (days 4 to 10) characterized by a decrease in edema and hyaline membranes and an increase in interstitial fibrosis. The final fibrotic phase (day 8 onward) is characterized by pronounced fibrosis that ultimately may obliterate areas of the lung. Histopathologic criteria are useful in understanding the pathophysiology and evaluating patients with ARDS, although this syndrome should be considered a clinical diagnosis; a lung biopsy or autopsy is not required for diagnosis.

The arterial hypoxemia observed in ALI-ARDS develops from a variety of factors including ventilation-perfusion (V/Q) mismatch, shunting of venous blood into the arterial circulation, and low alveolar partial pressure of oxygen (P_AO_2). Diffusion limitation is rarely a major contributor to hypoxemia in people with ARDS. V/Q mismatch is the most clinically relevant cause of hypoxemia in people with ARDS. Regions with low V/Q are a result of partial alveolar collapse or obstruction caused by factors such as accumulation of exudate and loss of surfactant. When complete alveolar collapse or obstruction occurs it creates a physiologic shunt.

Physiologic shunt will permit deoxygenated venous blood to flow directly into the arterial circulation without exposure to functional gas exchange units. The result is a reduction in the arterial partial pressure of oxygen (PaO_2). This cause of hypoxemia is not responsive to oxygen therapy; mechanical ventilation may allow recruitment of previously collapsed alveoli, reducing the degree of physiologic shunt. Importantly, venous oxygen desaturation will magnify abnormalities associated with shunting, and efforts to improve venous oxygenation by improving perfusion and decreasing oxygen consumption will improve arterial oxygenation in those with a significant physiologic shunt.

Decreased P_AO_2 may be caused by hypoventilation associated with low pulmonary compliance. This type of hypoxemia generally improves with supplemental oxygen.

In people with ALI-ARDS, pulmonary functional abnormalities noted in addition to hypoxemia include decreased functional residual capacity, mild to moderate reductions in the forced expiratory volume in 1 second and forced vital capacity, decreased diffusing capacity, decreased compliance, and increased resistance. Alterations in surfactant production and composition may also contribute to alveolar collapse, and pulmonary arterial hypertension may result from increased pulmonary vascular resistance. Limited pulmonary function testing has been performed in veterinary patients with ALI-ARDS.

The underlying cause for ALI and ARDS is often unknown. These syndromes should be considered the final end points of a variety of pathophysiologic insults that can be infectious, traumatic, inflammatory, or immune mediated in origin. Common features of massive injury include pronounced microvascular permeability, leukocyte activation, and alterations in cytokine production. Inflammatory mediators are responsible at least in part for the development and propagation of ALI-ARDS. Overzealous response on the part of the host may magnify the initially appropriate inflammatory response and result in perpetuation of injury. Major humoral mediators of ALI-ARDS include the proinflammatory cytokines interleukin-1 and tumor necrosis factor-α, and cellular mediators include neutrophils and macrophages.

Therapy for ALI-ARDS is primarily supportive, and no specific pharmacologic therapy is associated with an improved outcome. Inhaled nitric oxide and surfactant therapy have been shown to improve oxygenation, but positive survival benefits are not observed.[9] Surfactant therapy can be lifesaving in infants with respiratory distress syndrome, and modification of surfactant composition and administration technique trials are ongoing.[10,11] Cytokine blocking agents have not been effective despite initial early promise. Intravenous β_2-agonists have been shown to effectively lower lung water in the β-Agonist Lung Injury Trial (BALTI),[12] and both positive fluid balance and high tidal volumes have been associated with a worse outcome.[13] A major breakthrough in the treatment of patients with ARDS is the use of lower tidal volumes in mechanical ventilation, which have been associated with less ventilator-induced lung injury and improved patient outcomes.[14] Most guidelines include limiting fluid balance to prevent overhydration, limiting ventilator-induced lung injury by limiting tidal volumes, using appropriate positive end-expiratory pressure (PEEP), and preventing other complications of critical illness.[15,16]

Treatment with activated protein C, which has been effective in sepsis, is being evaluated for ARDS in a phase II clinical trial. The Prospective, Randomized Phase II Clinical Trial of Activated Protein C (Xigris) Versus Placebo for the Treatment of Acute Lung Injury is sponsored by the National Heart, Lung, and Blood Institute with an expected completion date of 2008. A variety of other trials evaluating other pharmacologic and ventilatory maneuvers including surfactant, inhaled nitric oxide, and granulocyte-macrophage colony-stimulating factor are recruiting patients, and further information can be found at www.clinicaltrials.gov.

Resolution of ARDS occurs in an orderly fashion, similar to repair in any other tissue. First, excessive fluid and proteins (soluble and insoluble) are removed from the airways and alveoli. Next the type II alveolar epithelial cells must repopulate the epithelial lining, and the abnormal interstitium must restore its normal matrix. Finally, the damaged endothelium must be repaired to restore blood flow, and unnecessary or residual cellular components must be removed.[4,17]

If recovery is incomplete, persistent deficiencies in lung function may remain. Most recovery occurs over the first 3 months following extubation, with some additional recovery over the first year.[18] Quality of life of survivors is typically good, although depending on the concurrent critical illness or injury, there may be persistent abnormalities.[18] Some long-term human survivors of critical illness develop psychologic sequelae and may require ongoing therapy to regain their predisease state.

24.4 CANINE PERSPECTIVE

ALI and ARDS are recognized with far less frequency in critically ill dogs than in people, although several case reports suggest a similar association with critical illnesses.[19-22] Parent and colleagues were the first to comprehensively describe the clinical characteristics and course of 19 dogs identified with ARDS on necropsy in 1996.[23,24] Risk factors identified for dogs included pneumonia, sepsis, and shock. Several other case reports have highlighted the histopathologic appearance of ARDS in dogs with a variety of critical illnesses.[19-22] Campbell and King described 10 dogs receiving mechanical ventilatory support for pulmonary contusions; many (if not all) of the dogs surviving the initial 24 hours likely had ARDS.[25] Other reviews on ventilatory management have also described dogs ventilated for respiratory failure that likely met the criteria for ARDS, albeit this was not definitively stated, as an underlying cause.[26,27] Finally, in 2005 Walker and colleagues described the recovery from ALI in a dog with anaphylaxis associated with multiple bee stings.[28]

Most veterinary critical care specialists appear to agree that ARDS exists as a clinical entity in dogs. However, because of the lack of a consensus statement in dogs and difficulty at times in excluding other causes of respiratory distress, the actual incidence remains unclear. In some instances, such as with severe pulmonary contusion, it may be easier to apply the diagnosis ARDS to the patient still in respiratory distress 72 hours after onset, and in others, such as with aspiration pneumonia, it may be difficult to ascertain if ALI has developed or if recurrent aspiration has occurred. Proposed criteria for defining canine ALI and ARDS are listed in Box 24-1.

Recommendations for the treatment of potential ALI-ARDS in dogs focuses on eliminating other causes that may be more treatable. Thoracic radiographs should be evaluated for diffuse bilateral infiltrates. A sample for arterial
blood gas analysis should be evaluated for hypoxemia and for calculation of the alveolar-arterial gradient. If the 103
animal is extremely stressed or experiencing marked respiratory distress, sampling for an arterial blood gas should 104
be postponed so as not to risk causing further compromise or even cardiopulmonary arrest. Similarly, in a dog that is experiencing severe respiratory distress, supplemental oxygen delivery should not be interrupted to make interpretation of blood gases more straightforward.

24.4.1

Box 24-1 Proposed Criteria for Identification of ALI and ARDS in Dogs

- Preexisting severe acute critical illness or injury (pulmonary or extrapulmonary)
- Increased respiratory rate and effort
- Bilateral pulmonary infiltrates on thoracic radiographs
- Significant hypoxemia defined as PaO_2/FiO_2 of 200 to 300 (ALI)*
- PaO_2/FiO_2 of less than 200 (ARDS)*
- No evidence of left atrial hypertension as assessed via either echocardiography or pulmonary artery catheterization

ALI, Acute lung injury; *ARDS,* acute respiratory distress syndrome.

* In some small or uncooperative patients it may be difficult to obtain an arterial blood gas sample. Although pulse oximetry is not a replacement for arterial blood gas analysis, marked desaturation (e.g., <90%) should be considered indicative of severe hypoxemia and appropriate measures taken.

Volume overload and congestive heart failure should be excluded by echocardiogram. Bacterial pneumonia should be treated aggressively with antibiotics effective against hospital-acquired organisms. Pulmonary thromboembolism should be considered, and patients of concern should be evaluated via echocardiogram, computed tomography, D-dimers, or other means. If pulmonary thromboembolism is suspected, anticoagulant therapy should be initiated if clinically advisable. Positive-pressure ventilation with PEEP is the mainstay of support for the dog with ALI or ARDS. Suggested strategies for ventilatory management of animals with ARDS are largely derived from human data; these have not been evaluated comprehensively in clinical veterinary patients.[29] Sometimes less severely affected dogs may be treated with cage rest and supplemental oxygen.

Recovery from lung injury occurs over weeks; thus severe decreases in pulmonary compliance (or increases in inspiratory pressures) should be considered ominous in dogs being supported with mechanical ventilation. No specific therapy for ALI-ARDS is available, and care is largely supportive. Limiting ventilator-induced lung injury is an essential aspect of mechanical ventilation, but optimal tidal volumes for dogs with ARDS have not been established. Because of the substantial difference in thoracic cavity dimensions (e.g., Pug versus an Irish Setter), it may be that ultimately breed- or body type-specific recommendations will be developed. For the time being, lung-protective ventilation strategies in which tidal volume is minimized in conjunction with moderate to high PEEP levels are recommended for ALI-ARDS patients (see Chapters 213 and 214, Basic Mechanical Ventilation and Advanced Mechanical Ventilation, respectively). Given the significant financial and emotional commitment required to support a critically ill dog undergoing mechanical ventilation, realistic and frequent patient evaluations are recommended.

As we expand our understanding of the pathophysiology and our experience with ARDS-ALI in dogs increases, future therapies and management strategies may be developed and tested to reduce morbidity and improve survival. An important first step involves increasing awareness and recognition of this disease entity in dogs. Efforts to better define this syndrome in dogs are warranted to allow comparison of any forthcoming case series and clinical trials.

24.5 FELINE PERSPECTIVE

There is even less known about ALI-ARDS in cats than in dogs. A single abstract describes 65 cats with ALI-ARDS identified by histopathology at postmortem examination.[30] This report suggests that the disease process in cats is analogous to that in dogs and humans. In the absence of evidence to the contrary, diagnostic and therapeutic treatment of feline patients is considered similar to that of the canine patient. Hopefully there will be further reports and investigations in the near future to improve our understanding of ALI-ARDS in cats.

25 Chapter 25 Pulmonary Contusions and Hemorrhage

Sergio Serrano, LV, MRCS, DACVECC

Amanda K. Boag, MA, VetMB, DACVIM, DACVECC, MRCVS

25.1 KEY POINTS

- Pulmonary contusions occur commonly in patients following blunt chest trauma. The contusions consist of interstitial and alveolar hemorrhage, accompanied by parenchymal destruction that starts immediately following the impact but can worsen for 24 to 48 hours after injury.
- The lesions typically resolve within 3 to 10 days, unless complications such as pneumonia or acute respiratory distress syndrome ensue.
- Clinical signs may be acute and severe or may develop progressively over several hours following trauma.
- The diagnosis of pulmonary contusions is based on a history of trauma and the presence of respiratory signs, ranging from tachypnea to respiratory distress, in conjunction with compatible blood gas abnormalities and characteristic changes on thoracic radiographs.
- Treatment of patients with pulmonary contusions is supportive and consists of oxygen therapy, judicious fluid administration, and analgesia for concurrent thoracic wall injuries. Ventilatory support may be necessary in severe cases.
- Less common causes of pulmonary hemorrhage include coagulopathies, thromboembolic disease, infectious disease (viral, bacterial, and parasitic), exercise-induced hemorrhage, and neoplasia.
- Treatment of atraumatic pulmonary hemorrhage is directed toward the underlying disease in addition to supporting respiratory and ventilatory function.

25.2 INTRODUCTION

Pulmonary contusions consist of pulmonary interstitial and alveolar hemorrhage and edema associated with blunt chest trauma, usually after a compression-decompression injury of the thoracic cage. Such injury is most commonly associated with motor vehicle trauma[1] and high-rise falls[2] in cats in urban areas. Other causes include animal interactions (e.g., horse kicks), human abuse, and shock waves from explosions.

Thoracic trauma has been reported in 34%,[3] 38.9%,[4] and 57%[5] of dogs and 17% of cats[4] that sustained limb fractures in road traffic accidents. Pulmonary contusions were the most prevalent lesion in roughly 50% of animals with thoracic injuries, although patients may display few clinical signs associated with the contusions. They may occur as an isolated abnormality or in combination with other thoracic injuries including pneumothorax, pleural effusion, rib fractures, diaphragmatic rupture, cardiac arrhythmias, and pericardial effusion.[4,6] Pulmonary contusions may be the most significant abnormality present; in one study, only 32% of dogs had concurrent fractures or luxations.[7] It is worth noting that in another study 79% of the dogs with abnormal thoracic radiographic findings or low arterial partial pressure of oxygen (PaO_2) had no physical findings that were suggestive of thoracic injury on initial examination.[5]

The clinical manifestations of pulmonary contusions, as in any thoracic trauma, can be acute and lead to immediate, severe respiratory distress, or may develop progressively over several hours after the injury. Radiographic changes may also be delayed. Because aggressive fluid therapy and general anesthesia have the potential to worsen contusions, the emergency clinician must not discount the possibility of their presence when evaluating more dramatic injuries, even if clinical signs of thoracic injury or respiratory distress are not apparent initially.

25.3 PATHOPHYSIOLOGY AND PATHOLOGY

Pulmonary contusions result from the release of direct or indirect energy within the lung. High-velocity missiles and blasts also lead to pulmonary contusions as shock waves pass through the parenchymal tissue and lead to bleeding into the alveolar spaces and disruption of normal lung structure and function. Several mechanisms have been postulated as important in the etiology of pulmonary contusion.[8]

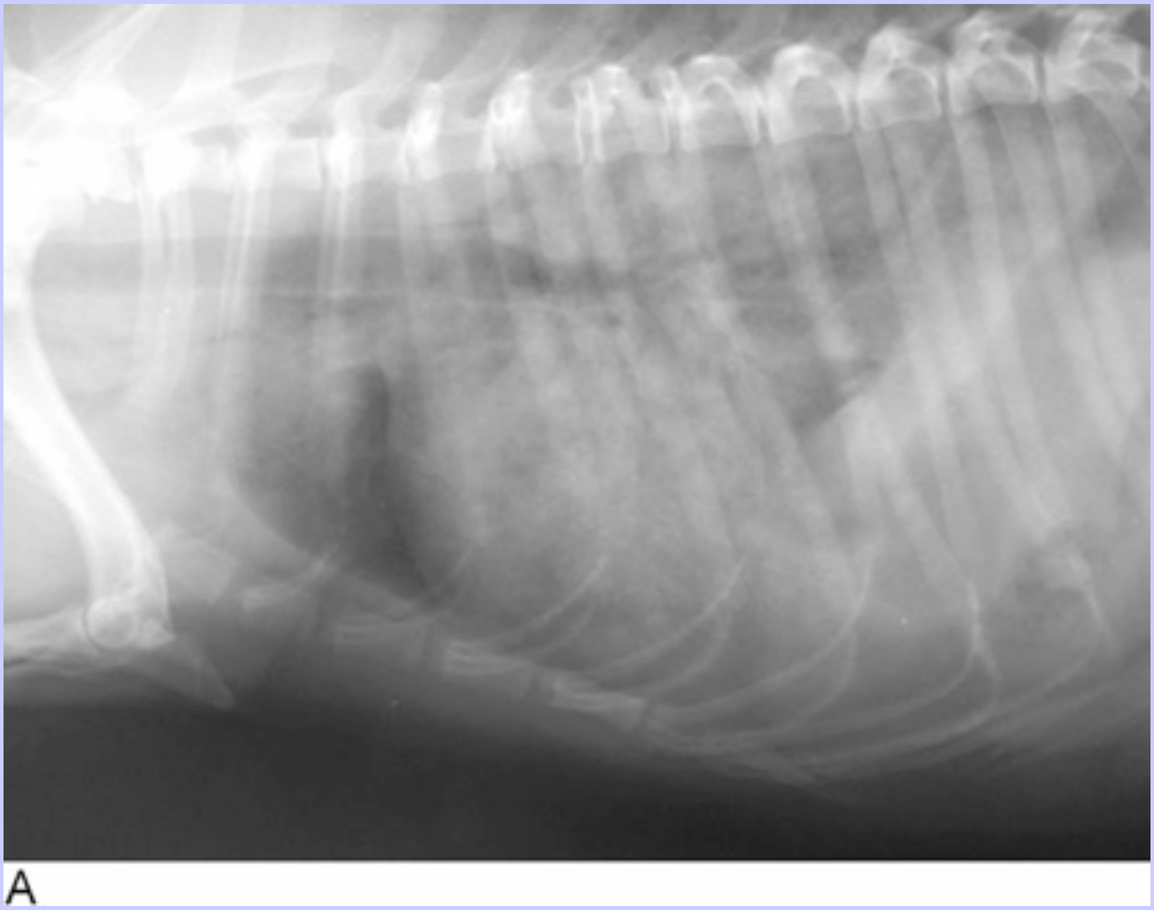
Due to the compressible nature of the thoracic cage, acute compression and subsequent expansion lead to transmission of mechanical forces and energy to the pulmonary parenchyma. As a result, the lung is injured directly by the increased pressure in the so-called spalling effect, a shearing or bursting phenomenon that occurs at gas-liquid interfaces and that may disrupt the alveolus at the point of initial contact with shock waves. The “inertial effect” that occurs when low-density alveolar tissue is stripped from heavier hilar structures as they accelerate at different rates results in both mechanical tearing and laceration of the lungs. Finally, an “implosion effect,” resulting from rebound or overexpansion of gas bubbles after a pressure wave passes, can lead to tearing of the pulmonary parenchyma from excess distention.[9,10] The parenchyma may also be injured by the displacement of fractured ribs. Subsequent hemorrhage results in bronchospasm, increased mucus production, and alveolar collapse due to decreased production of surfactant.[11]

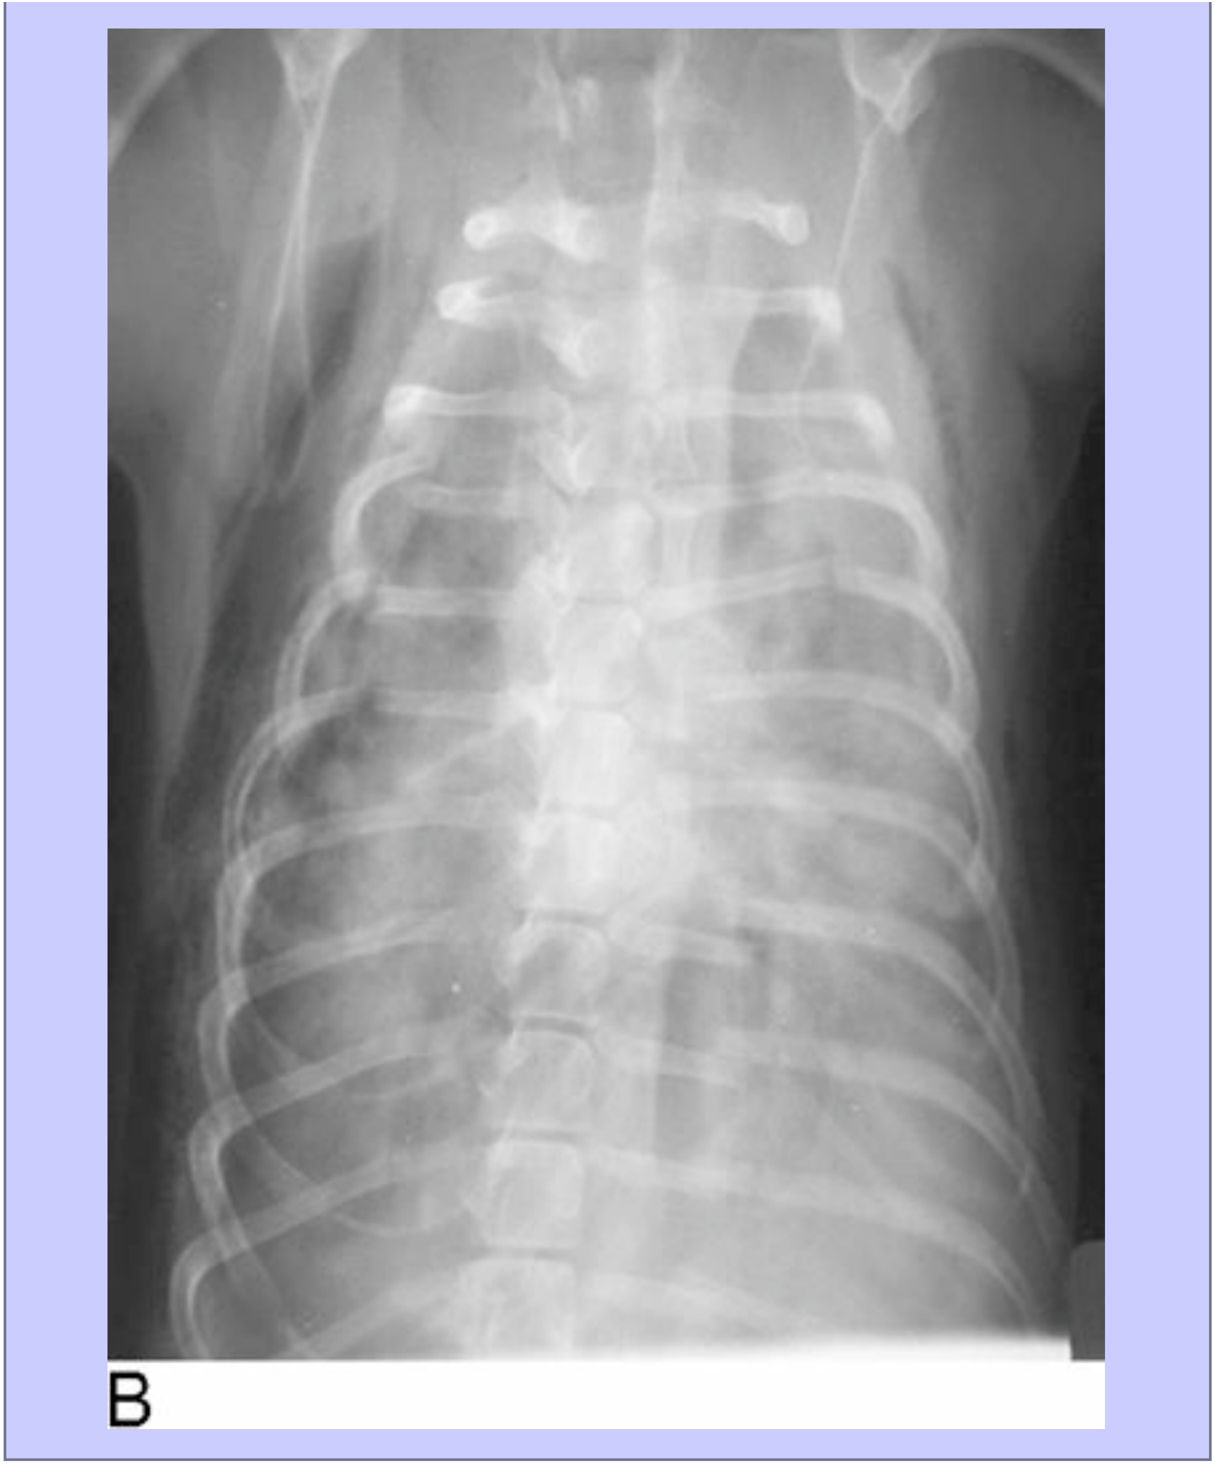
Damage to the lung leads to complex changes in respiratory function. The parenchymal damage causes ventilation-perfusion mismatch as the alveoli are flooded with blood and underventilated. There is also an increase in lung water due to the accumulation of protein-rich edema, subsequently decreasing lung compliance.[12] However, the initial vasoconstriction in response to local hypoxia (hypoxic pulmonary vasoconstriction) may be followed by a further decrease in local perfusion secondary to vascular congestion and thrombosis. This results in reduced perfusion to the unventilated lung, thus reducing the shunt fraction. The patient subsequently displays dyspnea from hypoxemia. Either hypocarbia or hypercarbia may be present depending on the severity of the contusions and the effects of concurrent injuries on ventilation.

In animals that survive the initial hours, the respiratory derangements associated with pulmonary contusions usually resolve in 3 to 7 days, but delayed deterioration may occur. Delayed clinical signs of pulmonary dysfunction may occur from complications such as bacterial pneumonia or acute respiratory distress syndrome (ARDS) secondary to the local or systemic inflammatory response.[11] The frequency of these complications has not been well described in dogs and cats. In humans, pulmonary contusions cause severe immunodysfunction both locally and systemically, and this immunosuppression is associated with a decreased survival rate if a septic insult occurs.[13]

Histologic progression of pulmonary contusions has been demonstrated in a canine experimental model.[14] Immediate interstitial hemorrhage is followed by interstitial edema and infiltration of monocytes and neutrophils during the first few hours. Twenty-four hours after injury, the alveoli and smaller airways have been filled with protein, red blood cells, and inflammatory cells. At this stage, the normal architecture has been lost and edema is severe. Alveoli adjacent to the affected region remain normally perfused, but they are less compliant due to the edema and disruption of the surfactant layer. Thus, they are poorly ventilated, which leads to an increase in ventilation-perfusion mismatch.[12,15-17] Furthermore, experimental studies in pigs have demonstrated that local pulmonary contusions may lead to generalized pulmonary dysfunction secondary to impaired surfactant activity and a subsequent decrease in alveolar diameter.[18] Forty-eight hours after injury, healing has started and the lymphatic vessels are dilated and filled with protein. The parenchyma and affected airways contain fibrin, cellular debris, granules from type II alveolar cells, neutrophils, and macrophages.[12] Another study found that within 7 to 10 days post trauma, canine lungs were almost completely healed with little scarring.[16]

Figure 25-1 Lateral **(A)** and dorsoventral **(B)** radiographs showing the characteristic appearance of pulmonary contusions. Note the diffuse alveolar pattern. It is common to see additional radiographic abnormalities, such as multiple rib fractures, subcutaneous emphysema, pneumomediastinum, and pneumothorax, as seen in this case.





B

25.4 DIAGNOSIS

25.4.1 Physical Findings

Clinically, patients have tachypnea or dyspnea dependent on the severity of the contusions and the time between injury and arrival at the veterinary clinic. Auscultation findings may be normal, or increased breath sounds and crackles can be present and may worsen over the initial 24-hour period. These abnormalities are often asymmetric or truly unilateral. Lung auscultation findings can be more difficult to interpret when concurrent conditions, such as pneumothorax, are present. Therefore frequent monitoring of respiratory rate, effort, and pulmonary auscultation is warranted. Hemoptysis (the expectoration of blood from distal to the larynx) is present in a high proportion of human patients. It appears to be an uncommon finding in small animals but is usually associated with severe lesions.

Because there is a high incidence of thoracic trauma associated with skeletal injuries and respiratory symptoms may be absent or masked initially, the clinician should maintain a high index of suspicion for contusions in any traumatized patient.

25.4.2 Imaging: Radiology and Computed Tomography

Dyspneic patients should undergo stabilization before imaging is attempted. Animals that sustain thoracic trauma may have multiple thoracic injuries, making a precise diagnosis based on the physical examination alone challenging. Imaging studies may be helpful in identifying the injuries. However, as with all dyspneic patients, the risk-to-benefit ratio of the imaging procedure should be considered carefully.

Radiographic changes in patients with pulmonary contusions consist of areas of patchy or diffuse interstitial or alveolar lung infiltrates that can be either localized or generalized (Figure 25-1). Radiographic changes may lag 106
behind clinical signs by 12 to 24 hours and therefore "normal" radiographic findings may be seen in animals 107
with pulmonary contusions. Patients with more severe radiographic changes initially may require a longer duration of oxygen supplementation and longer hospitalization times. However, the relationship between severity of the contusion based on radiographic changes and survival has not been established.[7]

Although computerized tomography (CT) has been shown experimentally to be more sensitive for detecting initial lesions and accurately reflecting the extent of the lesion than standard radiographic techniques, lack of availability and the need for sedation or anesthesia in a traumatized patient have limited its use. An experimental canine model of pulmonary contusions found that a CT scan enabled detection of 100% of the pulmonary lesions, but initial thoracic radiographs failed to visualize them. In addition, 21% were still not visible radiographically after 6 hours. Also, CT imaging underestimated the extent of the lesions in only 8% of the animals, whereas thoracic radiography underestimated the extent in 58% of the animals.[19]

25.4.3 Blood Gas Analysis and Pulse Oximetry

Arterial blood gas analysis is the most objective method for assessing and monitoring the physiologic effects of thoracic trauma (see Chapter 208, Blood Gas and Oximetry Monitoring). Clinical data in dogs reveal a high incidence of hypoxemia, however it is usually mild to moderate.[5,7] This may be because many of the most severe cases will die before arriving at the veterinary clinic. Either hypocarbia or hypercarbia may be seen, depending on the severity of the parenchymal injury, the nature of concurrent thoracic injuries, and other factors such as pain, distress, and the effect of concurrent metabolic acid-base derangements.

In humans, the arterial oxygen tension-to-fractional concentration of inspired oxygen ratio (PaO_2/FiO_2) is directly correlated with the volume of contused lung for the first 24 hours after injury, although this correlation is not consistent beyond 1 week.[20] Whether this association exists in small animal patients is unknown.

Although pulse oximetry has some limitations, it may be a useful quantitative assessment of oxygenation in cases in which an arterial blood gas analysis is not possible (i.e., cats). It is a less accurate indicator of impaired oxygenation, does not provide a measure of ventilation, and reliable measurements can be difficult to obtain in patients that are in shock. It is important to ensure that the pulse oximeter is reading an accurate pulse rate in order to acquire an accurate reading. A reading of less than 95% indicates hypoxemia and values less than 90% are consistent with severe hypoxemia.

25.5 MANAGEMENT

25.5.1 Initial Approach

Management of pulmonary contusions is supportive. Initial triage and major body system assessment should be done in any traumatized patient, and injuries should be ranked and managed based on their threat to patient life (see Chapter 2, Patient Triage). Prehospital management rarely occurs. However, the animal should be transported to the clinic lying in its preferred posture or kept in sternal recumbency if possible.

Oxygen therapy, judicious fluid therapy, and adequate analgesia are essential components of patient management.

25.5.2 Oxygen Therapy and Ventilation

Oxygen should be administered to all dyspneic patients (see Chapter 19, Oxygen Therapy). Noninvasive methods such as flow-by, nasal oxygen delivery, or oxygen cages and hoods are commonly used. In severely affected cases, intubation and ventilation may be necessary (see Chapters 213 and 214, Basic Mechanical Ventilation and Advanced Mechanical Ventilation, respectively). This decision should be made based on the severity of the dyspnea and an assessment of arterial blood gas values, if possible.

In people, pressure-controlled ventilation with positive end-expiratory pressure is the preferred method of mechanical ventilation.[21] One canine study examined 10 dogs with pulmonary contusions that required positive-pressure ventilation and found that 50% of the dogs benefited from this therapy, and animals that weighed more than 25 kg were more likely to survive.[22] Alveolar recruitment strategies and the use of low tidal volumes have been shown to increase both oxygenation and lung aeration in humans with severe chest trauma,[23] although similar studies in dogs and cats are lacking.

Other advanced ventilatory techniques such as jet ventilation, selective bronchial intubation, dual-lung ventilation, and extracorporeal membrane oxygenation may prove useful, but are not used routinely in the veterinary field.

25.5.3 Fluid Therapy

Many patients with thoracic trauma will have some degree of concurrent hypovolemic shock. The debate on optimal fluid therapy in trauma and shock has yet to be resolved, however it seems that optimizing fluid therapy to maintain adequate perfusion while avoiding overzealous administration is likely to give the best results. In any patient with multiple trauma, the clinician must prioritize treatment decisions based on which major body system is most severely affected.

As with any patient in noncardiogenic shock, several fluid options are available, and the fluid type and administration strategy chosen must take into account both the cardiovascular and pulmonary changes present (see Chapter 65, Shock Fluids and Fluid Challenge). Regardless of the type of fluid chosen, increases in pulmonary capillary hydrostatic pressure may lead to increased fluid extravasation into the alveoli and worsening of pulmonary function. The clinician should aim to optimize tissue perfusion while avoiding excessive fluid administration that could worsen the pulmonary edema and hemorrhage. Careful monitoring and tailoring of the fluid protocol to the patient are preferable to administering preset volumes and rates. Replacement crystalloids are the most economical fluids and are at least as effective as colloids for resuscitation of the patient in shock.[24,25] Despite the smaller volumes administered, hypertonic saline showed no benefit over isotonic solutions in the management of pulmonary contusions in experimental pigs.[26] Blood products and synthetic colloids may contribute to worsening pulmonary edema if they leak into the airways or interstitium. Hemoglobin-based oxygen carriers, when compared with 0.9% saline, led to poorer oxygenation and more extensive pulmonary lesions in a porcine model of pulmonary contusion and hemorrhage.[27]

In conclusion, although fluid restriction is not indicated, caution should be exercised in administering intravenous fluids to shock patients with suspected pulmonary contusions. Patients should be monitored carefully to detect any worsening of pulmonary function during fluid administration and fluid rates adjusted accordingly.

25.5.4 Analgesia

Hypoventilation due to pain secondary to concurrent injuries can be severe and should be managed proactively with analgesics (see Chapters 161 and 164, Pain and Sedation Assessment and Analgesia and Constant Rate Infusions, respectively). Ideally, drugs that cause minimal impairment of cardiac and respiratory functions should be used. Intercostal, intrapleural, and epidural analgesic administration can be used in conjunction with, or as an alternative to, systemic opioid administration.

25.5.5 Antibiotics

Based on the reported low incidence of pneumonia after pulmonary contusions (1%),[7] indiscriminate use of antimicrobial agents should be avoided to limit bacterial resistance. In the small number of patients that do develop bacterial pneumonia, antibiotic therapy should be based on culture and sensitivity results of airway cytology (see Chapter 22, Pneumonia).

25.5.6 Glucocorticoids

There are few supportive data for glucocorticoid use. Although some animal studies have shown a reduction in hypoxemia and lesion size with their use,[28] others have shown no benefit.[29] Due to their potential deleterious effects, including increased susceptibility to infection and gastrointestinal ulceration, and the lack of positive effects on outcome, these agents are not recommended in the routine management of pulmonary contusions.

25.6 PROGNOSIS AND OUTCOME

Outcome is related to the severity of pulmonary contusions as well as any coexisting thoracic and extrathoracic lesions. Survival rates of 82% have been described,[7] although the real survival rate may be lower because some of the most severely affected animals die before reaching a veterinary facility or before a diagnosis is made. Patients may require hospitalization for periods ranging from a few hours to several days, and oxygen supplementation can be required for several days to weeks.

In more severely affected patients, two retrospective studies have shown that approximately 30% of dogs requiring mechanical ventilation for contusions survived to discharge.[7,22] It is possible that newer lung-protective ventilatory strategies could improve outcomes (see Chapter 26, Ventilator - Associated Lung Injury).

Although the long-term prognosis for animals with pulmonary contusions has not been investigated, most animals that survive to discharge do not appear to have residual long-term sequelae.

25.7 ATRAUMATIC PULMONARY HEMORRHAGE

Atraumatic pulmonary hemorrhage may occur secondary to a diverse range of disease conditions (Table 25-1).

Although hemoptysis may occur in animals with pulmonary hemorrhage, it is an uncommon initial finding in small animals,[30] and pulmonary hemorrhage cannot be ruled out based on the absence of this symptom. In a population of cats undergoing airway cytologic analysis for a variety of disease conditions, pulmonary hemorrhage was identified in 63% of cases. It was not reported how many of them had hemoptysis.[31]

109

25.8 DIAGNOSTIC EVALUATION

Pulmonary hemorrhage is identified by hemoptysis or hemorrhage on cytologic samples from tracheal, bronchial, or bronchoalveolar washes. The emergency clinician must be careful to distinguish true hemoptysis from hematemesis or bleeding from a source cranial to the larynx (nasal cavity, oropharynx). When using cytology specimens, acute hemorrhage is defined by presence of red blood cells and white blood cells in proportions similar to those in peripheral blood. Platelets may be present but tend to disappear within minutes after the hemorrhagic event. Within minutes to hours, erythrophagocytosis is present within the macrophages. Considering the diverse range of differential diagnoses, a thorough and careful diagnostic evaluation including full history, diligent physical examination, as well as clinicopathologic testing and imaging may be required to reach the correct diagnosis.

Historical information that suggests certain diagnoses may include exposure to toxins such as rodenticides or animals living in or having traveled to areas with a high incidence of certain infectious diseases (e.g., heartworm or lungworm). The influence of any concurrent drug therapy should be considered, such as high doses of glucocorticoids, especially in patients that are at risk for pulmonary thromboembolism. Historical information may also be suggestive of chronic medical conditions and may guide and inform further testing. The patient's signalment may suggest an increased possibility of certain coagulopathies, such as von Willebrand disease in Doberman Pinschers.

The physical examination of animals with pulmonary hemorrhage may reveal clinical signs limited to the respiratory system including hemoptysis, dyspnea, tachypnea, cough, and abnormal auscultation findings. Auscultation findings are variable but may include focal or generalized harsh lung sounds progressing to crackles, focal muffled lung sounds corresponding to areas with consolidation or complete filling of the small airways, or wheezes. Heart murmurs or cardiac arrhythmias may also be noted and may suggest a cardiogenic cause for the pulmonary hemorrhage. However, because pulmonary hemorrhage may occur secondary to systemic disease, a full physical examination is mandatory. The presence of petechiae or ecchymoses should prompt the investigation of a bleeding disorder, whereas an elevated body temperature may suggest infectious or neoplastic disease.

Further diagnostic tests will be suggested by the patient's history and physical examination but may include a CBC, biochemical profile, coagulogram, urinalysis, and imaging techniques. An arterial blood gas analysis will provide the best evaluation of the functional impairment of the respiratory system and may reveal hypoxemia, hypocarbia (or hypercarbia in severe cases), and an increased alveolar–arterial gradient. However, in animals with suspected or confirmed pulmonary hemorrhage, arterial sampling should be avoided until clotting times and platelet numbers and function have been assessed. Animals with chronic diseases such as pulmonary neoplasia, chronic bronchitis, or pneumonia may have metabolic compensation for changes in arterial carbon dioxide tensions, whereas acutely affected animals often have uncompensated changes in acid-base status.

Thoracic radiographs may reveal an interstitial, alveolar, or mixed pattern, with a focal, patchy, or diffuse distribution. A peripheral interstitial and alveolar pattern in a young to middle-aged dog is a characteristic finding in *Angiostrongylus vasorum* infestation.[32] The cardiac silhouette may be enlarged and there might be signs of pulmonary congestion in cases of congestive heart failure or *Dirofilaria* spp infestation. If cardiac disease is suspected, echocardiography is the test of choice for characterization of the disease.

Hematology findings may be unremarkable or may show changes suggestive of the underlying diagnosis, including normocytic normochromic anemia in case of chronic disease, eosinophilia with parasitic disease, and neutrophilia with or without a left shift in cases of inflammatory disease. Platelet numbers may be normal, mildly to moderately reduced (e.g., in disseminated intravascular coagulation, angiostrongylosis, and some cases of thromboembolism), or severely reduced (e.g., in immune-mediated thrombocytopenia). If platelet numbers are adequate but petechiae are present, thrombocytopathia may be present and a buccal mucosal bleeding time should be performed (see Chapter 118, Bleeding Disorders).

Clotting times (prothrombin time and activated partial thromboplastin time) are prolonged in animals with coagulopathy. The prothrombin time is markedly prolonged in animals with anticoagulant rodenticide poisoning. Increases in fibrinogen degradation products or d-dimers may suggest pulmonary thromboembolism, although a CT scan with angiography is more definitive.[33]

A fecal Baermann analysis should be performed if *A. vasorum* or other lungworm infections are suspected. Antigen or antibody detection tests for heartworm are indicated in dogs or cats living in, or traveling to, endemic areas.

25.9 TREATMENT

Treatment will ultimately need to be directed toward the underlying disease process. If the degree of respiratory compromise is marked, it may be necessary to use supportive or empiric therapy while the diagnosis is pursued. Oxygen should be administered to any dyspneic patient, and in particular to those animals showing hypoxemia on arterial blood gas analysis or low pulse oximetry readings. If noninvasive oxygen supplementation does not restore adequate oxygen levels, severe hypercarbia is present, or if the patient displays significant dyspnea with impending fatigue, positive-pressure ventilation may be required (see Chapter 213, Basic Mechanical Ventilation). Fluid therapy should be tailored to each animal's needs based on the cardiovascular and respiratory status, as with pulmonary contusions. Analgesia and sedation should also be used when indicated by an animal's clinical status. It is often necessary to institute empiric antimicrobial therapy on the basis of a strong clinical suspicion while diagnostic test results are pending.

25.10 PROGNOSIS AND OUTCOME

Prognosis and long-term outcome will depend largely on the extent and severity of the process on admission, and on the exact nature of the cause. However, a mortality rate of up to 25%[30] has been reported in the short term, with more cases dying or being euthanized as a result of the disease in less than 6 months. It is difficult to predict whether there will be any long-term impairment of function, but this will likely depend on the underlying disease and its severity. Hence, owners should be given a grave to guarded prognosis until a definitive diagnosis is reached. 109

26 Chapter 26 Ventilator-Associated Lung Injury

Rebecca S. Syring, DVM, DACVECC

26.1 KEY POINTS

- Mechanical ventilation is often needed for support of critically ill patients with pulmonary dysfunction. However, mechanical ventilation can perpetuate or induce a form of lung injury, referred to as *ventilator-associated lung injury (VALI)*.
- VALI can occur in both healthy lungs and diseased lungs with prolonged mechanical ventilation.
- Overdistention of alveoli, often referred to as *volutrauma,* mechanical disruption of pulmonary tissues as a result of pressure, often referred to as *barotrauma,* and repetitive alveolar opening and collapse of alveoli, often referred to as *atelectrauma,* are the chief components of VALI.
- Therapeutic goals that may reduce the incidence of VALI include limited plateau pressures (<30 to 35 cm H_2O) to reduce the risk for barotrauma, limited tidal volume (≈6 ml/kg) to reduce alveolar overdistention, and positive end-expiratory pressure (PEEP) above the critical closing pressure to prevent cyclic recruitment of alveoli.

26.2 INTRODUCTION

Mechanical ventilation is being used with increasing frequency to support veterinary patients with respiratory failure secondary to impaired oxygenation or ventilation (see Chapter 213, Basic Mechanical Ventilation).[1-5] Common reasons for impaired oxygenation requiring mechanical ventilation include pneumonia, cardiogenic pulmonary edema, and acute respiratory distress syndrome (ARDS). Impaired ventilation, or the inability to eliminate carbon dioxide through the lungs, can be seen as a result of an impaired ventilatory drive secondary to intracranial disease, neuromuscular disease, or as a sequela to respiratory fatigue from increased work of breathing or severe pulmonary disease.

Two of the most common causes of respiratory failure requiring mechanical ventilation in human medicine are ARDS and acute lung injury (ALI). ARDS represents a diffuse, inflammatory pulmonary disorder resulting from a wide variety of clinical conditions, both intrapulmonary and systemic, and is clinically characterized by a sudden onset, bilateral alveolar infiltrates, an arterial-to-inspired oxygen tension ratio (PaO_2-to-FiO_2) under 200 mm Hg, and the absence of left-sided heart failure. ALI describes a similar clinical scenario, however pulmonary dysfunction is marginally better, with PaO_2-to-FiO_2 ratios of 200 to 300 mm Hg. These syndromes have been recognized in both dogs and cats with naturally occurring disease (see Chapter 24, Acute Lung Injury and Acute Respiratory Distress Syndrome).[6-8] Although mechanical ventilation is vital for the support of respiratory function in patients with ARDS and other causes of respiratory failure, mechanical ventilation itself can potentiate or even induce lung injury.

26.3 VENTILATOR-INDUCED LUNG INJURY AND VENTILATOR-ASSOCIATED LUNG INJURY

Ventilator-induced lung injury (VILI) is characterized by increased capillary permeability, pulmonary edema, cellular injury, and diffuse structural damage to alveoli that is clinically indistinguishable from the damage that occurs in ARDS. For this reason, the term *VILI* is often restricted to describe pulmonary changes as a result of mechanical ventilation in experimental animal models. Ventilator-associated lung injury (VALI) describes a lung injury resembling ARDS that develops or worsens during the course of mechanical ventilation in clinical patients—this injury can only be associated with ventilation, rather than saying that it is definitively caused by ventilation, because the underlying disease process may be responsible for progression of lung injury.[9] During the past decade, positive-pressure ventilation strategies have evolved based on experimental evidence of VILI and clinical trials studying the effects of ventilator management on VALI.

The role that positive-pressure ventilation plays in perpetuating lung injury is easiest to appreciate in studies of human patients who do not have ALI or ARDS at the onset of therapy. One study evaluated 332 human patients who did not fit the criteria for ALI prior to the onset of more than 48 hours of mechanical ventilation. In this study, 24% of these patients went on to develop ALI during the course of mechanical ventilation. Two of the risk factors identified for VALI in this study included larger day 1 tidal volumes (above 6 ml/kg) and a history of restrictive pulmonary disease which would result in reduced pulmonary compliance. Interestingly, larger tidal volumes were more likely to be used in presumed lower risk patients: those who were ventilated postoperatively, had lower predicted mortality rates, or had better gas exchange and pulmonary mechanics.[10] This emphasizes that ventilation, be it manual or mechanical, and the risk for VALI should never be taken lightly in any patient population.

26.4 PRIMARY CAUSES OF VALI

26.4.1 Barotrauma

The term *barotrauma* refers to the mechanical disruption of tissues as a result of pressure.[11] Pulmonary barotrauma occurs when excessive positive pressure accumulates within the proximal airways and ultimately alveoli, resulting in alveolar membrane rupture and accumulation of free air within the pleural space. During positive-pressure ventilation, pneumothoraces can progress rapidly, because the positive distending pressure promotes air leakage into the pleural space, and the air cannot escape when the thoracic cavity is closed. Left unmanaged, excessive intrapleural pressure develops and impairs not only pulmonary expansion and gas exchange, but also impedes venous return to the heart. Tension pneumothorax refers to a life-threatening condition in which respiratory and cardiac function are both significantly compromised as a result of elevated intrathoracic pressure from the accumulation of free air in the pleural space.

Prior to lung-protective ventilatory strategies, the incidence of barotrauma was as high as 40% to 60% in mechanically ventilated humans[12] and was reported in 50% of dogs with clinical symptoms of ARDS.[6] Since the advent of lung-protective ventilatory strategies in human patients with ARDS, barotrauma occurs much less frequently, ranging from 6% to 14%.[12] This lower incidence has been associated with the underlying disease process, with patients who have suffered multiple trauma and patients with reduced pulmonary compliance (<30 ml/cm H_2O) who are at greater risk for developing a pneumothorax after the onset of mechanical ventilation.[12] A study in cats requiring ventilatory support for a variety of reasons reported a 28% incidence of barotrauma, approximately half of which occurred despite peak inspiratory pressures below 25 cm H_2O.[1] A larger, more recent study in dogs and cats requiring mechanical ventilation for a variety of reasons reports the lowest incidence of barotrauma (6.6%).[1,4] This may represent adaptations of ventilatory strategies in veterinary medicine toward more lung-protective ventilation; however, because this study was not limited to patients with ARDS, it is difficult to compare it with previous studies.

26.4.2 Volutrauma

Volutrauma refers to lung injury occurring secondary to alveolar overdistention. Although volutrauma eventually can result in elevated airway pressures and air leak, lung injury can occur when barotrauma is absent. Instead, elevated transpulmonary pressure and alveolar overdistention can result in more subtle injuries to alveolar endothelial and epithelial cells. These changes include ultrastructural breaks in the cell membranes, intraalveolar hemorrhage, hyaline membrane formation, alveolar collapse, and proliferation of type II pneumocytes. Ultimately this results in increased permeability and high-protein pulmonary edema. In addition, capillary blood flow to the alveoli may be compromised secondary to excessive airway distention.

26.4.3 Atelectrauma

Atelectasis of dependent alveoli, which is relatively common in patients with ALI and ARDS, results in reduced functional residual capacity of the lungs. If collapsed alveoli are not recruited (opened up) during ventilation, when a set tidal volume is delivered it is distributed to a smaller portion of the lung, increasing the risk for volutrauma to open alveoli. Alternatively another component of VALI, referred to as *atelectrauma,* can occur if collapsed alveoli are recruited during inspiration but allowed to collapse during expiration (derecruitment). Atelectrauma has also been referred to as *cyclic recruitment, tidal recruitment,* and *repetitive alveolar collapse and expansion*.

The alveoli within and adjacent to atelectatic lung are subjected to excessive shearing forces in order to open these alveoli during ventilation.[13] These shearing forces and the cyclic recruitment and collapse of alveoli induce inflammatory mediator release within the lungs,[14] which can increase capillary leak and pulmonary edema, induce inflammatory cell influx, and upregulate the systemic inflammatory response.

26.5 VENTILATOR STRATEGIES TO AVOID VALI

The primary risk factor for barotrauma during mechanical ventilation is excessive proximal airway pressure. The incidence of barotrauma increases as higher plateau airway pressures are applied. Therefore efforts should be made to use the lowest plateau pressure that maintains oxygenation and ventilation within an acceptable range. When a cutoff of 35 cm H_2O was used as a plateau pressure, the risk for barotrauma was dramatically reduced in a review of data on ventilated humans.[12] With more severe pulmonary disease compliance often decreases, resulting in higher airway pressures for a given tidal volume. In order to avoid excessive airway pressures, alterations in other ventilator settings such as respiratory rate, PEEP, and inspiratory-to-expiratory ratio may be necessary to maintain oxygenation and ventilation at an acceptable plateau pressure (see Chapters 213 and 214, Basic Mechanical Ventilation and Advanced Mechanical Ventilation, respectively).

The risk for barotrauma also applies to manual ventilation during general anesthesia, a scenario in which detailed pulmonary function monitoring is uncommon. Care should be taken to avoid pressure accumulation in the anesthetic circuit either by keeping the pop-off valve open or by reducing oxygen flow rates (10 to 15 ml/kg/min) when the pop-off valve is partially or fully closed during low-flow anesthesia. In addition, during manual breaths one should pay attention to the maximum airway pressure generated in the anesthetic circuit. Airway pressures should not exceed 25 to 30 cm H_2O. If oxygenation cannot be maintained at or below this pressure, PEEP should be applied to recruit alveoli and minimize the need for higher airway pressures whenever possible.

Paying close attention to the absolute tidal volume delivered with volume-controlled ventilation or relative tidal volume with pressure-controlled ventilation is warranted. Limited tidal volume strategies reduce mortality in lung-injured patients, likely as a result of reduced overdistention and volutrauma. A large prospective clinical trial in human patients with ALI demonstrated that low tidal volume (6 ml/kg) ventilatory strategies reduced mortality rates by 22% compared with conventional tidal volumes of 12 ml/kg.[15]

One of the most common ventilator strategies for preventing atelectrauma is PEEP. Maintenance of expiratory pressures above the critical closing pressure (where alveolar collapse occurs) helps to maintain lung recruitment through all phases of the respiratory cycle and limit shearing injury.[16] An experimental study that compared equivalent tidal volume ventilation with and without PEEP demonstrated that PEEP helped to reduce the inflammatory response in the lungs.[14] To date, the use of high levels of PEEP to keep the lung open has not been shown to improve outcome in ARDS. A large prospective study showed no difference in outcome when low (8 cm H_2O) versus high (13 cm H_2O) levels of PEEP were used in humans with ARDS.[17]

Thus lung-protective ventilatory strategies focus on tidal volume reduction, with a goal of 6 ml/kg compared with traditional recommendations of 10 to 15 ml/kg, and limitation of peak airway pressures to the lowest value possible to maintain oxygenation, optimally below 30 to 35 cm H_2O (see Chapter 214, Advanced Mechanical Ventilation). Despite lack of clinical evidence, there is still a strong feeling that using PEEP to maintain alveolar recruitment throughout the ventilatory cycle is beneficial. One human clinical study, which used a variation of the aforementioned criteria, demonstrated a marked reduction in 28-day mortality and improved ability to wean patients from the ventilator in patients with ARDS.[18] Experimental studies suggest that manipulation of exhalation times, by altering respiratory rate[19] or inspiratory-to-expiratory ratios,[20] may provide an alternative method to maintain alveolar recruitment and avoid atelectrauma.

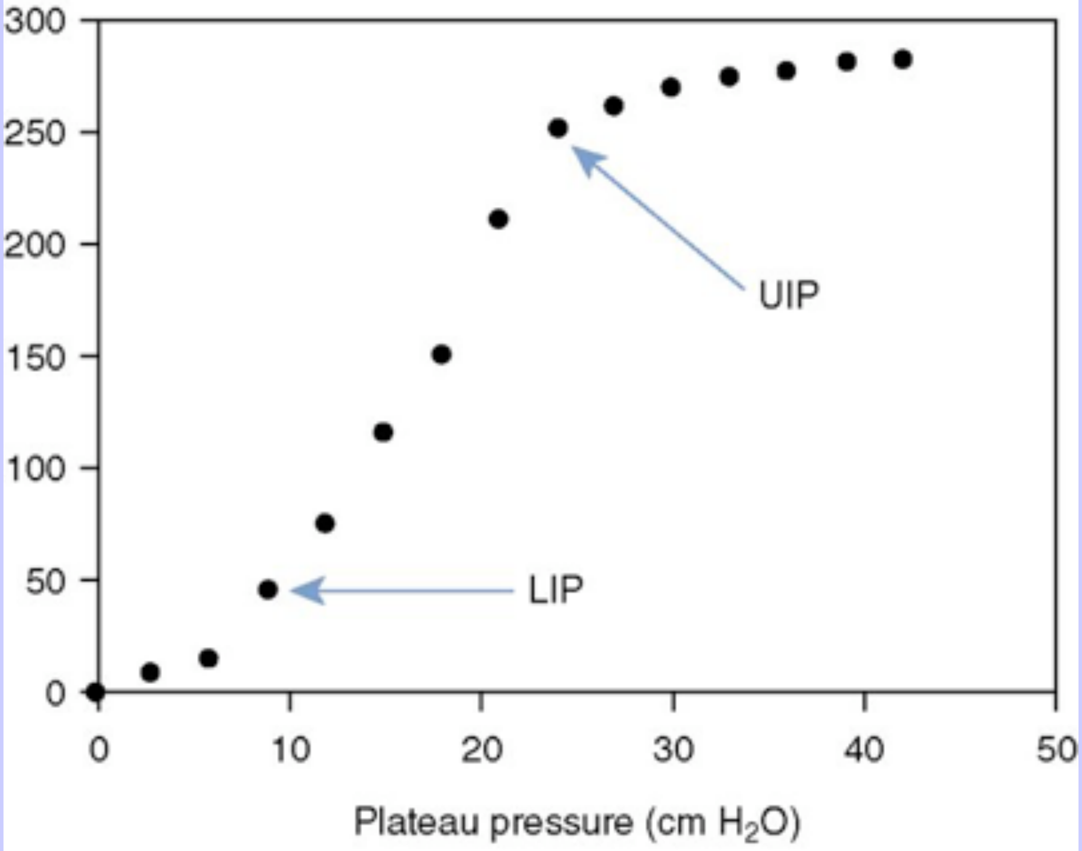
26.6 MONITORING TO REDUCE VALI

Barotrauma can be difficult to recognize initially in the ventilated patient. Auscultation of the thorax may reveal dull lung sounds. Palpation of the neck may reveal subcutaneous emphysema in cases with large-airway rupture; however, this finding will not be present when the rupture occurs within the alveoli. Cardiovascular instability, particularly tachycardia and hypotension, will occur when intrapleural pressure is sufficient to tamponade venous return to the heart. Hypoxemia and hypercarbia are late findings in patients with pneumothoraces. A spirometer that measures both inspiratory and expiratory tidal volumes may detect expiratory tidal volumes that are significantly lower than inspiratory tidal volumes, suggesting air leakage into the pleural space and pneumothorax.

Pulmonary function monitors that are inserted at the patient's airway and measure pressure and volume provide more reliable information about tidal volume delivery than do monitors located within the ventilator. This is because ventilator tubing compliance can lead to an overestimated tidal volume when measured at the ventilator. Depending on the mode of ventilation used, changes in pulmonary compliance will alter either tidal volume or peak airway pressures. For example, with pressure-controlled ventilation, changes in pulmonary compliance alter the tidal volume delivered for a ventilator breath; however, changes in compliance alter peak airway pressures with volume-controlled ventilation. With either mode of ventilation care should be taken to monitor serial changes in tidal volume and peak airway pressures to limit the risk for volutrauma and barotrauma.

Static pressure-volume (PV) curves have been recommended as a clinical tool to adjust ventilator settings to reduce the risk for VALI. Theoretically, PV curves provide valuable information about alveolar distention and recruitment, which should reduce the risk for both volutrauma and atelectrauma, respectively. Measurement of the PV curve involves incrementally increasing airway pressure over a wide range and measuring the tidal volume achieved for each step change (Figure 26-1). The upper inflection point on the inflation curve, denoted by limited changes in tidal volume despite continued increases in pressure, is thought to reflect the point above which overdistention and volutrauma occur. The lower inflection point on the inflation curve, denoted by the point at which a rapid increase in tidal volume occurs as pressure increases, is thought to reflect the pressure at which atelectatic lung is recruited. 21

Figure 26-1 A static pressure-volume curve. Airway pressure is incrementally increased over a wide range. At each pressure the resultant tidal volume is recorded. The lower inflection point represents the airway pressure at which increases result in linear increases in tidal volume. The upper inflection point represents the airway pressure at which increases in pressure no longer result in marked increases in tidal volume. *LIP,* Lower inflection point; *UIP,* upper inflection point.



The upper and lower inflection points on the PV curve may aid in setting peak airway pressure and tidal volume, and PEEP, respectively. However, these points should not be interpreted as precise pressures above or below which alveoli can be recruited. Controversy exists as to whether the upper and lower inflection points on the inflation curve accurately represent the points at which overdistention during inhalation and derecruitment during exhalation occur. Thus, newer recommendations include the use of incremental PEEP trials at set tidal volumes or determining the lower inflection point, or critical closing pressure, based on an exhalation PV curve to set optimal PEEP.[22,23] Use of the PV curve to select ventilator settings in a study of human patients with ARDS demonstrated reduced inflammatory mediators in bronchoalveolar lavage fluid, which may indicate reduced VALI, compared with control settings.[24] Despite the theoretic benefits, PV curves are used infrequently in many clinical human and veterinary patients because they are technically difficult to perform safely and their interpretation is not straightforward in many cases.

Direct monitoring of volutrauma and atelectrauma is technically difficult to impossible in the clinical patient. Tools that directly monitor overdistention (such as dynamic CT scanning) or cyclic recruitment of atelectasis (such as dynamic CT scanning, electrical impedance tomography, fast-responding intraarterial oxygen probes, and subpleural vital microscopy) have either limited clinical availability and financial limitations[25,26] or can be used only in the experimental setting.[19,27] Bedside techniques such as electrical impedance tomography may provide useful clinical tools for limiting VALI if they can be shown to help clinicians adjust ventilator settings in order to optimize alveolar recruitment while limiting cyclic collapse and overdistention. Additionally, the NICO machine (Novametrix Medical Systems Inc., Wallingford, CT) integrates airway flow and mainstream capnography to give the volume of carbon dioxide eliminated through the lungs per minute, also known as volumetric carbon dioxide. This measurement may be useful in determining optimal PEEP by detecting derangements in diffusion or ventilation that may occur secondary to overdistention, but the value can also be affected by changes in circulation, perfusion, or metabolism.[28] Further research in dogs is warranted.

27 Chapter 27 Pulmonary Thromboembolism

Lynelle R. Johnson, DVM, PhD, DACVIM

27.1 Box 27-1 Disorders Associated With Pulmonary Thromboembolism

- Immune-mediated hemolytic anemia
- Neoplasia
- Sepsis
- Protein-losing nephropathy and enteropathy
- Cardiac disease
- Hyperadrenocorticism
- Central catheter use
- Hemodialysis
- Total parenteral nutrition
- Hip replacement surgery
- Trauma

27.2 KEY POINTS

- Pulmonary thromboembolism (PTE) is a challenge to diagnose antemortem.
- PTE is a complication of diseases associated with hypercoagulability, endothelial damage, and stasis of blood flow.
- Identification of risk factors for PTE and disease associations is important for clinical recognition of this complication.
- Diagnostic results that can be used to support a diagnosis of PTE in a patient include positive D-dimer concentrations, echocardiographic detection of echogenic material in the pulmonary artery or evidence of acute right ventricular overload, and perfusion deficits on nuclear scintigraphy.
- Therapy for PTE includes management of the primary condition, support of oxygenation, and limitation of further growth of the clot with anticoagulants or thrombolytic agents.
- PROPHYLAXIS against thromboembolic complications should be considered in animals hospitalized with serious disease syndromes that have been associated with PTE.

27.3 INTRODUCTION

Obstruction of the pulmonary vascular bed can occur through blockage with fat, septic emboli, metastatic neoplasia, parasites (*Dirofilaria* or *Angiostrongylus*), or blood clots. It is likely that PTE results most commonly from formation of clot material (in the right side of the heart or at a distant site in the venous system) that breaks free and lodges in the pulmonary vasculature. Thrombosis in situ may also occur in association with pulmonary hypertension, heartworm disease, or other disorders of the pulmonary vasculature. PTE is likely as underdiagnosed in the veterinary population as it is in human medicine. Thrombi undergo 50% reduction in clot volume in the first 3 hours postmortem due to fibrinolytic dissolution; with heparin administration, clot volume is further reduced due to inhibition of further clot formation.[1] Thus necropsy confirmation of PTE can be difficult.

Antemortem clinical recognition of PTE is low because clinical signs and physical examination findings mimic those found in a variety of cardiopulmonary conditions. In an early report, PTE was a differential diagnosis for respiratory distress in less than 5% of dogs with PTE confirmed at necropsy.[2] In a more recent study,[3] PTE was suspected in 65% of dogs that had relevant respiratory signs and a recognized predisposing condition for thromboembolism, suggesting increased awareness of the condition. In dogs, immune-mediated hemolytic anemia, sepsis, neoplasia, amyloidosis, hyperadrenocorticism, and dilated cardiomyopathy are associated with increased risk for PTE, and neoplasia and cardiomyopathy are found most often in cats with PTE.[3,5]

As has been shown in human and veterinary studies, most veterinary cases have comorbid conditions complicating the primary clinical disease and potentially increasing the risk for thromboembolism. Because PTE is associated with nonspecific clinical symptoms such as tachypnea or difficulty breathing, knowledge of predisposing conditions (Box 27-1) is important for appropriate diagnosis and treatment.

27.4 PATHOPHYSIOLOGY

The key pathophysiologic responses to PTE include alterations in hemodynamics due to increased pulmonary vascular resistance, abnormalities in gas exchange, altered ventilatory control, and derangements in pulmonary mechanics. Rarely, pulmonary infarction contributes to the clinical picture. The pulmonary circulation is normally resistant to changes in blood flow that occur with vascular obstruction because distention of the elastic vasculature allows the pulmonary bed to accept the increase in flow from embolized regions without a change in pressure. However, vascular obstruction from embolization results in both physical obstruction and arterial vasoconstriction due to release of vasoactive mediators. The combination of these events causes a reduction in the cross-sectional area of the pulmonary circulatory bed and increased vascular resistance.

PTE results in hypoxemia primarily from ventilation–perfusion (V/Q) mismatch, although physiologic shunting and reduced diffusion capacity also contribute to reduced arterial oxygen content. Hypoxemia can be present with as little as 13% obstruction of the vascular bed in humans,[6] suggesting that even minor embolic disease is physiologically relevant. The severity of hypoxemia will be affected by underlying cardiopulmonary disease, reflex bronchoconstriction, and atelectasis. In the normal lung, most lung units have a V/Q ratio of 1; however, PTE causes a redistribution of blood flow, resulting in a wide spectrum of high, normal, and low V/Q units. Low V/Q units are the most important contributor to hypoxemia. As the degree of vascular obstruction exceeds 50% of the surface area of the circulatory bed, intrapulmonary shunting occurs, leading to venous admixture of blood and decreased oxygen responsiveness.[7]

Ventilation is controlled by the interaction between the sensors activated by elevated carbon dioxide in the central nervous system (CNS) and decreased partial pressure of arterial oxygen (PaO_2) in the periphery with the responders (respiratory muscles). PTE is associated with tachypnea and alveolar hyperventilation, although the mechanisms responsible for hyperventilation remain obscure. Platelet aggregation with release of humoral mediators and cytokines could activate C fibers and irritant receptors to effect breathlessness. Also, embolization of additional organs often occurs,[3,8] and obstruction of blood flow in the CNS could affect ventilatory control.

Changes in lung mechanics are likely important contributors to tachypnea, because increased resistance and decreased compliance greatly affect the work of breathing. Experimental studies in dogs have documented increased airway resistance following PTE; 5-hydroxytryptamine likely mediates this bronchoconstriction.[9] Lung compliance is reduced in patients with PTE because of pulmonary edema and atelectasis. Pulmonary edema appears to result from increased hydrostatic pressure associated with increased blood flow to nonembolized lung regions and from release of humoral factors that increase microvascular permeability.

27.5 HISTORY AND CLINICAL SIGNS

Historical features consistent with PTE included labored breathing, tachypnea, lethargy, and altered neurologic status. Additional clinical signs that may be observed include cough, syncope, and hemoptysis. Altered mental state is reported in 20% of human patients with PTE and may be related to transient hypoxemia or cerebral ischemia. In a report in dogs, abnormal neurologic status was recorded in over one third of affected animals[3] and thus may be a common finding with PTE. Importantly, obvious respiratory distress and tachypnea may be absent in some dogs or cats that have pulmonary embolization documented during necropsy.

Information regarding concurrent disease processes is essential to determine the risk of embolization for animals. In dogs with a variety of clinical syndromes leading to PTE, intravenous catheters had been placed in most, exogenous glucocorticoid excess was reported in half, use of cytotoxic agents was found in over one third, 21% had undergone recent surgical procedures, and 10% of dogs had been given blood transfusions.[3]

27.6 PHYSICAL EXAMINATION

Dogs with PTE typically demonstrate tachypnea or hyperpnea. Physical findings potentially consistent with PTE include labored breathing or tachypnea, tachycardia, and adventitious lung sounds (crackles or wheezes). Alternatively, lung and heart sounds may be damped because of pleural effusion. Cardiac murmurs are not uncommon in dogs or cats due to underlying cardiac pathology (particularly cardiomyopathy in cats) or pulmonary hypertension.

27.7 DIAGNOSTIC TESTING

The history of a disease association along with the acute onset of tachypnea and labored respirations is highly suspicious for pulmonary embolization; however, proving the presence of embolic disease antemortem is challenging. Routine laboratory work (complete blood count and chemistry profile) is submitted to investigate the underlying disease. Suspected risk factors for PTE identified in dogs with immune-mediated hemolytic anemia included high serum bilirubin levels, multiple intravenous catheters, and multiple blood transfusions.[4] Because urinary protein loss is a risk factor for PTE, a urinalysis is an essential part of routine screening. A urine protein-to-creatinine ratio over 0.5 is abnormal, and in animals with substantial urinary protein loss, an antithrombin level should be investigated. Concentrations less than 50% of 75% of normal are considered indicative of hypercoagulability and thus an increased risk for embolic complications.

Assessment of D-dimer concentration has been recommended to exclude PTE as a diagnosis when the test result is negative, or to increase the likelihood that embolization is present when a high titer is detected.[10] D-Dimer is a degradation product of fibrin that has undergone cross-linkage. It is more specific for fibrin formation than the standard fibrin degradation products test, which detects both fibrin and fibrinogen breakdown products. Unfortunately, many diseases in veterinary medicine result in elevation of D-dimer, and a negative test result does not exclusively rule out thromboembolism. A recent study in human medicine evaluating the accuracy of D-dimer testing versus location of embolus reported that a negative D-dimer result could be used to rule out most (93%) of large pulmonary emboli but only half of the subsegmental emboli.[11]

Arterial blood gas analysis generally reveals hypoxemia, hypocapnia, and a widened alveolar-arterial (A-a) gradient in most patients assessed. Calculation of the A-a gradient corrects for the contribution of alveolar hypoventilation to arterial hypoxemia but does not differentiate V/Q mismatch from other causes of hypoxemia. The A-a gradient is measured by the following formula using data obtained from an arterial blood gas.

$$(A - a) = PAO_2 - PaO_2$$

$$PAO_2 = \left[FiO_2 \left(P_b - P_{H_2O} \right) - PaCO_2 \middle/ RQ \right]$$

where FiO_2 = fraction of inspired oxygen, P_b = barometric pressure (760 mm Hg at sea level), PH_2O = water vapor pressure at a given body temperature (47 mm Hg), and RQ = respiratory quotient (0.8 to 1.0). The normal A-a is considered less than 10 to 15 mm Hg when the subject is breathing room air. Unfortunately the normal A-a in patients breathing supplemental oxygen cannot be defined accurately.

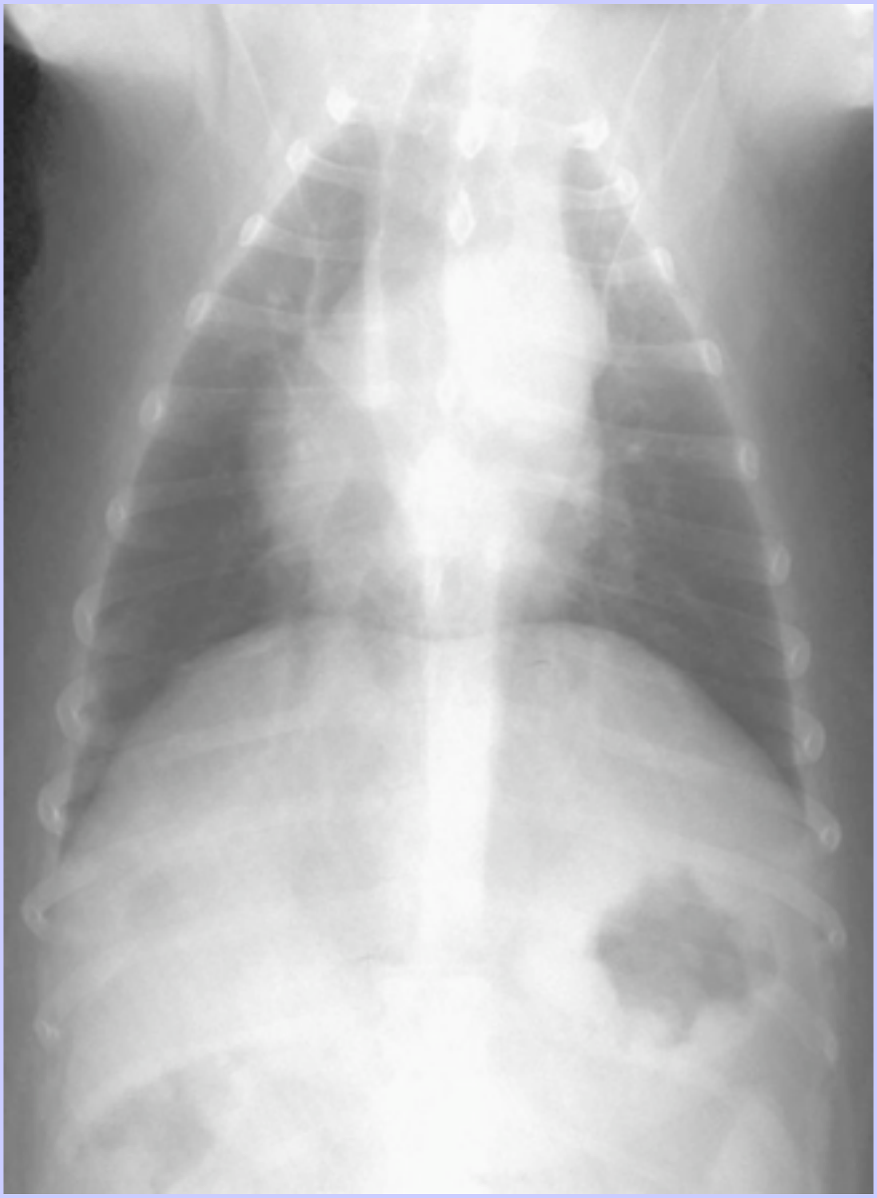
Arterial blood gas analysis during oxygen supplementation provides information on the potential mechanism underlying hypoxemia but does not help determine prognosis for recovery. A positive response to exogenous oxygen supplementation suggests that V/Q mismatching is the primary pathophysiologic event responsible for hypoxemia. A negative response suggests that intrapulmonary shunting or pulmonary infarction may be present.
Trends in oxygen responsiveness can be followed by calculating the oxygenation ratio (OR), also known as the PF 115
ratio, for PaO_2-to-FiO_2 ratio. This value is calculated by dividing the PaO_2 by the FiO_2. Normal values should 116
exceed 450 mm Hg.

Radiographs may help elucidate the underlying disease responsible for embolization or can reveal abnormalities associated with vascular obstruction (Figure 27-1). Previously reported thoracic radiographic abnormalities associated with PTE in dogs include pleural effusion, loss of definition of the pulmonary artery, alveolar infiltrates, cardiomegaly, hyperlucent lung regions, and enlargement of the main pulmonary artery.[12] Interstitial or alveolar infiltrates can represent focal or diffuse edema associated with overperfusion or atelectasis. Normal chest radiographic findings do not rule out the possibility of pulmonary thromboembolization, and normal findings in a patient with dramatic tachypnea and respiratory distress should be considered highly suspicious for PTE.[3]

Echocardiography can be considered a diagnostic modality for noninvasive assessment of the pulmonary vasculature. Clots occasionally can be seen in the right atrium or pulmonary arteries, or signs of acute right ventricular overload may be evident, such as right ventricular hypokinesis or dilation, abnormal septal motion, or tricuspid regurgitation. In human medicine, echocardiographic changes of right ventricular dilation, paradoxic septal motion, and increased velocity of tricuspid regurgitant jet are evident in most patients with clinically relevant pulmonary embolization.[13]

Definitive diagnosis of pulmonary embolization requires selective pulmonary angiography. Contrast angiography during computed tomography might also be employed; however, both techniques require anesthesia in veterinary patients. Nonselective pulmonary angiography can sometimes elucidate regions of absent vascular supply, but dilution of contrast medium can make this study difficult to interpret. V/Q scans have compared favorably with angiography for diagnosis of PTE in human and veterinary patients and are less invasive.[14] The utility of V/Q scans is limited in the veterinary clinical setting because the ventilation phase of the study is usually done under anesthesia to ensure adequate deposition of radioactive gas throughout the airways. Perfusion scanning, using technetium-labeled macroaggregated albumin, is a less invasive tool that can be performed without anesthesia. This diagnostic tool can reveal regions with absent radioactivity due to loss of pulmonary blood supply from embolization (Figure 27-2). In human medicine, a normal perfusion scan virtually excludes pulmonary embolization while an abnormal perfusion scan may reflect PTE or a variety of pulmonary conditions including pneumonia, atelectasis, edema, or contusions. The utility of perfusion scans for excluding PTE has not been evaluated in veterinary medicine.

Figure 27-1 Dorsoventral radiograph of the dog whose scan is displayed in Figure 27-2. Note the subtlety of the changes. The artery to the right caudal lung lobe appears to terminate abruptly at the eighth intercostal space. There is mild enlargement of the main pulmonary artery, but the cardiac silhouette is unremarkable. Lung fields are essentially unremarkable, with the exception of a focal area of interstitial opacity at the periphery of the right caudal lung lobe. (Courtesy Dr. Narelle Brown, University of California, Davis.)

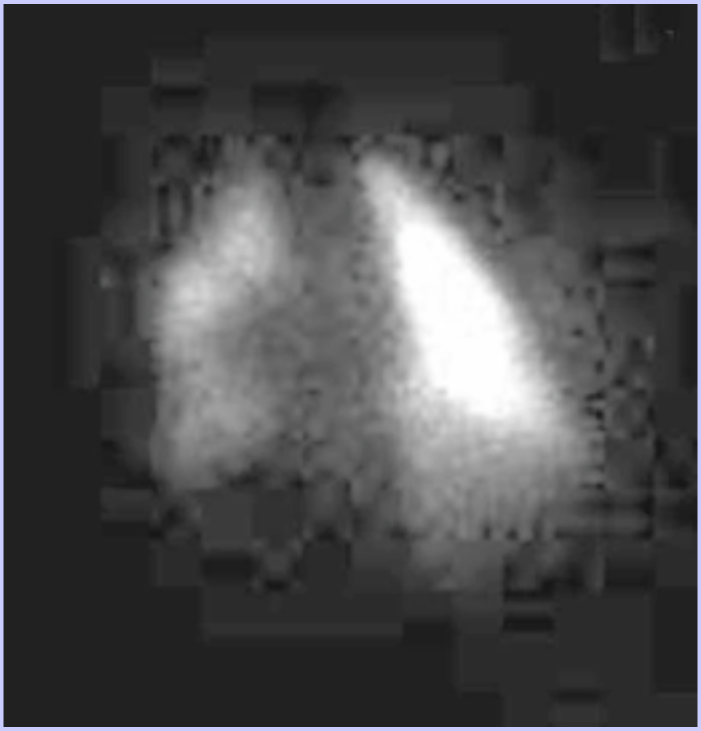


27.8 TREATMENT

Treatment and stabilization of the underlying condition should be initiated in order to limit further thrombus formation and subsequent embolization. Oxygen therapy is essential to reverse hypoxemia associated with V/Q mismatching and diffusion impairment. It is important to note that the degree of improvement in PaO_2 in response to exogenous oxygen supplementation will depend on the percentage of the vascular bed that is obstructed, the concentration of inspired oxygen administered, the distribution of V/Q mismatching across the lung, and the degree of shunting that is present.

Definitive therapy of pulmonary emboli through thrombolysis is possible but rarely is performed clinically because of the difficulty in establishing an antemortem diagnosis with conviction, as well as the side effects and costs of thrombolytic drugs. Primary drawbacks of thrombolytic therapy are induction of a hemorrhagic state and ischemia-reperfusion injury in the lung. Thrombolysis can be achieved with streptokinase, an enzyme that activates plasminogen conversion to plasmin. This drug has been used successfully for treatment of systemic embolization in the dog.[15] It is administered as an intravenous infusion at a loading dose of 90,000 U over 20 to 30 minutes, then 45,000 U over 3 to 7 hours. Clotting parameters must be followed throughout the course. Alternatively, tissue plasminogen activator can be used to cause direct fibrinolysis at the site of the clot. This drug directly activates plasmin within the clot and thus has fewer systemic side effects. Cost is substantial, and use of this drug has not been reported in animal pulmonary embolization.

Figure 27-2 Nuclear scintigraphy using technetium 99m–labeled macroaggregated albumin. This ventral view reveals a large perfusion deficit in the region of the right caudal lung lobe.



Anticoagulation with heparin and warfarin therapy can also be employed. Heparin therapy is instituted for 3 to 4 days before starting warfarin to avoid induction of a hypercoagulable state through inactivation of the natural anticoagulant, protein C, with warfarin therapy. Unfractionated heparin can be administered at 200 to 400 U/kg SC q6-8h to prolong activated partial thromboplastin time three-fold to four-fold. Alternatively, low-molecular-weight heparin preparations (enoxaparin, dalteparin) can be used. This class of drugs has more predictable pharmacokinetics in human medicine, and has enhanced factor Xa to IIa activity, which avoids the need for repeated testing of coagulation panels. Dosages are often extrapolated from human dosages. After heparinization, warfarin therapy can be started. Initial dosage recommendations are 0.5 mg per day in the cat or 0.1 mg/kg q24h in a dog. The goal of warfarin therapy is to prolong the one-stage prothrombin time (OSPT) to give an international normalized ratio (INR) of 2 to 3. The INR is calculated by:

$$\mathrm{INR} = (\text{patient OSPT} \;/\; \text{control OSPT})^{\mathrm{ISI}}$$

The ratio of patient-to-control OSPT is raised to the power of the ISI, the international sensitivity index of the thromboplastin in the kit used to determine the OSPT. This value is found in the instruction manual supplied by the kit manufacturer. Warfarin therapy is greatly complicated by individual differences in bioavailability, interference of metabolism by other drugs, the need for frequent monitoring of clotting times, and the risk of hemorrhage.

Newer platelet-inhibiting drugs such as clopidogrel and ticlopidine, which inhibit platelet aggregation, and fondaparinux, an inhibitor of thrombin, are under investigation for use in treatment or prevention of thromboembolism.

27.9 PROPHYLAXIS

In animals considered at risk for embolization, prophylaxis should be considered. Appropriate drugs that can be used include heparin, low-molecular-weight heparin, or aspirin; warfarin can also be used. Heparin can be administered at low dosages (75 to 100 U/kg SC q8h) that do not alter clotting times and thus do not require repeated monitoring. Aspirin must be dosed at a very low level to inhibit platelet production of thromboxane A_2 (a potent platelet aggregator) while maintaining endothelial production of prostacyclin (a vasodilator). In dogs a dosage of 0.5 mg/kg q12h is recommended, while in cats 25 mg/kg q72h has been suggested.

27.10 SUMMARY

Pulmonary thromboembolization is often a devastating consequence of an already serious illness. Treatment of the primary condition and supportive care during recanalization of the clot can be successful, however the possibility of further embolization exists. Prophylaxis for PTE should be considered in animals predisposed to embolic complications.

28 Chapter 28 Smoke Inhalation

Shailen Jasani, MA, VetMB, MRCVS

Dez Hughes, BVSc, MRCVS, DACVECC

28.1 KEY POINTS

- The lack of clinical veterinary information on smoke inhalation likely reflects a very high incidence of preadmission mortality. Hypoxia from carbon monoxide poisoning is presumed to be the most common cause of acute death.
- Direct thermal injury to the upper respiratory tract can cause laryngeal obstruction. Lower respiratory tract injury from irritant gases and superheated particulate matter can result in atelectasis, pulmonary edema, decreased lung compliance, and acute respiratory distress syndrome.
- Bacterial bronchopneumonia typically occurs later in the course of the condition and is usually secondary to therapeutic interventions or sepsis.
- Acute neurologic dysfunction may be seen initially or as a delayed syndrome.
- Significant dermal burn injury exacerbates morbidity and mortality.
- Aggressive oxygen supplementation is the immediate priority to hasten carbon monoxide elimination. Supportive measures for respiratory and neurologic complications follow.
- If carbon monoxide poisoning resolves, the prognosis is good in the absence of significant dermal burn injury, bronchopneumonia, or acute neurologic signs.

28.2 INTRODUCTION

A significant number of dogs and cats are likely to be involved in residential fires each year, yet there is very little information available regarding clinical cases. Most information is derived from experimental animal studies or extrapolated from the human literature. This dearth of clinical veterinary information is most likely due to a very high incidence of preadmission mortality.

28.3 PATHOPHYSIOLOGY

28.3.1 Carbon Monoxide

Carbon monoxide (see Chapter 87, Carbon Monoxide) is a nonirritant gas that competitively and reversibly binds to hemoglobin at the same sites as oxygen, with an affinity that is 230 to 270 times greater and results in marked anemic hypoxia.[1,2] It is produced by incomplete combustion of carbon-containing materials and is therefore most significant in enclosed fires as there is increasingly less oxygen available.[3] The resultant carboxyhemoglobin (COHb) also shifts the oxygen-hemoglobin dissociation curve to the left, resulting in less offloading at the tissue level.[1] There are three possible outcomes in pure, uncomplicated carbon monoxide poisoning: (1) complete recovery with possible transient hearing loss but no permanent effects, (2) recovery with permanent central nervous system abnormalities, and (3) death.[1,4-8] Carbon monoxide poisoning is the main cause of acute death from smoke inhalation in humans, and death is due to cerebral and myocardial hypoxia.[5,6]

28.3.2 Hydrogen Cyanide

Hydrogen cyanide (HCN) (see Chapter 86, Cyanide) is most prevalent in fires involving wools, silks, and synthetic nitrogen–containing polymers (e.g., urethanes, nylon). It is a nonirritant gas that interferes with the utilization of oxygen by cellular cytochrome oxidase, thereby causing histotoxic hypoxia.[2,5] The incidence and significance of cyanide toxicity in veterinary smoke inhalation victims remain undefined.[3,9]

28.3.3 Thermal Injury

Direct thermal injury involving hot, dry air is highly unusual distal to the larynx because heat is dissipated effectively by the thermal regulatory system of the nasal and oropharyngeal areas.[10,11] Thermal injury can manifest as mucosal edema, erosions, and ulceration. Of greatest concern is the potential for laryngeal edema that may result in fatal upper respiratory tract obstruction. Although these changes may not be apparent initially, they can be progressive. In one study, a tracheostomy was required for laryngeal obstruction in 2 of 27 dogs and was performed 24 and 72 hours after admission.[7] Steam has a much greater heat capacity than dry air and is therefore liable to produce more extensive injury throughout the respiratory tract.[10] Inhalation of superheated particulate matter (mainly soot) can result in thermal injury to the trachea and lower respiratory tract.

28.3.4 Irritant Gases and Superheated Particulate Matter

A variety of irritant noxious gases can be inhaled during a fire, depending on the nature of the materials undergoing combustion. These include short-chain aldehydes, gases that are converted into acids in the respiratory tract (e.g., oxides of sulfur and nitrogen), highly water-soluble gases (e.g., ammonia, hydrogen chloride), and benzene (from plastics).[5,11] Particulate matter acts as a vehicle by which these gases can be carried deep into the respiratory tract. The pathophysiology that results depends on the types of gases and particulate matter inhaled, the duration of exposure, and underlying host characteristics.[10,12]

28.3.4.1 Reduced Lung Compliance

Lung compliance may be markedly reduced as a result of alveolar atelectasis and pulmonary edema. Alveolar atelectasis can occur within seconds of injury due to impaired pulmonary surfactant activity (see Chapter 29, Atelectasis).[2,13,14] Pulmonary edema results from increased permeability of the microvasculature, possibly associated with sequestered leukocytes (see Chapter 21, Pulmonary Edema).[14,15] Alveolar edema is exacerbated by a concurrent increase in epithelial permeability.[15] Pulmonary edema can occur within minutes of smoke inhalation, although it typically develops over a period of up to 24 hours.[10] Ventilation-perfusion alterations also occur, and acute lung injury and acute respiratory distress syndrome are potential sequelae (see Chapter 24, Acute Lung Injury and Acute Respiratory Distress Syndrome).

28.3.4.2

Airway Damage and Obstruction

The mucociliary escalator is significantly impaired following smoke inhalation. Progressive mucosal edema may be accompanied by mucosal sloughing over several hours and the damaged epithelium gives rise to pseudomembranous casts.[10,14] Marked tracheobronchitis, necrotizing bronchiolitis, alveolar hyaline membrane formation, and intraalveolar hemorrhage may all follow.[10,14] Smoke inhalation induces a reflex bronchoconstriction, and airway obstruction is exacerbated by the copious secretions and edema fluid.[10]

28.3.4.3

Bacterial Pneumonia

Smoke inhalation may increase the likelihood of bacterial pneumonia by impairment of alveolar macrophage function. In addition, the stagnant luminal contents create a milieu conducive to bacterial colonization. Nevertheless, bacterial pneumonia is thought to typically occur as a secondary phenomenon following therapeutic interventions such as endotracheal intubation and tracheostomy, or due to sepsis associated with dermal burn injuries.[12,16] Infection usually is not seen for at least 12 to 24 hours and is associated with a higher incidence of respiratory failure. [10,12,16] *Pseudomonas aeruginosa, Staphylococcus* spp, and *Streptococcus* spp are most commonly involved in humans, but it is unknown if the same is true of dogs and cats.

28.3.5

Dermal Burn Injury

The morbidity and mortality associated with smoke inhalation are much greater when significant concurrent dermal burn injury is present.[7,9,11] This is due to both the pulmonary pathophysiology (pulmonary edema, bacterial pneumonia, acute lung injury, and acute respiratory distress syndrome) associated with dermal burns and their management requirements, including more aggressive fluid therapy and repeated general anesthesia (see Chapter 158, Thermal Burn Injury).[9,11]

28.4

HISTORY

If owner contact is possible, a full medical history should be obtained at the appropriate time. The history of current illness is usually related to being involved in an enclosed-space fire, and the duration of exposure and types of items involved should be ascertained. The patient's neurologic status at the scene predominantly reflects the degree of carbon monoxide poisoning. Paroxysmal or intractable coughing may suggest the inhalation of more irritating gases.

28.5

PHYSICAL EXAMINATION

Physical examination findings depend on a number of factors including the type, severity, and duration of smoke inhalation; the presence of dermal burn injuries; oxygen supplementation by human paramedics; delay in arrival at the hospital; and the patient's preexisting health status.

Neurologic abnormalities on admission may include reduced mental status, from depression through to coma, as well as anxiety, agitation, ataxia, and the developement of convulsions. New neurologic signs have been reported after 2 to 6 days in dogs that had neurologic dysfunction initially.[17,18] Lethargy may be a common finding in cats.[19]

Respiratory signs may be absent initially and can take 24 hours or more to develop; however, two studies found that animals without respiratory abnormalities at admission typically did not go on to develop any significant problems.[7,14,19] Clinical signs include tachypnea, panting (dogs), open-mouth breathing, dyspnea, inspiratory stridor, increased tracheal noise, harsh lung sounds, expiratory wheezes, and nasal discharge.[5,7,10,15]

Cardiovascular findings may or may not be normal and depend on both the myocardial effects of carbon monoxide and HCN toxicity and the coexistence of significant dermal burn injury. Cardiovascular status tends to normalize quickly in uncomplicated cases, but complicated cases are more likely to have a range of cardiovascular abnormalities that persist for a longer period.[10,12,19] The cherry red appearance of mucous membranes (and skin) attributed to carboxyhemoglobinemia is rarely witnessed in clinical cases. This probably represents a high level of preadmission mortality in patients that would fall into this category.[6] Individuals that live long enough to be treated are more likely to have either normal or hyperemic mucous membranes. Hyperemia may be due to carboxyhemoglobinemia, cyanide toxicosis, systemic vasodilation, and local vasodilation due to mucosal irritation, and this may mask both concurrent perfusion abnormalities and cyanosis.[7]

The animal's coat is likely to smell of smoke. Ptyalism may be present and there may be evidence of soot in the oral cavity (or on microscopic examination of saliva). Mucosal edema and burns inside the oral cavity as well as on the face and lips may suggest smoke inhalation injury to the respiratory tract, but such findings can carry a high incidence of false positives in humans.[14] In two retrospective veterinary studies, only 1 of the 27 dogs and none of the 22 cats had a major dermal burn injury; minor injuries such as singed hair and skin lacerations were more common in dogs.[7,19] Evidence of ocular irritation, including conjunctival hyperemia, blepharospasm, corneal lesions, and ocular discharge, may be present.

28.6 CLINICAL EVALUATION

28.6.1 Arterial Blood Gas Analysis

Initially, when carbon monoxide (and HCN) poisoning is likely to be the predominant cause of morbidity, arterial partial pressure of oxygen (PaO_2) may remain within normal limits (see Chapter 87, Carbon Monoxide).[1,2,10] Oxygen saturation, based on pulse oximetry, may also appear normal because these devices do not differentiate between COHb and oxyhemoglobin.[3] Co-oximetry allows direct measurement of oxyhemoglobin and COHb (see Chapter 208, Blood Gas and Oximetry Monitoring).[9] A reduction in the arterial-venous oxygen gradient may be suggestive of significant HCN toxicity.[9,20] Repeated arterial blood gas analysis is invaluable in the detection and monitoring of the potentially progressive respiratory complications of smoke inhalation. Hypoxemia, hypercarbia, and an increased alveolar-arterial oxygen gradient may be present. In one retrospective study of 14 dogs the PaO_2-to-FiO_2 (inspired oxygen concentration) ratio had a nadir at 32 hours postadmission (median value 269); this seemed to correlate with the worst clinical respiratory signs.[7]

28.6.2 Acid-Base Status

Acidosis is likely and may be of respiratory, metabolic, or mixed origin.[10-12] Hyperlactatemia may be present as a result of tissue hypoxia, and excessively high plasma lactate levels at admission are a sensitive indicator of HCN intoxication (independent of hypoxemia) in humans.[20]

28.6.3 Thoracic Radiography

Thoracic radiographic abnormalities may be absent initially but usually appear within the first 24 hours and can be expected in 70% to 80% of affected dogs and cats.* Radiographic changes do not always correlate with either the severity of respiratory tract injury or with patient morbidity.[7,10,15,19] An asymmetric radiographic pattern consistent with pulmonary edema is typical with alveolar, interstitial, and peribronchial changes.[7,15,19,21] Diffuse coalescing consolidation, collapse of the right middle lung lobe, and pleural effusion (especially in cats) have all been reported.[7,10,19,22] If bacterial pneumonia develops, a more pronounced alveolar pattern with air bronchograms can be expected.[15]

* References 3, 7, 9, 10, 19, 21.

28.6.4 Laryngoscopy, Bronchoscopy, and Transtracheal Aspiration

Laryngoscopy is useful in sedated or unconscious animals to detect potentially progressive laryngeal obstruction. Fiberoptic bronchoscopy is used widely in humans to examine the lower airway. Carbonaceous particulate matter in the airway confirms the diagnosis and direct visualization of the anatomic level, and extent of airway injury is possible along with sample collection.[3] Serial examinations may need to be performed as respiratory changes progress.[9] General anesthesia is required in veterinary patients in the absence of a tracheostomy, so a risk-benefit assessment must therefore be made in considering this procedure. Transtracheal aspiration may be used in veterinary patients. Samples may reveal carbonaceous particulate matter as well as cytologic changes consistent with thermal injury affecting the ciliated epithelial cells in particular.[23] This technique is also useful for the diagnosis of bacterial bronchopneumonia and in obtaining samples for culture and sensitivity testing.

28.7 DIAGNOSIS

Smoke inhalation is suspected in cases with a history of involvement in an enclosed-space fire along with facial burns, especially if carbonaceous particulate matter is present in the oral cavity or on microscopic examination of saliva. The results of physical examination and clinical evaluation support the diagnosis. In animals with significant dermal burn injury, and in the absence of a COHb measurement, the use of a transtracheal wash or bronchoscopy may be necessary to diagnose smoke inhalation as the cause of respiratory abnormalities.

28.8 TREATMENT

On the basis of the history and the initial findings of physical examination and clinical evaluation, smoke inhalation victims can be divided broadly into the following groups: (1) those that are without clinical signs and assessed to be at low risk of progression, (2) those with mild signs but assessed to be at high risk of progression, and (3) those that require intensive treatment from the outset.[3] Treatment of smoke inhalation must be tailored to this initial assessment and adapted thereafter based on regular patient evaluation.

28.8.1

Oxygen Supplementation

Oxygen supplementation is the immediate priority for a patient with presumed carbon monoxide toxicity and may cause significant clinical improvement within minutes.[7,16,18] The half-life of carbon monoxide is approximately 250 minutes in patients with normal respiratory exchange on room air, but is reduced to 26 to 148 minutes with an FiO_2 of 100%.[5,24] The use of hyperbaric oxygen therapy has been reported in humans, but providing an FiO_2 of 100% via endotracheal intubation is an effective, readily available alternative that allows access to the patient. Treatment periods ranging from 30 minutes up to 6 hours have been described.[10,25,26] Oxygen supplementation clearly has a crucial therapeutic role in the respiratory complications that may develop subsequently.

28.8.2

Cyanide Toxicity

Treatment for cyanide toxicity involves intravenous sodium nitrite followed by intravenous sodium thiosulfate (see Chapter 86, Cyanide). However, sodium nitrite may not be appropriate in smoke inhalation victims because it results in the formation of methemoglobin and will further compromise oxygen-carrying capacity.[5] Sodium thiosulfate should therefore be used alone.

28.8.3

Airway Management

A tracheostomy may be required to treat laryngeal obstruction. Given the potentially disastrous effects of bacterial pneumonia in these patients, strict aseptic technique must be maintained during the procedure, with regular suctioning and humidification thereafter. The empiric use of bronchodilators is indicated, especially in patients with wheezes on auscultation. Options include terbutaline (0.01 mg/kg IV or IM in both dogs and cats), aminophylline (dogs: 10 mg/kg slowly IV [diluted], cats: 4 mg/kg slowly IV [diluted]); and inhaled albuterol. Supplemental oxygen must be humidified and regular saline nebulization followed by coupage should also be 120
performed. Human clinical studies have suggested that coupage is contraindicated in the presence of bacterial 121
pneumonia (see Chapter 23, Aspiration Pneumonitis and Pneumonia). Gentle activity is to be encouraged if possible, and mucolytics such as bromhexine and acetylcysteine may also be helpful. Antitussives are best avoided because they will reduce airway clearance.

28.8.4

Sedation

Animals that are agitated at initial contact may be exhibiting neurologic symptoms associated with carbon monoxide (and HCN) toxicity. Appropriate chemical restraint to allow more aggressive oxygen supplementation is empirically justified in such cases. Thereafter, sedation may be required to minimize anxiety associated with dyspnea. Low-dosage opioids may be adequate, and additional sedation (e.g., acepromazine) may be necessary, especially in patients with upper respiratory tract compromise (see Chapter 162, Sedation of the Critically Ill Patient).

28.8.5 Mechanical Ventilation

Assisted ventilation may be required either due to inadequate spontaneous ventilation or respiratory failure (see Chapter 213, Basic Mechanical Ventilation).[9] Positive end-expiratory pressure is beneficial in patients with atelectasis.[9,13] Continuous positive airway pressure, provided to spontaneously breathing patients, may be an alternative in the absence of hypoventilation, but this will usually necessitate orotracheal intubation or tracheostomy.[27,28]

28.8.6 Intravenous Fluid Therapy

Smoke inhalation victims may require only maintenance fluid therapy; however, fluid requirements are significantly increased in those with dermal burn injury (see Chapter 158, Thermal Burn Injury). Although a number of experimental studies have demonstrated an increase in extravascular lung water following aggressive intravenous fluid therapy in smoke inhalation victims, there appears to be no consensus regarding the clinical relevance of this finding.[9,14,29] Pulmonary pathology in smoke inhalation certainly justifies caution with fluid therapy, but excessive fluid restriction has been associated with increased morbidity and a “conservatively aggressive” approach with close monitoring may be rational.[30]

28.8.7 Additional Therapies

Prophylactic antibiotics are not recommended due to the risk of selecting for resistant organisms. In animals with suspected bacterial pneumonia, antibiotic selection should be based on culture and sensitivity testing of samples collected by transtracheal wash or bronchoscopy. Gram stain examination of these samples can guide drug selection while results are awaited. Otherwise broad-spectrum coverage for both gram-negative and gram-positive infections should be instituted and then amended if necessary once the results are obtained. Blood cultures are recommended in animals that are thought to have developed bacterial pneumonia due to sepsis.[3]

The use of glucocorticoids following smoke inhalation has been widely studied. Experimental studies report variable effects associated with this treatment, but the vast majority of clinical reports point to an increased incidence of bacterial pneumonia with no clear clinical benefit.[3,7,11,14,31] The use of glucocorticoids is therefore not recommended in these patients.[3,9,14]

The permeability edema following smoke inhalation was said to be less responsive to standard diuretic therapy than high-pressure edema. However there is more recent evidence in support of multimodal beneficial effects of furosemide administration in such cases (see Chapter 21, Pulmonary Edema). Empiric diuresis should be avoided in hypovolemic or dehydrated patients.

28.9 PROGNOSIS

Mortality rates in people following admission for smoke inhalation have been reported as less than 10% without and 25% to 65% with dermal burn injury.[9] Of the 27 dogs in one retrospective canine study, 4 died and a further 4 were euthanized. In uncomplicated cases, dogs recovering from the initial carbon monoxide poisoning had a favorable prognosis, with improvements in respiratory signs over 24 hours. However, dogs that were clinically worse the following day were more likely to die, be euthanized, or require prolonged hospitalization.[7] In another study, dogs admitted with acute neurologic signs had an overall mortality rate of 46%.[17] Despite initial improvement, acute, delayed neurologic signs developed in 46% of the dogs within 2 to 6 days. Mortality rate for this group was 60%.[17] None of the 22 cats in a retrospective feline study died, but 2 were euthanized for severe respiratory or neurologic signs.[19] Animals with concurrent dermal burn injury should be given a more guarded prognosis from the outset. Although smoke inhalation can result in permanent changes to lung structure, any long-term effects on lung function are unlikely to be clinically significant.[3,7,9,15]

29 Chapter 29 Atelectasis

Janet Aldrich, DVM, DACVECC

29.1 KEY POINTS

- Atelectasis is an important cause of hypoxemia in critically ill patients.
- The three major mechanisms causing atelectasis are compression, oxygen absorption, and depletion of surfactant.
- Critically ill patients are at risk for atelectasis because they are often recumbent, receive high inspired oxygen levels, and can have decreased lung expansion.
- A multimodal approach to respiratory care includes techniques to minimize atelectasis.

29.2 INTRODUCTION

Atelectasis is an airless or partly airless state of the lung that leads to alveolar collapse.[1] Diagnosis of atelectasis is important because it is a potentially reversible cause of severe hypoxemia, and management protocols to decrease its risk and to reexpand the lung are available.

29.3 PATHOPHYSIOLOGY

29.3.1 Factors Preventing Alveolar Collapse

Alveoli and small airways are extremely delicate structures with no distending properties of their own. Ultimately the size of a given alveolus will depend on the balance between the coexisting collapsing and distending forces to which it is subjected. The primary collapsing force is surface tension, and this is opposed by four main distending forces: (1) transpulmonary pressure, (2) the tethering effect of surrounding structures, (3) surfactant, and (4) the gaseous nitrogen skeleton.[2,3] When the collapsing forces outweigh the distending forces alveoli and small airways will collapse, producing atelectasis. Due to their inherent stability issues, alveoli and small airways are in one of three states: (1) fully open, (2) open but smaller than normal (hypoventilated), or (3) collapsed. Atelectasis creates areas of lung that are perfused but not ventilated (no ventilation-perfusion [V/Q] regions) so they can no longer participate in gas exchange. Unlike that of low-V/Q regions, this mechanism of hypoxemia will not improve with oxygen therapy.

29.3.2 Atelectasis

Compression, airway obstruction, inadequate lung expansion, alveolar fluid accumulation, and alveolar trauma are all well-recognized causes of atelectasis. Airway obstruction and hypoventilation predispose to atelectasis secondary to absorption. Compression of lung tissue forces air out of alveoli to cause collapse, and fluid accumulation within alveoli increases the surface tension forces and may also result in atelectasis. Alveolar trauma can lead to fluid exudation into alveoli and loss of surfactant, increasing the likelihood of collapse. Shear forces generated during cyclic alveolar collapse and reexpansion constitute a mechanism of ventilator-induced lung injury that creates alveolar trauma and atelectasis.[3] Alveolar surfactant production is dependent on an adequate alveolar blood supply. When pulmonary perfusion is compromised, such as following pulmonary embolism, inadequate surfactant production can occur and may lead to atelectasis.

29.3.3 Absorption Atelectasis

Gases trapped distal to a closed airway are reabsorbed into the pulmonary circulation because the partial pressure of gases in end-capillary mixed venous blood is lower than in the alveoli, thus establishing a gradient for reabsorption. The alveolus eventually becomes airless and collapses. Air contains nitrogen, which is poorly soluble and absorbed more slowly than highly soluble oxygen. Hence nitrogen provides support for the alveolus preventing collapse (a “nitrogen skeleton”) and may persist in the alveolus for hours to days. Absorption atelectasis occurs far more rapidly in patients breathing enriched oxygen mixtures because the nitrogen skeleton is diminished or absent.[2] In situations of airway obstruction, atelectasis may be mitigated by entry of gas from adjacent lobules. Respiratory bronchioles and alveolar ducts anastomose between adjacent lung segments in dogs and are the most likely primary site of collateral ventilation in this species.[4] In patients breathing high oxygen concentrations, hypoventilated alveoli may also fall victim to absorption atelectasis when the rate of gas leaving alveoli and entering the pulmonary blood exceeds the degree of ventilation.

29.3.4 Atelectasis Without Volume Loss

Classically atelectasis is associated with a loss of lung volume, and this is often used as an aid in its radiographic diagnosis. Atelectasis may, however, be associated with edema or infiltration of inflammatory cells into the collapsed alveoli and airways, thus creating a condition of airlessness without volume loss.

29.4 CAUSES OF ATELECTASIS

29.4.1 Inadequate Lung Expansion

Weakness of respiratory muscles, pain, and centrally mediated respiratory depression can cause inadequate lung expansion and atelectasis. This atelectasis will occur predominantly in the dependent regions of the lung where transpulmonary pressure is smallest at functional residual capacity (FRC). Recumbent, larger animals are particularly prone to this dependent collapse. Atelectasis as a result of inadequate lung expansion can also occur with positive-pressure ventilation strategies that include low end-expiratory volume, which may be used in an effort to avoid volutrauma.[5]

29.4.2 Extramural Airway Compression

Airway compression can result from parenchymal and extraparenchymal masses; pleural space disease with accumulation of air, fluid, or intrusion of abdominal contents; or chest wall disease (flail chest) that allows the underlying lung to collapse.

29.4.3 Intraluminal and Mural Obstruction

As described previously, airway obstruction can contribute to absorption atelectasis. Intraluminal obstruction may be caused by foreign bodies or excessive accumulation of secretions. Mural lesions include loss of structural integrity of the cartilaginous airways and proliferative lesions that protrude into the airway. Bronchoconstriction may narrow airway diameter enough to cause obstruction.

29.4.4 Anatomic Predisposition

Segments of lung with a high ratio of pleural surface-to-volume may be more prone to atelectasis after airway obstruction. In these segments, high resistance to collateral flow limits collateral ventilation. Based on these characteristics, the right middle lung lobe and the left upper lobe in dogs were predicted to be more likely to develop atelectasis following airway obstruction.[4]

29.4.5 Anesthesia

Numerous factors that are associated with general anesthesia may increase the likelihood of atelectasis. These include inadequate lung expansion, high inspired oxygen concentrations, and endobronchial intubation. During anesthesia, reduction in chest wall movement and relaxation of the diaphragm allowing its anterior displacement contribute to reduction in lung volume (decreased FRC) and small airway closure in the dependent lung.[6] In healthy, spontaneously breathing dogs anesthetized for orthopedic procedures, atelectasis caused static respiratory compliance to decline progressively.[7] In addition, anesthetic agents are almost universally respiratory depressant in nature, which may further contribute to poor lung expansion. Anesthetized patients are also at risk of absorption atelectasis as a consequence of breathing high concentrations of oxygen. As mentioned previously, this is a particular problem in poorly ventilated regions of the lung.

Endobronchial intubation will result in ventilation of only one lung, and without ventilation the other lung will soon become atelectatic. Endotracheal tubes move caudally and cranially with flexion and extension of the head and neck. Therefore an endotracheal tube may move into and out of the mainstem bronchus if it is positioned too close to this area.[6] Atelectasis of the obstructed, unventilated lung will be accelerated by breathing high oxygen concentrations.

29.4.6 Other Mechanisms

Atelectasis secondary to prolonged recumbency occurs commonly in critically ill patients. Contributing factors include inadequate lung expansion because of positioning, pain, drugs, or concurrent disease, and high inspired oxygen concentrations. Pulmonary thromboembolism may cause edema and atelectasis because of depletion of surfactant as a result of decreased delivery of the components of surfactant production.[8] Chest physiotherapy with either hand clapping or a mechanical percussor in anesthetized, paralyzed, ventilated dogs may cause atelectasis, and thoracic compression by elastic bandaging can reduce lung volume below FRC, also predisposing to atelectasis.[9] Massive pulmonary collapse has been reported as an infrequent complication of asthma in human patients; it has not been reported to date in veterinary patients.[10] Improper technique in suctioning an endotracheal tube can also cause atelectasis. Suction catheters that are too large and occlude the endotracheal tube prevent entraining of room air and can cause excessive reduction in airway pressure and small airway and alveolar collapse.

29.5 CONSEQUENCES OF ATELECTASIS

29.5.1 Hypoxemia

Airway obstruction decreases ventilation relative to perfusion (low V/Q) or completely obstructs airflow (no V/Q, shunt) in a lung that is still perfused. The blood leaving that unit is not adequately oxygenated and contributes to venous admixture and hypoxemia. Hypoxemia as a consequence of no-V/Q regions is not responsive to oxygen therapy. In the normal lung the severity of hypoxemia due to atelectasis may be attenuated by hypoxic pulmonary vasoconstriction. This pulmonary vascular reflex decreases blood flow to poorly ventilated alveoli, improving V/Q matching and decreasing venous admixture. Hypoxic pulmonary vasoconstriction is decreased by acidemia, increased cardiac output, and severe systemic hypoxemia but was shown to be stable for 4 hours in experimental dogs without these complications.[11]

29.5.2 Prolonged Atelectasis

Pulmonary function can be restored to regions of collapsed lung despite prolonged periods of atelectasis. In experimental dogs, complete obstruction of a bronchus was created for periods ranging from 5 weeks to 10 months after which the patency of the bronchus was reestablished. Biopsy specimens were obtained at various intervals. The atelectatic lobes were small, with a liver-like appearance and rubbery consistency. Reexpansion resulted in a nearly normal histologic appearance.[12]

29.5.3 Reexpansion Pulmonary Edema

Pulmonary edema may follow rapid expansion of areas of the lung that have been collapsed for several days or more and is more likely to occur when negative pressure is applied manually to the chest tube than with more passive techniques of reexpansion.[13] Reexpansion pulmonary edema is associated with an increase in cytokines and in the inflammatory response, both in the reexpanded and in the contralateral lung.[14] Gradual reexpansion is recommended when treating prolonged atelectasis.

29.6 CLINICAL SIGNS

29.6.1 History and Physical Examination

Prolonged recumbency, high inspired oxygen concentrations, and recent anesthesia are associated with atelectasis.

Clinical signs include tachypnea, dyspnea, and cyanosis. The most notable change in thoracic auscultation is a decrease in breath sound intensity over the affected area. Wheezes (musical, monophonic, or polyphonic breath sounds) suggest a significant flow obstruction, but the correlation between airway obstruction and detectable wheezing is variable. Crackles (discontinuous breath sounds) occur when airways previously closed snap open. They may be present in small airway and alveolar collapse.[15] Fever has been reported in humans and experimental dogs with atelectasis.[16] In a rat model of atelectasis, alveolar macrophages produced increased interleukin-1 and tumor necrosis factor, and these were thought to be responsible for the fever.[17]

29.7 DIAGNOSTIC TESTS

29.7.1 Blood Gas Analysis

Atelectasis may cause hypoxemia of a magnitude that will correlate with the degree of shunt present.[5] This is a non-specific finding as atelectasis is only one of many causes of hypoxemia. Chapters 9 and 15, Tachypnea and Hypoxemia and Respiratory Failure, respectively, discuss the causes of hypoxemia further. The $PaCO_2$ may be decreased secondary to hyperventilation stimulated by hypoxemia and/or pulmonary receptors in the atelectatic regions.[3]

29.7.2 Radiography

Radiographic changes suggestive of atelectasis include mediastinal shift, elevation of the hemidiaphragm, rearrangement of the borders of the inflated lung lobes, increased lung density of the affected lobes, separation of the heart from the sternum, and asymmetry of the rib cage. Most signs of atelectasis are more easily seen in dorsoventral or ventrodorsal projections.[18] Some types of atelectasis do not result in radiographically detectable volume loss, because either the area of involvement is small or the collapsed alveoli have been infiltrated with fluid.

Positioning is important because a diseased lung positioned toward the table in an animal in lateral recumbency rapidly collapses.[18] In anesthetized animals an increase in lung density indicating partial collapse is common, and inflating the lungs a few times before radiographs are taken has been recommended.[19]

29.7.3 Computed Tomography

Computed tomography may be more sensitive than radiographs in detecting the presence and severity of atelectasis.

29.8 TREATMNET

So far as is possible, predisposing causes of atelectasis should be eliminated. Recumbent and critically ill patients have many factors predisposing to atelectasis such as recumbency, anesthesia, high inspired oxygen concentrations, and preexisting conditions. Anesthetized patients may also be at increased risk for atelectasis.

29.8.1 Oxygen

Although high concentrations of inspired oxygen may hasten alveolar collapse, oxygen therapy is an essential part of the management of hypoxemia caused by atelectasis. If airway obstruction is partial (low V/Q), hypoxemia is responsive to oxygen therapy.

29.8.2 Positive-Pressure Ventilation

If airway obstruction is complete (no V/Q, shunt) the condition is not responsive to oxygen therapy because the airways are occluded. If hypoxemia is severe positive-pressure ventilation is needed to open the closed airways and prevent recurrent collapse. Positive-pressure ventilation has been successful in atelectasis management, and positive end-expiratory pressure can be essential in reducing atelectasis in at-risk anesthetized patients.[20]

29.8.3 Airway Obstruction

Airway foreign bodies are often removed successfully with a variety of techniques, including direct visualization and retrieval, Heimlich maneuver, and bronchoscopy, providing the bronchoscope can be passed to the level of the obstruction. Bronchoscopy is used with varying success in human patients to remove airway secretions in an attempt to resolve atelectasis.[21] The applicability of this technique in veterinary patients is unknown at this time, but patient size may be a significant limitation.

29.8.4 Adjunctive Respiratory Therapy

The goals of multimodal approach to respiratory care are to improve gas exchange, minimize atelectasis, and promote clearance of secretions.[21] Adjunctive therapy includes the following:

- Frequent repositioning for recumbent patients
- Nebulization, chest percussion, and postural drainage
- Appropriate endotracheal suctioning
- Vital capacity maneuvers
- Positive end-expiratory pressure

29.8.5 Drugs

Bronchodilators, mucoactive agents, and antibiotics may be indicated, depending on individual patient needs.

30 Chapter 30 Pleural Space Disease

Valérie Sauvé, DVM, DACVECC

30.1 KEY POINTS

- The pleural space is a potential space that contains a small amount of fluid and maintains a negative pressure.
- Clinical symptoms in animals with pleural space disease include tachypnea, open-mouth breathing, extended head and neck, crouched sternal recumbency with elbow abduction (orthopnea), cyanosis, and short, shallow breathing with an increased abdominal component. Thoracic auscultation often reveals muffled or absent breath sounds over affected areas of the thorax.
- Abnormalities within the pleural space may include pleural effusion, pneumothorax, or space-occupying soft tissue (diaphragmatic hernia, neoplasia). A diagnostic thoracentesis may also prove therapeutic in severely affected patients.
- Cytologic and fluid analysis should always be performed on aspirate from a newly diagnosed pleural effusion of unconfirmed etiology.
- Aerobic and anaerobic cultures with sensitivity testing of suppurative effusion are imperative.
- Pleural fluid triglyceride levels and cholesterol concentrations are necessary to establish the diagnosis of chylothorax.
- Clinical evidence of cardiovascular shock will often precede dyspnea in patients with hemothorax.
- Tension pneumothorax, regardless of its origin, may be rapidly fatal. Immediate thoracentesis is required before taking thoracic radiographs.
- Clinical signs of a traumatic diaphragmatic hernia may be delayed; however, early detection and correction are important because perioperative outcome is worse in patients with a preexisting hernia.

30.2 PLEURAL SPACE

The pleural space is a potential space formed by the parietal and visceral pleura. It normally contains a minimal amount (few milliliters) of serous fluid to facilitate motion of the lungs in relation to the thoracic cavity and to each other.[1] The pleura is a thin epithelium formed of mesothelial cells overlying a thin basal membrane. The pleura contain a superficial network of lymphatic ducts, blood vessels, and rare nerves.[2] The partition between the right and left hemithoraces is incomplete in small animals, but unilateral or unevenly distributed disease is common.[3]

30.2.1 Box 30-1 Modified Starling's Law Applied to the Pleural Cavity

Net filtration = $K\{[(P_{c\ parietal}-P_{c\ visceral})-P_{if}]-(\pi_c-\pi_{if})\}$

P_{cap}: capillary hydrostatic pressure of the visceral and parietal pleura

P_{if}: intrapleural hydrostatic pressure

π_{cap}: plasma oncotic pressure

π_{if}: intrapleural oncotic pressure

Modified from Pleural effusion and diseases of the pleura, *Vet Clin North Am Small Anim Pract* 15:1069, 1985.

Physiologic fluid flux in the pleural space is governed by Starling's law (Box 30-1). Hydrostatic pressure favors fluid accumulation within the pleural cavity (where pressure is subatmospheric), and the parietal pleura (systemic circulation) has greater filtration capacity than the visceral pleura (pulmonary circulation). However, oncotic pressure favors reabsorption of fluid from both pleura because the colloid osmotic pressure of the pleural space is 3.2 cm H_2O in dogs (compared with 24.5 to 27 cm H_2O in the vascular space). The visceral pleura assumes a larger role in determining the net pressure and favors reabsorption of fluid from the pleural space, where a greater vascular supply and lower hydrostatic pressure exist. Pleural lymphatic vessels are also an important component of fluid and blood reabsorption from the thorax.[3]

There is an average pleural pressure of –5 cm H_2O, representing the difference between the lung recoil and the thoracic cavity expanding forces, at rest.[4] Air, fluid, or soft tissue within the pleural space can cause the lungs to collapse and the chest wall to spring out by increasing the subatmospheric pressure within the thorax.[5] Pleural pathologies such as these subsequently lead to a decrease in tidal volume, total vital capacity, and functional residual capacity.[6] The resulting atelectasis can lead to both hypoxemia and hypoventilation.

30.3 CLINICAL EVALUATION

Clinical signs of pleural disease may include tachypnea, open-mouth breathing, extended head and neck, crouched sternal recumbency with elbow abduction (orthopnea), cyanosis, and short, shallow breathing with an increased abdominal component. The degree of dyspnea will vary depending on the amount of fluid, rate of fluid accumulation, and concurrent respiratory and metabolic disturbances. Auscultation reveals muffled breath sounds ventrally (fluid or tissue) or dorsally (air). Thoracic percussion reveals a low-pitched (fluid) or high-pitched (air) resonance of the affected area. The heart sounds may be muffled by fluid or tissue, or abnormally loud or displaced with unilateral or focal disease.

Thoracic radiographs are extremely helpful in diagnosing and quantifying pleural space disease and other intrathoracic pathology. Repeat radiographs after thoracentesis can be of diagnostic utility but were found to rarely be beneficial in providing additional diagnostic information in one human study.[7] Routine radiographs after thoracentesis are considered unnecessary for stable patients in the absence of suspicion, clinical indication, or risk factors for complications (mostly pneumothorax)[7,8] (Figure 30-1). Because the shape of the canine and feline chest is much different from that of humans, it is possible that dorsoventral radiographs in animals with pleural effusion (following thoracentesis) may still have improved diagnostic utility for evaluating the dorsal lung fields. Ultrasonographic examination is very helpful for rapid identification of pleural fluid in the emergency setting. In human medicine, indications for use of ultrasonographically guided thoracentesis include a small-volume effusion, inability to properly position the patient, failure of fluid to layer out on radiographs, and coagulopathy.[9] "In veterinary medicine, ultrasound guidance is used routinely to confirm the ideal point of needle insertion for thoracentesis, mostly in patients with a small volume of effusion, fluid pockets or those at increased risk for complications."

Thoracic ultrasonography may reveal underlying pathology such as a diaphragmatic hernia, neoplastic process, or lung lobe torsion.[10,11] Echocardiography will permit a diagnosis of cardiac disease, heart base tumor, and pericardial disease. Ultrasonography may also identify a pneumothorax by identifying the presence or absence of "lung sliding" (normal respiratory movement) at the lung surface.[12] Computed tomography is commonly used to characterize pleural and pulmonary lesions.[10] Thoracic scintigraphy is used mostly in small animal practice to identify pulmonary thromboembolism.[10] Thoracoscopy is another useful diagnostic and therapeutic tool in patients with pleural effusion and other intrathoracic pathology.[13]

Thoracentesis is an invaluable diagnostic, and often therapeutic, tool (see Chapter 31, Thoracentesis). Its indications include (1) the presence of any undiagnosed pleural effusion and (2) therapeutic thoracentesis to relieve respiratory signs caused by large amounts of air or fluid. However, if the etiology of the effusion is known and the patient is not dyspneic, the procedure may be delayed and the clinical signs followed.[14] Fluid analysis has great diagnostic utility in patients with pleural effusion of an undetermined etiology.[14,15]

30.4 PLEURAL EFFUSION

30.4.1 Pure Transudate and Modified Transudate

Transudative pleural effusion, or hydrothorax, is the result of variations in the Starling forces that govern pleural fluid flux (see Box 30-1). Pure transudates are characterized by a low total protein and total nucleated cell count (Table 30-1). Hydrothoraces generally develop secondary to decreased oncotic pressure within the vasculature and are commonly associated with hypoalbuminemia, although it also may be secondary to an increased hydrostatic pressure or neoplasia. Modified transudates are associated with an increased hydrostatic pressure (i.e., heart failure) or vascular permeability (e.g., vasculitis, lung lobe torsion, diaphragmatic hernia) causing leakage of a higher protein ultrafiltrate.[16] However, in animals with chronic effusion, irritation of the pleura may cause an increased nucleated cell count and water can be reabsorbed in excess of protein and cells.[6] Translocation of abdominal effusion, neoplastic effusion, and chylothorax are other causes of transudates.

30.4.2 Exudates

Exudative effusions are the result of chemotactant (causing white blood cell accumulation) and vasoactive substances (causing high-protein fluid efflux) within the pleural cavity secondary to an inflammatory process. Degenerate neutrophils usually will predominate with a bacterial infection.[16] Bacteria may originate from hematogenous or lymphatic spread, penetrating insults (iatrogenic, inhaled or external foreign body, bite wound, trauma), or spread from infected organs (lung, gastrointestinal).[16] Aerobic and anaerobic cultures are recommended for all exudates. *Nocardia* spp, *Actinomyces* spp, and *Fusobacterium* spp are filamentous rods that are difficult to grow on culture media or identify with culture, cytologic, or histologic examination.[16,17] Other types of organisms, such as fungi, protozoa, and rickettsiae, may also cause septic pleural exudates.[16]

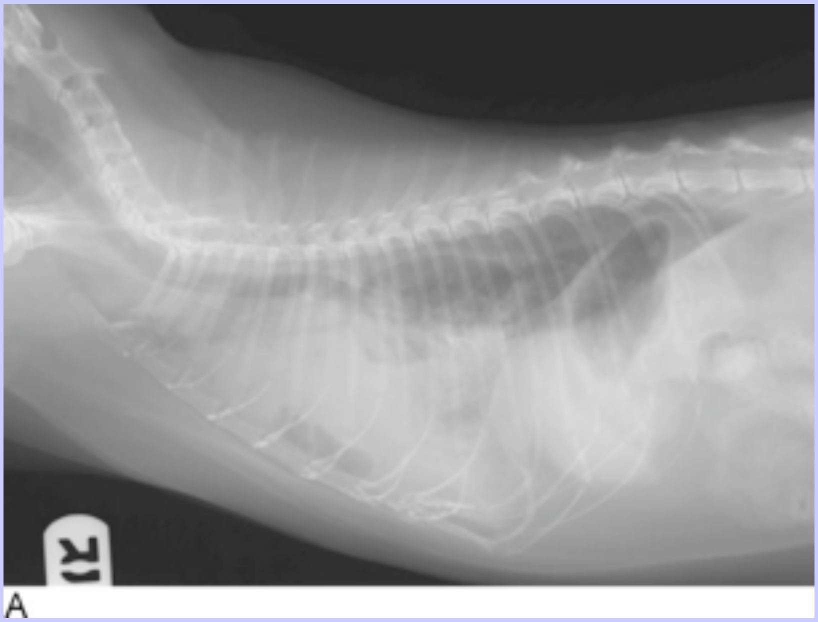
In aseptic exudates, the predominant cell type may vary to include nondegenerate neutrophils (inflammation), small lymphocytes (chylothorax), or neoplastic cells. Potential causes of an aseptic exudate include pneumonia and other well-circumscribed infections (e.g., abscess), generalized sepsis, pancreatitis, or necrosis of intracavitary neoplasia.[16]

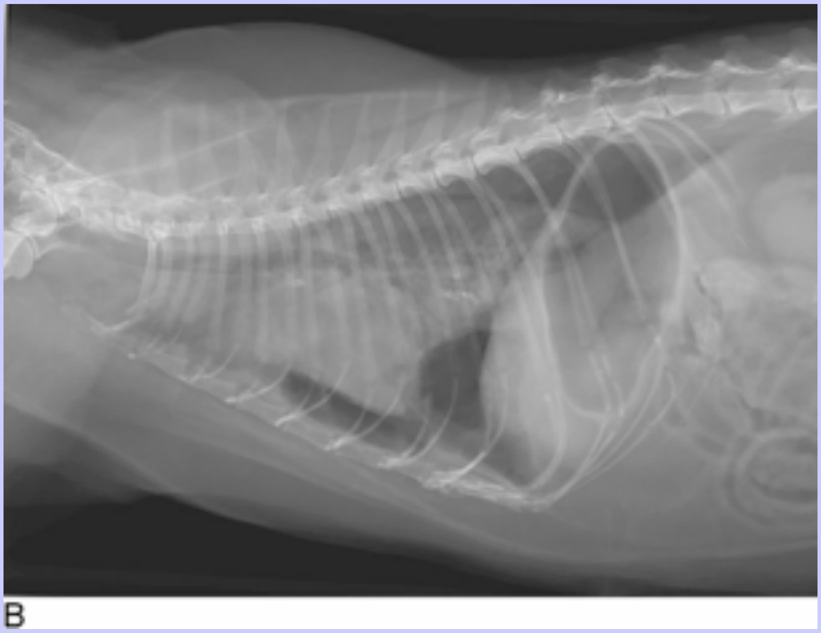
30.4.3 Feline Infectious Peritonitis

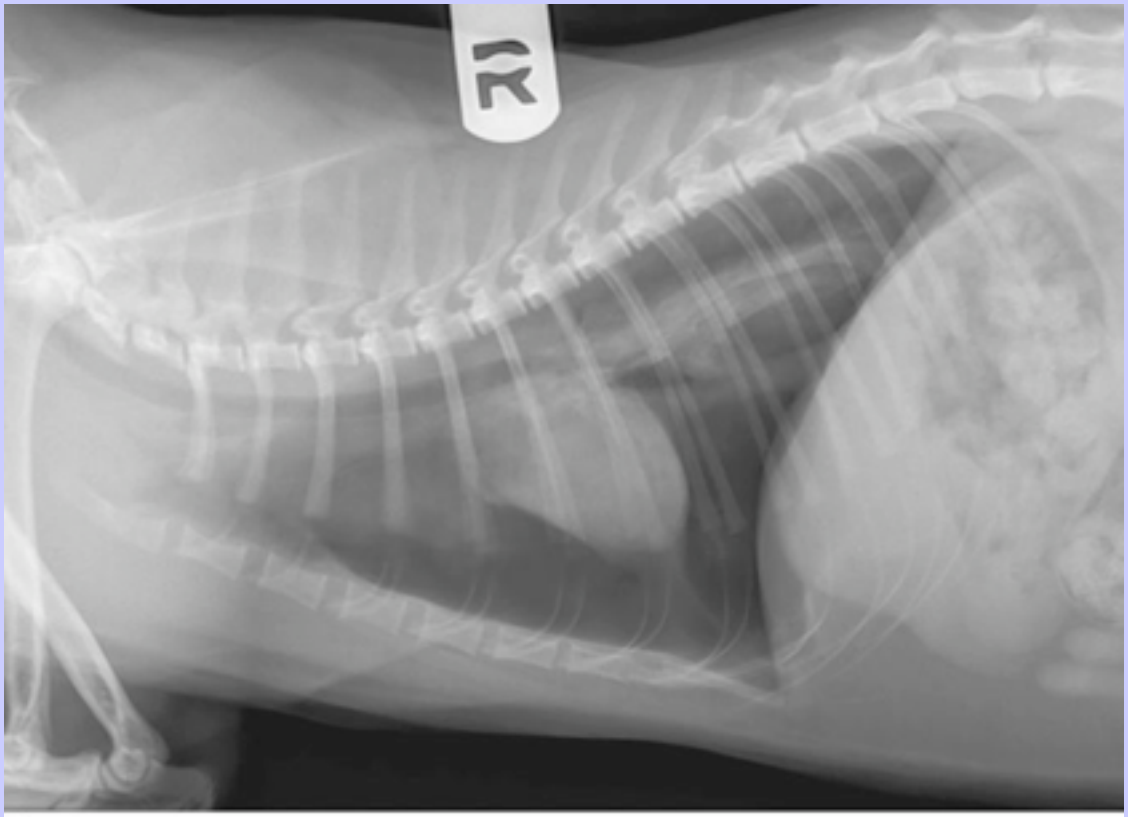
Feline infectious peritonitis (FIP), caused by a coronavirus (feline immunodeficiency virus [FIPV] or feline coronavirus [FCoV]), is a common cause of aseptic pleural exudative effusion in cats, but it may also cause a modified transudate. Abdominal and pericardial effusion can be concomitant. The effusive form is a more acute disease process but may be present terminally in noneffusive FIP.[17] The effusive form results from either a greater viral load causing a larger quantity of circulating immune complexes or an ineffective cell-mediated immune response.[17,18] Deposition of infected macrophages and immune complexes on the endothelium result in complement-mediated, severe pyogranulomatous vasculitis.[18]

FIP is most often found in young, purebred, intact males.[19] Clinical signs will vary depending on the form and organ systems affected. Pleural or peritoneal fluid typically will be viscous, straw-colored, and have a high protein concentration (>3.5 g/dl) with a relatively low nucleated cell count (<5000 cells/ml).[17] Nondegenerate neutrophils predominate in the fluid, with or without macrophages and lymphocytes.[17] Immunofluorescent staining of intracellular FCoV antigen has high specificity, and anti-FCoV antibody testing has both high positive and negative predictive values.[20] The highest serum antibody titer (1:1600) is an excellent predictor of disease, and reverse transcriptase polymerase chain reaction on the effusion has shown promising results although false results are possible.[20] Histopathology remains the gold standard for diagnosing this disease.[18] The prognosis for recovery is grave; however, a new treatment protocol including feline recombinant interferon-ω and glucocorticoids has been described in a small group of cats, with more promising results.[21]

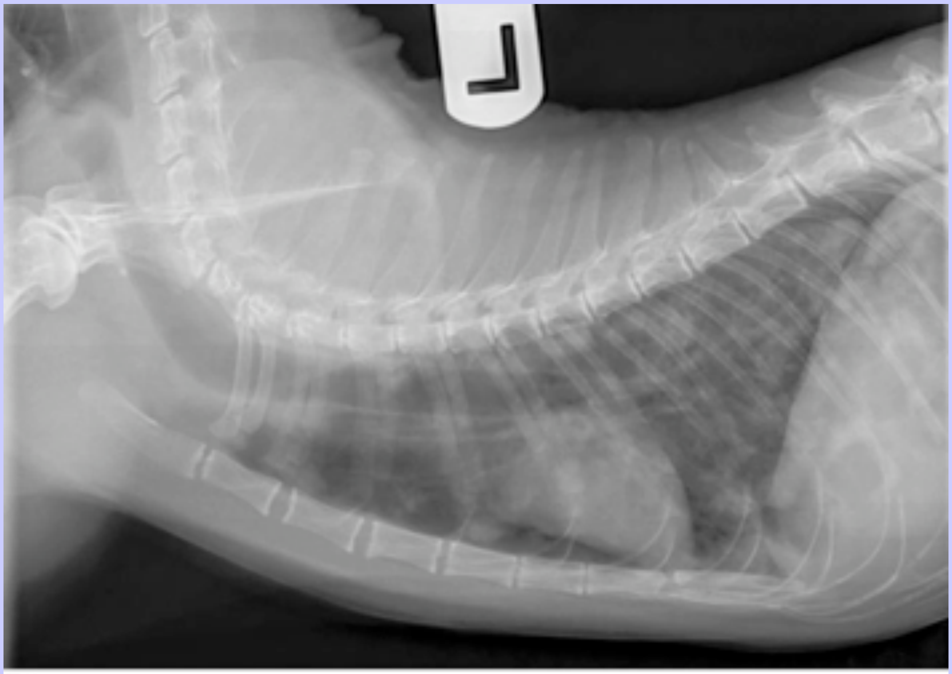
Figure 30-1 Cats with pleural space disease. **A,** Moderate volume of malignant effusion secondary to bronchogenic adenocarcinoma. **B,** Pneumothorax after thoracentesis in the patient shown in *A*. **C,** Traumatic pneumothorax from high-rise syndrome. **D,** Spontaneous pneumothorax from diffuse pulmonary metastasis of salivary gland adenocarcinoma.







C



D

Table 30-1 Fluid Type and Characteristics[16]

Fluid Type	Fluid Characteristics
Pure transudate	TP <2.5 g/dl TNCC <1500/µl
Modified transudate	TP 2.5 to 7.5 g/dl TNCC 1000 to 7000/µl
Exudate	TP >3.0 g/dl TNCC >7000/µl

TP, Total protein; *TNCC,* total nucleated cell count.

30.4.4 Pyothorax

A pyothorax is defined as an accumulation of purulent exudate within the thoracic cavity. Bacterial infection within a feline thorax is most often the result of bite wounds in young cats from multicat households.[22] Migrating inhaled foreign bodies, and traumatic thoracic penetration are more frequent in dogs.[23,24] Young adult hunting or working breeds are over-represented.[25] Other bacterial sources reported include pneumonia, pleuropneumonia, lung abscess, aberrant migration of *Cuterebra* larvae or grass awns, hematogenous or lymphatic dissemination, esophageal or tracheal perforations, lung parasites, diskospondylitis, neoplasia with abscess formation, and iatrogenic causes.[22-24] Septic suppurative effusion typically is diagnosed when intracellular organisms are present on cytologic examination and the presence of intracellular organisms. Culture and sensitivity testing should be performed on the fluid and antibiotic therapy initiated. Ancillary tests such as glucose and lactate levels and pH may also be helpful to diagnose the presence of sepsis.[25,28] Anaerobic bacteria 127
are found most commonly,[25,26] and infections with multiple organisms are highly prevalent.[22,25] In cats, 128
nonenteric bacteria are most common and *Pasteurella* spp is most frequently isolated.[22,26] In dogs, *Escherichia coli* and other members of the family Enterobacteriaceae are isolated most often.[26,27]

Hospitalization for appropriate supportive care and intravenous antibiotics is indicated. Pending culture and sensitivity results, broad spectrum intravenous antibiotic therapy, such as enrofloxacin for gram-negative bacteria and ampicillin with sulbactam or ticarcillin with clavulanate for gram-positive and anaerobic infections,[29] should be instituted as soon as possible. However, an increasing resistance of *E. coli* to enrofloxacin has been documented, and amikacin and ceftizoxime have shown to have better efficacy against this organism.[26] Clindamycin is also effective against many of the offending organisms in cats. Medical management with thoracostomy tubes (bilateral in most cases) is recommended, and sterile lavage with physiologic saline (10 to 20 ml/kg q6-12h daily) may be used initially if the effusion is thick and flocculent (see Chapter 32, Thoracostomy Tube Placement and Drainage). Absorbed lavage solution by the inflamed pleura can lead to fluid overload, so close monitoring of fluid “ins and outs” is recommended. Intermittent thoracentesis is not a recommended means of drainage and is associated with increased mortality.[17] Tubes will often be necessary for 4 to 6 days,[22,25,27] and removal is based on daily fluid reevaluation and the quantity of fluid produced (<2.2 ml/kg per tube q24h, although this can vary depending on the severity of pleuritis).[30] Thoracic radiographs or ultrasonographic examination should be used to monitor the efficacy of drainage. A thoracotomy should be performed if pocketed fluid is persistently not drained by the thoracostomy tubes; if lung or pleural abscess, foreign body, or neoplasia is suspected; or if medical management is failing.

In cats with a pyothorax, reported survival is 66.1% overall, 77.6% after the first 24 hours of hospitalization. A lower heart rate and hypersalivation were associated with death, and a higher white blood cell count was associated with survival. The need for surgical exploration has not been associated with poorer outcome, and recurrence is rare (5.9%).[22] In dogs, surgical treatment is associated with a better outcome: 78% were disease free after 1 year versus 25% with medical treatment.[27]

30.4.5 Chylothorax

Chylous effusion is opaque and white or pink. Small lymphocytes usually predominate; however, nondegenerate neutrophils may become predominant after repeated thoracocenteses or with chronic disease.[16] The triglyceride concentration within the effusion is higher than the concentration in the serum, while the cholesterol level is equal to or lower than that of the serum. Causes of chylothorax include heart disease (cardiomyopathy, congestive heart failure, pericardial disease), thoracic duct obstruction (intraluminal neoplasia or granuloma or extraluminal), traumatic rupture of the thoracic duct, cranial mediastinal mass (thymoma, lymphosarcoma, aortic body tumor), lung lobe torsion, diaphragmatic or peritoneopericardial hernia, post–pacemaker implantation in cats, heartworm disease, congenital malformations, cranial vena caval thromboembolism, ligation of the left brachiocephalic vein, and idiopathic contributors.[31,32]

Idiopathic chylous effusion is diagnosed by exclusion in most animals with true chylothorax.[33] Medical management consists of intermittent thoracentesis, a reduced-fat diet, and rutin (a benzopyrone). Rutin is a nutraceutical that stimulates macrophage breakdown of protein in lymph, accelerating its reabsorption.[31,34] Thoracostomy tubes are indicated only in animals with a traumatic chylothorax, if thoracentesis is required several times weekly, or following surgery.[6] Surgical intervention is recommended if the medical management is unsuccessful at providing good quality of life to the animal. Multiple interventions have been described, however a recent study has shown improved success rates with a combination of thoracic duct ligation and subtotal pericardectomy (100% of dogs and 80% of cats had resolution of pleural fluid accumulation for at least 60 days following the procedure).[33] Other surgical interventions reported include omentalization, passive pleuroperitoneal shunt, active pleuroperitoneal or pleurovenous shunt, and pleurodesis, but these procedures have shown a worse outcome.[31,33] Thoracoscopic ligation of the thoracic duct has been described in an experimental study.[35]

Complications of chylous effusion and its drainage include weight loss, electrolyte abnormalities (pseudoaddisonian), lymphopenia, hypoproteinemia, dehydration, and fibrosing pleuritis.[31] Rarely, spontaneous resolution of idiopathic effusion occurs. This is expected in most animals suffering from traumatic thoracic duct rupture.

30.4.6 Hemothorax

A hemothorax is defined as a pleural space effusion with a hematocrit that is 25% greater than that of the peripheral blood.[6] Evidence of erythrophagocytosis and absence of clotting or platelets on cytologic examination differentiate iatrogenic hemorrhage from a true hemorrhagic effusion (unless peracute). Hemorrhage within the pleural cavity can be caused by a severe coagulopathy, often associated with ingestion of an anticoagulant rodenticide that causes vitamin K epoxide reductase inhibition. Blunt or penetrating trauma, diaphragmatic hernia, thymic hemorrhage, neoplasia, pulmonary thromboembolism, lung lobe torsion, and dirofilariasis are other reported causes. Finally, iatrogenic hemorrhage may be caused by venipuncture, jugular catheter placement, Swan-Ganz catheter placement, thoracentesis, intrathoracic biopsy, intrathoracic fine-needle aspiration, and following thoracostomy or herniorrhaphy.

Cardiovascular shock often precedes respiratory compromise because as much as 30 to 60 ml/kg (dogs) or 20 ml/kg (cats) of pleural effusion is required to impair ventilation in those with normal pulmonary parenchyma.[36,37] Therefore treatment includes appropriate fluid resuscitation and blood transfusions as needed. Only sufficient blood should be retrieved from the pleural space to relieve dyspnea and allow adequate oxygenation, because the red blood cells that remain will be reabsorbed over the ensuing several days. Autotransfusion should be considered in trauma patients if more than 10 ml/kg of effusion is present.[36] Thoracostomy tube placement should be considered if the animal cannot be stabilized with thoracentesis and the hemorrhage is ongoing (see Chapter 32, Thoracostomy Tube Placement and Drainage). Surgery is rarely indicated with traumatic hemothorax unless a penetrating injury or uncontrollable hemorrhage is present.

30.4.7 Neoplastic Effusions and Pleural Neoplasia

Intrathoracic neoplasia may result in transudates or exudates by causing increased vascular permeability, obstruction of pleural and pulmonary lymphatic vessels or veins, shedding of necrotic material at the pleural surface (increasing oncotic pressure within pleural space), and obstruction or perforation of the thoracic duct.[38] Hemorrhage and pneumothorax may also result from neoplasia. Common primary thoracic cancers include mesothelioma, pulmonary carcinomas, and lymphosarcoma, but metastatic disease can also result in pleural abnormalities. Fluid analysis and cytologic studies are informative, but thoracic ultrasonography and computed tomography with fine-needle aspiration or biopsy will often be necessary to obtain a definitive diagnosis.

30.4.8 Fibrosing Pleuritis

Fibrosing pleuritis is a chronic condition in which the visceral pleura becomes thickened and restricts lung expansion as a result of inflammation within the thoracic cavity. Causes of this condition in humans include chylothorax, hemothorax, pleural infection, drugs, neoplasia, asbestosis, rheumatoid pleurisy, coronary bypass surgery, and uremia.[38] In veterinary medicine, this pathology is most frequently associated with chylous effusion.[39] Development of fibrosis depends on the degree of mesothelial cell and basement membrane damage and regeneration. A disorder of fibrin turnover is thought to lead to deposition of the intrapleural fibrin matrix.[39] Radiographs will show rounded, retracted lung lobe(s) that will not expand following thoracentesis. Pulmonary edema and interstitial fibrosis may contribute to dyspnea.[40] Decortication is the only successful therapy in humans and should be considered early for better outcome, while pulmonary changes are minimal. Pneumothorax is a common complication and reexpansion pulmonary edema is also possible. The prognosis is guarded with diffuse disease.[40]

30.5 PNEUMOTHORAX

A pneumothorax is open if it results from an insult to the thoracic wall, such as a penetrating thoracic trauma. In patients with a closed pneumothorax, the thoracic cavity is intact and the air originates from a lesion within the lung parenchyma, trachea, airways, esophagus, mediastinum, or diaphragm. A tension pneumothorax develops if the site of air leakage creates a one-way valve during inspiration and results in a rapidly increasing pleural pressure that exceeds atmospheric pressure.

Traumatic pneumothorax is a common sequela of motor vehicular accidents and was found concurrently in 47% of dogs with pulmonary contusions.[41] It has also been reported in most (63%) cats with high-rise syndrome.[42] External wounds, such as a projectile injury, bite wounds, and penetrating sharp objects to the thorax and cervical spine, are also frequent causes. Iatrogenic pneumothorax following thoracentesis is common, with an incidence of 3% to 20% in humans, with approximately 20% of those patients requiring a thoracostomy tube(s) placement.[14] Other common iatrogenic causes include leakage following lung lobectomy or respiratory tract surgery, thoracostomy tubes, fine-needle lung aspiration, barotrauma during positive-pressure ventilation, and tracheal tears. Spontaneous pneumothorax is most often associated with pulmonary bullous emphysema in dogs, with the Siberian Husky being overrepresented.[43] Multiple other pathologic conditions can lead to a spontaneous pneumothorax: neoplasia, feline asthma, pulmonary abscess, heartworm disease and other parasitic infections, foreign body migration, subpleural blebs, and pneumonia.[6] Finally, an infectious pneumothorax can be created by gas-forming bacteria within the thoracic cavity.

A tension pneumothorax can rapidly become life threatening, and immediate thoracentesis is indicated in animals suspected to have this condition. If the pneumothorax is not easily relieved with thoracentesis, an emergency minithoracostomy, with intubation and mechanical ventilation may prove lifesaving. Decreased venous return to the thorax in animals with a tension pneumothorax can be associated with cardiovascular collapse and shock. The thorax may become barrel shaped, and limited chest expansion is noted despite significant respiratory effort. However, animals with subclinical air accumulation may not require thoracentesis and the animal's progression should be followed closely because the air will be reabsorbed over days to weeks. A small amount of air in animals with severe pulmonary pathology may contribute significantly to dyspnea and should be relieved. Most patients with a closed traumatic or iatrogenic pneumothorax require thoracentesis only once or twice.

Animals should be monitored closely after thoracentesis for return of dyspnea, and cage rest is recommended for 2 weeks. The indications for a thoracostomy tube vary according to the clinical situation, but a tube should be placed in patients requiring more than two thoracocenteses within 6 to 12 hours (see Chapter 32, Thoracostomy Tube Placement and Drainage). Other indications include patients with a tension pneumothorax and those with a pneumothorax that require mechanical ventilation.

Constant negative pressure applied within the pleural cavity is recommended using a two-chambered or three-chambered continuous suction device, or commercially available Pleur-evac. Alternatively, a Heimlich valve may be used in medium and large breed dogs (although caution should be exercised if fluid accumulation is also present within the pleural space).

An exploratory thoracostomy is indicated if a closed traumatic pneumothorax does not resolve after 3 to 5 days of drainage. If an open pneumothorax is caused by a penetrating injury, the injury should be covered with an occlusive bandage, thoracentesis performed, and surgical repair is required as soon as the patient is stable. A spontaneous pneumothorax in dogs is best treated with surgical exploration, leading to a higher survival rate and decreased recurrence.[43] Thoracoscopic lobectomy has also been described in these patients.[44] Overall prognosis is good, with an 86% survival rate for treated dogs and cats with various causes of air accumulation. Favorable prognostic factors included absence of dyspnea, no need for thoracentesis, longer intensive care stay for dogs, and normal body temperature on admission in cats.[45]

30.6 SPACE-OCCUPYING LESIONS

Space-occupying lesions within the pleural space may occur secondary to benign or malignant masses within the mediastinum or chest wall. These typically are diagnosed with thoracic radiographs or computed tomography. Further details on these diseases are beyond the scope of this chapter.

30.7 DIAPHRAGMATIC HERNIA

Acquired diaphragmatic hernias are usually the result of blunt trauma associated with vehicular trauma, high-rise syndrome, or dog fighting or attacks, but may also be iatrogenic. Congenital diaphragmatic hernias are a result of aberrant embryogenesis and may be pleuroperitoneal, peritoneopericardial, or hiatal. These hernias are rare and beyond the scope of this chapter.

Clinical signs may occur immediately after the traumatic event, but are considered chronic if present for more than 2 weeks.[46,47] Dyspnea varies from none to severe according to the organ herniated, resulting pleural effusion, and concomitant thoracic injuries. The organs most frequently involved are the liver, stomach, and small intestine; the omentum and spleen are also frequently herniated.[46-48] On physical examination, borborygmus over the chest or asymmetrically quiet heart and/or lung sounds may be auscultated. The abdomen may be further tucked in or palpated “empty,” with failure to distinguish certain organs. Thoracic radiographs may reveal gas-filled abdominal organs within the thorax, an incomplete diaphragmatic border, pleural effusion, and/or cranially displaced abdominal organs. Additional radiographic views, ultrasonography, positive contrast celiography, and an upper gastrointestinal contrast study may aid in the diagnosis.

Thoracentesis and gastrocentesis may relieve the dyspnea prior to surgery. Cardiovascular stabilization prior to surgery is also important. Indications for immediate surgical intervention include herniated stomach, strangulated bowel or organs, inability to oxygenate properly after medical intervention, and ruptured viscera. Most data suggest that early surgical intervention (within 24 hours of admission) provides an excellent prognosis for acute cases.[47]

Postoperative complications include pneumothorax, hemorrhage, aspiration pneumonia, sepsis, arrhythmias, and death.[46-48] Reexpansion pulmonary edema (RPE) is a rare complication following surgery. It results from release of endotoxins and oxygen free radicals released, decreased surfactant concentrations, negative interstitial pressures, and/or chronic hypoxia causing increased vascular permeability and protein-rich pulmonary edema. Increased incidence of RPE has been associated with a longer duration of collapsed lung (≥72 hours). Care should be given to keep peak airway pressure below 20 cm H_2O to avoid positive end-expiratory pressure, and pleural air should be slowly evacuated postoperatively (>12 hours).[49] Prognosis for full recovery is excellent for acute cases (survival rate 94%).[47] Perioperative survival rate is lower (82% to 89%) when chronic acquired cases are included in the statistical analysis.[46-48] In some studies, dyspnea did not affect prognosis,[47] but older age, lower respiratory rate, and concurrent multiple injuries were associated with higher mortality in cats.[48]

31 Chapter 31 Thoracentesis

Nadja E. Sigrist, Dr.Med.Vet., FVH, DACVECC

31.1 KEY POINTS

- Thoracentesis is an easily performed diagnostic and therapeutic procedure and is safe if performed by skilled personnel.
- Blind thoracentesis is performed between the seventh and ninth intercostal spaces.
- Thoracentesis for fluid removal is best guided by ultrasonography.
- Strict aseptic technique is required.
- Indications for thoracentesis are pneumothorax and pleural effusions (chyle, transudate, blood).
- Contraindications to thoracentesis include severe coagulopathies, thrombocytopenia, and thrombocytopathia.

31.2 INTRODUCTION

The removal of fluid or air by puncturing the chest with a hollow needle, catheter, or tube is called *thoracentesis,* and it can be used as both a diagnostic tool and a therapeutic intervention.[1] In contrast to the emergency patient, pleural effusions are more common than pneumothorax in the critically ill patient.[1,2] In this patient population, pleural effusion may be caused by the primary disease process or can have secondary cardiovascular or iatrogenic causes. In humans, pleural effusions commonly accompany edematous states due to heart failure or volume overload, pneumonia, or acute respiratory distress syndrome.[2] Thoracentesis is an easy and potentially lifesaving procedure that every emergency and critical care veterinarian should be able to perform. Several techniques are discussed in this chapter.[3,4]

31.3 INDICATIONS

Animals with pleural space disease experience respiratory distress and may show an inward abdominal movement during inspiration. Other animals (especially cats) often show superficial and fast breathing. On auscultation, decreased lung sounds may be heard unilaterally or bilaterally. Lung sounds are generally decreased in the dorsal lung fields in association with pneumothorax and in the ventral regions of the chest in association with pleural effusion. Other clinical signs such as a heart murmur, distended jugular veins, increased lung sounds, coughing, bowel sounds heard during chest auscultation, or the feeling of missing organs on abdominal palpation might help in the differentiation of pleural space diseases. Thoracic radiographs, ultrasonography, echocardiography, packed cell volume and total solids, and albumin measurements may further help identify the cause of respiratory distress and the need for thoracentesis. Thoracentesis can be an important diagnostic and life- saving therapeutic intervention in the animal with severe respiratory distress and should not be withheld in the absence of a confirmed diagnosis of pleural space disease.

31.3.1

Box 31-1 Equipment Needed for Thoracentesis

- Clippers
- Surgical prep solution
- Lidocaine (1% to 2%)
- Gloves (sterile)
- Butterfly needle or over-the-needle catheter or hypodermic needle of appropriate size
- Extension set
- Three-way stopcock
- 10- to 60-cc syringe, depending on patient size and expected amount of fluid or air
- Tubes for fluid analysis (ethylenediaminetetraacetic acid, heparin, sterile tube for bacterial culture)
- Sterile saline (if using the needle technique)

Indications for thoracentesis are diagnosis or suspicion of pneumothorax, tension pneumothorax, or pleural effusion.[1,3] Pneumothorax can be traumatic or spontaneous in nature. Pleural effusion can arise from heart failure, inflammation associated with pneumonia, pancreatitis, pyothorax or feline infectious peritonitis, chylothorax, neoplasia, bleeding disorders, trauma, or lung lobe torsion.[2,5] Thoracentesis is indicated when air or fluid accumulation in the pleural space is believed to be causing or contributing to respiratory difficulties. Diagnostic thoracentesis in critically ill patients is indicated for pleural effusions that cannot be otherwise explained. Treatment of suspected infectious processes such as feline infectious peritonitis and pyothorax will usually include pleural drainage.[2,3]

Relative contraindications are pleural space diseases that cannot be treated by thoracentesis. These include pneumomediastinum, diaphragmatic hernia without fluid accumulation, and pleural masses. Other possible contraindications are bleeding disorders and large bullae because they may lead to deterioration of the patient's respiratory status.[1]

31.4 MATERIALS

If not already initiated, supplemental oxygen should be administered to all patients before any handling or restraint.[3] Material for orotracheal intubation, including a functional strong light source, should be prepared and ready to use when handling dyspneic patients. The required materials for the procedure should be prepared before handling the patient. Equipment needed for thoracentesis is summarized in Box 31-1.

Thoracentesis is performed with a needle, peripheral catheter, or flexible tube placed within the pleural space.[1] It is generally recommended to use the smallest gauge catheter or needle possible.[1] For example, to aspirate air, a 22-gauge butterfly needle can be used in cats and small dogs, and an 18-gauge butterfly needle may be effective in medium and large dogs. The catheter size is generally increased for the aspiration of pleural effusions.

Thoracentesis requires a minimum of two, and ideally three, people. One person is needed to restrain and limit patient movement, one to place and stabilize the needle, and one to aspirate and collect the fluid or air. The person operating the syringe and stopcock needs both hands, so if only two people are available, the person doing the tap and holding the needle in place also has to restrain the patient.

31.5 TECHNIQUES

The time of intervention has to be coordinated with all members of the team in order to minimize patient stress. The animal should choose its most comfortable position. Thoracentesis can be done with an animal standing, sitting, or lying on its side.[3] The region of the tap is clipped and aseptically prepared. The only exemption to this is an animal in severe respiratory distress in which the clinical signs do not allow time for surgical preparation. The anatomic site for thoracentesis should be based on auscultation results, position of the animal, and the nature of the suspected problem. Blind thoracentesis is performed at intercostal spaces 7 to 9 (Color Plate 31-1, *A*). If a pneumothorax is suspected, then the needle is inserted in the mid to upper thorax.[3] Fluid may be best aspirated in the lower third of the chest and fluid thoracentesis should be performed under ultrasonographic guidance whenever possible. When ventral thoracentesis is performed, care must be taken to avoid the internal thoracic arteries, which run along the ventral thorax, a few centimeters either side of the sternum, because laceration of this artery can result in significant hemorrhage.[3]

Before puncture, the subcutaneous tissue and the pleura can be infiltrated with a local anesthetic such as lidocaine (1 to 2 mg/kg).[1,3] The puncture site should be cranial to the rib or in the middle of the intercostal space in order to minimize damage to vessels and nerves located caudally to every rib.[1,6]

Several techniques for thoracentesis are described.[1,3,4,7,8]

31.5.1 Needle Insertion Techniques

31.5.1.1 Thoracentesis Using a Butterfly Needle

Using a butterfly needle, the three-way stopcock and syringe can be attached before the puncture is performed (see Color Plate 31-1, *A*). The needle is inserted through the skin and slowly advanced into the pleural space while gentle negative pressure is applied with the syringe (Color Plate 31-1, *B*).[4, 7] The needle is advanced until either it feels like the pleura has been penetrated or air or fluid can be aspirated. Once the pleural space has been entered, the needle is angled so that it is lying flat against the chest wall (directed caudally or ventrally) with the needle bevel directed away from the chest wall (Color Plate 31-1, *C*). Aspiration is performed gently and is stopped if negative pressure is obtained or the lung can be felt scratching against the needle.

The author prefers this technique for thoracentesis because it is fast and relatively safe. The short needle is an advantage in small animals but might be too short in large dogs. In large dogs, a hypodermic needle connected to an extension set and collection system can be used as an alternative.[3]

31.5.1.2 Thoracentesis Using a Hypodermic Needle with a Saline-Filled Hub

The hub of a hypodermic needle is filled with sterile saline before slowly advancing the needle through the skin. The needle is advanced until the saline is either sucked inward (indicating entry into the pleural space) or expelled (indicating a tension pneumothorax). The needle is then directed in a caudal direction. The extension tubing and stopcock are connected to the needle, and aspiration is performed as described above.[3]

31.5.2 Over-the-Needle Catheter Insertion Technique

31.5.2.1 Thoracentesis Using an Over-the-Needle Intravenous Catheter

Over-the-needle catheters are available in a variety of sizes and lengths and following placement provide a relatively atraumatic option for thoracentesis. An 18-gauge catheter is recommended for cats and small dogs, a 16-gauge catheter for medium size dogs and a 14-gauge catheter for large dogs. An over-the-needle catheter is advanced through a small relief incision and into the pleural space. Location in the pleural space is confirmed by removal of the stylet and aspiration of fluid or air after connection of the extension tubing and stopcock to the catheter. Alternatively the extension set can be connected to the stylet and gentle suction applied while advancing the catheter into the pleural space. When air or fluid is aspirated, indicating entry into the pleural space, the stylet is retracted a short distance such that the point of the stylet is enclosed within the catheter. The catheter and stylet are then advanced together in a ventral direction as a unit. Once fully inserted, the stylet is removed and the extension set is connected to the catheter.[1] Over-the-needle catheters can be fenestrated with a scalpel blade to improve the ability to aspirate viscous pleural effusions. Care must be taken to make the fenestrations small, evenly spaced and smooth.

31.5.2.2 Thoracentesis Using a Thoracentesis Tube

Commercially available thoracentesis tubes with several holes at the tip can be used for drainage of large amounts of fluid or air. These tubes have a sharp stylet or trochar that can be used for insertion of the tube into the pleural cavity. Once the tube enters the pleural space, the stylet is held in place and the tube is advanced over the stylet.[2]

31.5.3 Through-the-Needle Catheter Technique

This technique uses a 14- to 18-gauge introducer needle through which a flexible catheter is inserted once the needle enters the pleural space. First the catheter is connected to the extension set, three-way stopcock, and syringe, and then it is set aside. A second syringe is then attached to the empty introducer needle, and gentle suction is applied while the needle is entered into the pleural space. Once fluid or air can be aspirated, the needle 132
is held in place, the aspiration syringe is detached, and the catheter is inserted quickly through the needle into the 133
pleural space and advanced as far as possible. The needle is then withdrawn from the chest, leaving the catheter in place.[1]

31.5.4 Seldinger Technique

The Seldinger technique may be indicated to drain large amounts of fluid or air.[9] A guidewire is fed through a needle (similar to the technique above) into the pleural space. The needle is then removed, leaving the guidewire in place. A flexible catheter with several holes at the tip is then inserted over the guidewire. Once the catheter is inserted into the pleural space the guidewire is removed and the drainage tubing can be connected. This technique is rarely used for thoracentesis but might be an option in animals that require aspiration of large amounts of fluid when a thoracotomy tube is not possible or not desired.

Whatever procedure is used, once the needle has entered the pleural space, the entire needle should be placed parallel to the body wall with the bevel directed toward the lung to avoid iatrogenic lung laceration or puncture (see Color Plate 31-1, *C*).[7] It might be necessary to redirect the needle, however, and this must be done with the length of the needle parallel to the thoracic wall. Once negative pressure is achieved or the lung can be felt scratching at the needle, it is important to stop aspiration and to remove the needle in the flat position in order to decrease the risk of lung laceration.[7] Usually, the thorax is emptied maximally, which might require bilateral thoracentesis.

The amount of aspirated air or fluid should be measured and diagnostic evaluation of fluid initiated. Specific gravity, packed cell volume, cell count, total solid measurement, cytologic evaluation, and aerobic and anaerobic culture testing may be indicated.

In case of a negative result on thoracentesis and strong suspicion for pneumothorax or pleural effusion, it is recommended to repeat the procedure at another location.

31.6 POSTPROCEDURE CARE

Routine thoracic radiographs may not be essential, however they can be helpful in determining the cause of pleural space disease after fluid or air has been removed. They are also indicated in cases of unsuccessful thoracentesis. Postprocedure chest radiographs are recommended in human patients who are being ventilated, and this may be a consideration for veterinary patients as well.[2]

After thoracentesis, the thorax is auscultated on a regular basis and respiratory rate and effort are monitored. Thoracentesis should be repeated whenever the patient's respiratory status deteriorates. If repeated thoracentesis is necessary, chest tube placement should be considered.

31.7 COMPLICATIONS

Thoracentesis in human patients can have a high complication rate.[2] Pneumothorax and arterial laceration causing hemothorax are the most common complications.[1] The rate of pneumothorax after thoracentesis has been reported to be as high as 30% in human patients.[2] This rate can be diminished to 0% to 3% using ultrasonographic guidance when thoracentesis is done for pleural effusion.[2] Pneumothorax can occur as a result of laceration of the lung by the needle, by introduction of air through the needle or catheter system, by puncture of a bulla, or by exertion of extreme negative pressure with an nonexpandable lung, leading to pressure-related lung laceration.[1]

Hypotension and reexpansion pulmonary edema may occur if a large volume of fluid or air is evacuated in cases of chronic pleural space disease.[1,2] Vagal reactions have also been reported. Minor complications include formation of a hematoma or seroma at the puncture site. The incidence of complications of thoracentesis in animals has not been reported.

In the author's opinion, more animals are lost by not doing a thoracentesis than by performing an unnecessary thoracentesis, provided appropriate technique and asepsis are used. Thoracentesis performed by experienced personnel is a safe, simple, and potentially lifesaving technique.

32 Chapter 32 Thoracostomy Tube Placement and Drainage

Nadja E. Sigrist, Dr.Med.Vet., FVH, DACVECC

32.1 KEY POINTS

- Chest tubes are used to remove air or fluid from the pleural space.
- The diameter of a chest tube should be similar to the size of the mainstem bronchus. Smaller diameter tubes can be used for a simple pneumothorax; larger diameters are used to drain viscous fluid such as purulent exudate.
- Chest tubes are best inserted in an anesthetized and intubated animal. Sedation and local anesthesia may be sufficient in some cases.
- Several tubes and placement techniques exist.
- Thoracic radiographs are recommended following tube placement.
- Suction can occur on a continuous or intermittent basis.
- Patients with chest tubes need 24-hour monitoring.
- Strict aseptic placement and management are required.

32.2 INTRODUCTION

Therapeutic drainage of the pleural space dates back more than 200 years, and the technique of chest tube placement for various indications has been adapted and perfected since then.[1] Thoracostomy tubes, also known as *chest tubes* or *thoracic drains,* are used to evacuate air or fluid or both from the pleural space. The reader is also referred to Chapter 31 for a discussion of thoracentesis. In many cases, tube thoracostomy can be lifesaving. The technique, however, requires familiarity with pulmonary and pleural anatomy and physiology. Indications, insertion technique, maintenance, and complications are discussed in this chapter.

32.3 INDICATIONS

The purpose of a chest tube is the removal of air or fluid from the pleural space in order to relieve pulmonary collapse and restore pleural subatmospheric pressure. Pneumothorax and pleural effusion are usually managed initially with thoracentesis, which can be repeated several times (see Chapter 31, Thoracentesis). Placement of a thoracostomy tube should be considered if repeated thoracentesis is required for ongoing air leakage or fluid production, if thoracentesis is insufficient for the severity of the disease (e.g., tension pneumothorax), if ongoing fluid production is expected (e.g., chylothorax), if suction as well as lavage is planned (e.g., pyothorax), or following thoracic surgery (Box 32-1).[2-6]

In the unstable patient with ongoing pneumothorax or pleural effusion, there are no absolute contraindications to thoracostomy tube placement. Relative contraindications in stable patients are coagulopathies or pleural adhesions.[2]

32.3.1 Box 32-1 Indications for Chest Tube Placement

- Tension pneumothorax
- Ongoing air leakage despite repeated thoracentesis
- Pyothorax
- Chylothorax
- Penetrating chest injury
- After thoracic surgery
- Performance of pleurodesis

32.4 THORACOSTOMY TUBE PLACEMENT

32.4.1 Material

There are numerous commercially available thoracostomy tubes. They come in various sizes and materials. Each has its advantages and disadvantages regarding material, price, and tissue compatibility.[7]

Thoracostomy tubes are commercially available as single tubes and complete thoracostomy kits. Other tubes can be modified to perform as thoracostomy tubes; however, several criteria must be fulfilled. The tube must be sterile, elicit minimal tissue reaction in situ, have multiple fenestrations at the distal end, and be able to withstand the generation of negative pressure during suctioning without collapsing.[8-10] A radiopaque line along the tube helps localize its position on radiographs. Most commercially available chest tubes come with a stylet to aid insertion into the pleural space and may have an open or closed end.

Adapters such as Christmas tree connectors, tubing with a Luer-Lok, a noncollapsing extension set, and a three-way stopcock are used to connect the tube to the suction device. It is advisable to have a tube thoracostomy set available in the ready area of the hospital (Box 32-2).[2]

A key to chest tube size selection is the flow rate of either air or liquid that can be accommodated by the tube.[7] This depends on the diameter and length of the tube and viscosity and rate of formation of the fluid. In humans, chest tube size is selected based on the type of lung disease and whether mechanical ventilation is required. Pleural drainage catheter flow capabilities vary significantly.[7]

Generally chest tube size is chosen with consideration of the nature of the pleural disease and the width of the patient's intercostal space. An unnecessarily large chest tube is likely to be associated with increased pain and discomfort. Aspiration of pleural effusion, especially pyothorax, generally is aided by a larger tube diameter in 134 order to remove 135 clots, cell debris, and fibrin, but thoracostomy tubes for drainage of a pneumothorax do not need to be of maximal diameter.

32.4.1.1

Box 32-2 Tube Thoracostomy Emergency Set

- Instrument set with hemostat, straight Kelly or Carmalt clamp, forceps, needle holder, scalpel holder, suture scissors
- No. 10 and 15 scalpel blades
- Two 30-cm extension sets
- Two three-way stopcocks
- Christmas tree adapters, two of each size
- 20- and 50-cc syringes, one of each
- Thoracostomy tube of appropriate size
- Sterile gauze
- Antibiotic ointment
- 3-0 and 1-0 monofilament suture

32.4.2

Anesthesia

Patients requiring chest tube placement should be supplemented with oxygen and be preoxygenated for anesthesia induction.[2] Analgesia is maintained by infiltration of a local anesthetic at the site of insertion, a regional nerve block, or by general anesthesia including analgesics.[10] Animals can be sedated, however the author prefers general anesthesia with the animal intubated in order to control ventilation and oxygenation. A rapid induction protocol is recommended[10] (see Chapters 162 and 163, Sedation of the Critically Ill Patient and Anesthesia of the Critically Ill Patient, respectively). If possible, thoracentesis under local anesthesia is performed before chest tube placement to make the animal a better anesthesia candidate.

Before sedation or anesthesia is administered, all materials should be ready and the chest wall should be clipped if the animal will tolerate it with minimal stress. Maintaining sternal recumbency during the procedure may be necessary to avoid respiratory compromise.

32.4.3

Techniques

Thoracostomy tube placement can be classified as either closed or open.[11] The key point in placement is the generation of a subcutaneous tunnel between the skin incision and the point of entry into the pleural space to create an airtight seal around the tube.[8]

Strict aseptic rules are required with all techniques.[1] The lateral thorax is clipped from behind the scapula to the last rib and surgically prepared. The animal ideally is placed in lateral recumbency, pending sufficient ventilation and oxygenation in this position. Once the area is prepared and appropriate anesthesia or analgesia has been provided, the area is draped. The material including tube, adapter, and suction device and a small surgery pack should already be prepared.

Several techniques for closed placement of a chest tube exist.[2,8,9,11,12] The author prefers the following (Color Plate 32-1).[8,12] The skin over the lateral chest is pulled cranially by an assistant. While the skin is held in this position the appropriate intercostal space is identified, usually the seventh, eighth, or ninth. The length of tube to insert into the thorax is estimated at this time by holding the chest tube along side the chest with the tip aligned to the second rib, without compromising sterility. A small skin incision, slightly larger than the diameter of the tube, is made overlying the desired intercostal space midway between the dorsal midline and the center of the lateral thorax. The subcutaneous tissue and muscle layers are bluntly dissected with a hemostat. The pleura is then penetrated bluntly using a large hemostat or Carmalt forceps (see Color Plate 32-1, *A*). During this maneuver, the anesthetist is asked to stop ventilation in order to minimize injury to the lung.[13] Also, injury to the underlying organs is minimized by holding the hemostat close to the tip with the nondominant hand to avoid overpenetration.

Once the pleura is penetrated, the tips of the hemostat are opened, thereby creating an opening for the thoracostomy tube (see Color Plate 32-1, *B*). Before insertion, the trochar can be retracted slightly so that the sharp tip is protected by the tube. The tip of the tube is introduced into the thorax and is then advanced toward the uppermost elbow. Once the tip of the tube is well inside the thorax, the hemostat can be removed. The thoracostomy tube should be inserted so that the tip is roughly at the level of the second rib. It is essential that all tube fenestrations are within the thoracic cavity.[2] The stylet is then withdrawn and the hemostat or a tube clamp can be used to clamp the tube off.

Alternatively, the tube is connected directly to the suction device. As the skin is released and retracts caudally over the tube, a subcutaneous tunnel is created. The Mac technique can be used to rule out kinking of the tube: the tube is twisted 180 degrees in each direction and then released. If the tube spins back into its position, this is indicative of kinking.[14] Depending on the urgency for pleural evacuation, suction is instituted prior to or after securing the tube. A purse-string suture is placed around the skin incision if the fit is not firm. The tube is then fixed using a finger-trap suture pattern.[15] A single interrupted suture is placed through the skin at the site of insertion. This suture may pass through the periosteum of the rib (this requires additional local anesthetic) and is tied in a gentle loop, leaving equal and long suture tags. The sutures tags are used to perform the finger trap by placing a single knot on top of the tube, then crossing underneath the tube followed by another single knot on top of the tube and so on. After four to six finger traps, the tube is once more anchored to the skin, therefore minimizing the chance of dislocation (see Color Plate 32-1, *C*). The tube is then connected to the suction system of choice.

Antibiotic ointment is applied to the insertion site and the area is covered with sterile gauze. A bandage is applied to secure the thoracostomy tube to the chest wall and minimize risk of accidental removal.[8]

If no assistant is available to pull the skin forward, the subcutaneous tunnel can be made with a large hemostat or Carmalt forceps. The skin incision is made more caudally (eighth to tenth intercostal space), and the hemostat is tunneled cranially through the subcutaneous tissues' two intercostal spaces, to the desired insertion point at the level of the sixth to eighth intercostal space. At this point, the pleural space is entered and the tube is inserted as described earlier.[2,11]

A thoracostomy tube with a sharp-ended stylet can be placed without the aid of a hemostat[11]; however, the technique of perforating the pleura by punching the distal end of the stylet is not recommended because of increased risk of injury to intrathoracic organs. A combination of blunt dissection through the intercostal space with hemostats and penetration of the pleura with the stylet is preferable.

An alternative for thoracostomy tube placement is the Seldinger technique.[2] The tube is inserted into the thorax with the use of a guidewire that has been inserted through a small needle. After removal of the needle, the guidewire stays in place and the modified tube is advanced over the wire. Once the tube is placed, the guidewire is removed and the tube is secured as described above. Care is taken not to compromise the lumen of the catheter with the finger-trap suture. The Seldinger technique has the advantage of a smaller incision and might therefore be less painful and leakage less likely.

Open insertion of a thoracostomy tube is performed during thoracotomy, with the advantage that the tube is placed safely under direct visualization. Under certain circumstances, such as when an animal has an open penetrating chest injury, a thoracostomy tube can be inserted directly into the thoracic cavity through the wound. The wound is then sealed with nonadhesive dressing and the thorax is evacuated immediately. Proper wound debridement and lavage and placement of a new and sterile thoracostomy tube are required as soon as the patient is stable enough for anesthesia.

32.5 DRAINAGE

After placement of a thoracostomy tube, negative pressure is generated by manual aspiration or a continuous suction apparatus. The smallest number of connections should be used because they are potential sites for leaks. Cable ties are recommended to secure all connections. Too much negative pressure should be avoided because it can lead to lung tissue trauma and occlusion of the tube by mediastinal or pleural tissue. The normal difference between the pleural pressure and the intraalveolar pressure is 4 to 8 mm Hg, which translates to 5 to 10 ml of vacuum in a syringe.[11]

Thoracic radiographs are recommended to confirm proper tube placement, evaluate expansion of the lung, and identify residual pleural fluid or air.[2] Tubes that are kinked or tubes that are not placed between the chest wall and the lung should be partly removed and redirected (only if sterility will not be compromised). Insertion as far as the thoracic inlet might cause extensive pain, and in this case the tube should be pulled back to the level of the second rib.

Further drainage is accomplished using either intermittent or continuous suction. The method used depends on the nature of the pleural space disease and the availability of equipment.[2,8,16,17] In veterinary patients, intermittent manual syringe aspiration every 1 to 6 hours is sufficient in many cases and allows for adequate drainage and maintenance of negative pleural pressure.[11]

32.5.1 Passive Drainage Techniques

Passive drainage of the pleural space relies on the increased intrathoracic pressure generated during exhalation in a spontaneously breathing patient to force air or fluid from the pleural space. Alternatively, in patients receiving positive-pressure ventilation pleural drainage will occur during the inspiratory phase. These techniques generally are not as effective as active drainage and are more suited to mild pleural space disease. Interestingly, in one human study passive drainage following thoracoscopy for spontaneous pneumothorax led to more rapid recovery than active thoracic drainage techniques.[18] Human patients usually are more comfortable with passive drainage than with active drainage. Passive drainage is also enhanced by keeping the patient higher than the drainage apparatus; this may not be possible in larger veterinary patients.

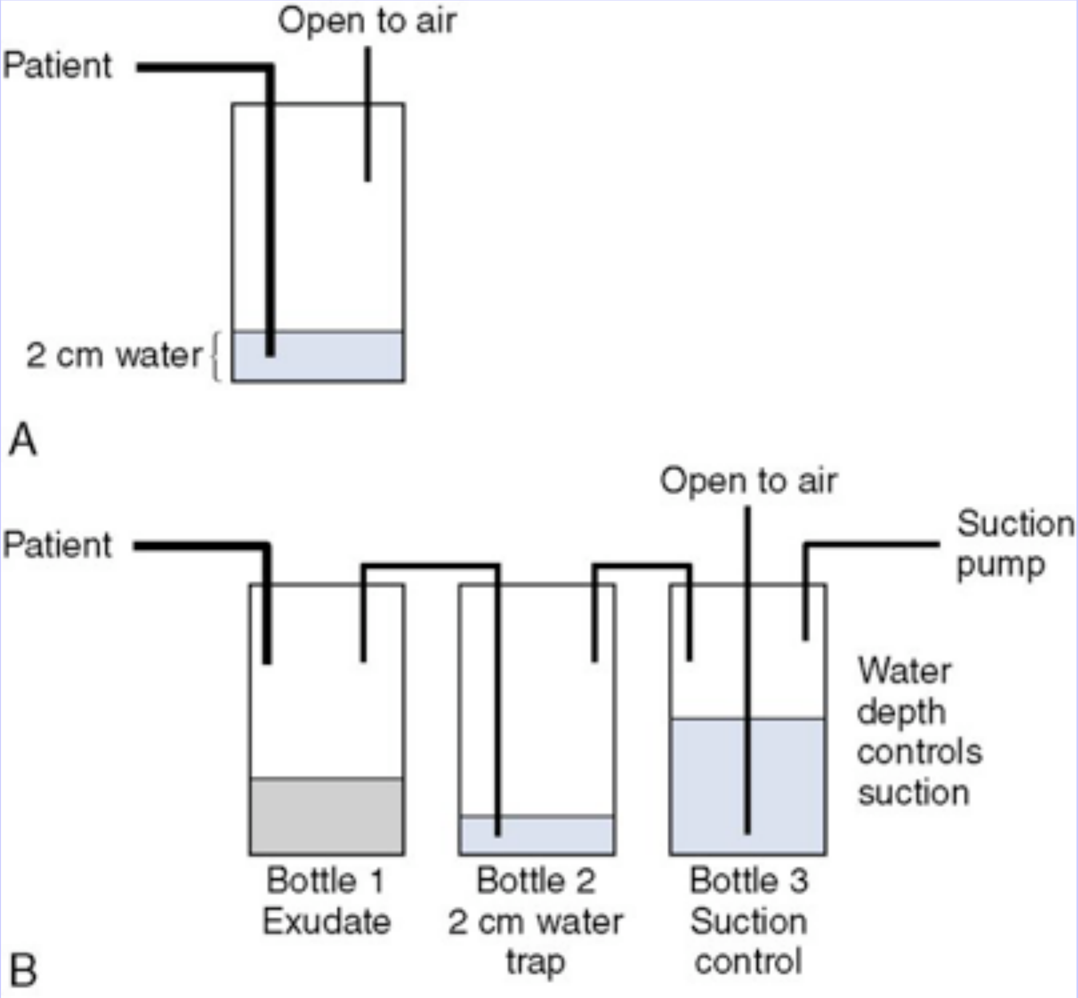
Passive drainage can be achieved with a simple one-bottle water seal (Figure 32-1, *A*) or with a Heimlich valve. Heimlich valves are one-way flutter valves that can be attached to chest tubes to allow pleural air to be expelled during exhalation (if breathing spontaneously) but prevent entrainment of air into the pleural space during inspiration.[2] They provide a simple and inexpensive option for drainage but are effective only in the management of relatively mild pneumothoraces and are prone to malfunction. The Heimlich valve can be occluded readily by secretions, which may be a life-threatening complication, and requires constant monitoring.

32.5.2 Active Drainage Techniques

With continuous air leaks or severe fluid accumulation, continuous active suction may be necessary. Continuous suction may also allow sustained lung expansion and better healing of leaks by pleural adhesion. Continuous suction requires a water seal between the suction pump and the chest tube; this can be achieved with a two-chamber or three-chamber suction apparatus.[2] In connecting chest tubes to a suction system the smallest number of connections should be used because they are potential sites for leaks. Cable ties are recommended to secure all connectors.

The three-chambered, waterseal suction apparatus is recommended. These are commercially available or can be constructed with three bottles (Figure 32-1, *B*).[2,17] A suction pressure of 10 to 20 cm H_2O is used.[2,9] This is 136 achieved by filling the third chamber (connected directly to the suction pump) with water to a depth of 10 to 20 137 cm. The central chamber is the water seal, which is achieved by submerging the tubing entering the second bottle in 2 to 3 cm of water. The first chamber is connected to the chest tube and collects fluid aspirated from the thorax. Pleural effusion can be quantitated by measuring the fluid accumulation in the first chamber, while ongoing air production from a pneumothorax is evidenced by bubbles in the central water seal container. With persistent air leakage, continuous suction may be necessary for several days. If intrapleural air continues to accumulate after more than 2 to 5 days, surgical exploration of the thoracic cavity may be indicated.[2,6,19]

Figure 32-1 **A,** Single-bottle suction apparatus. This single-bottle system acts both as a water seal and a collection chamber so that the depth of liquid may increase with time, which will reduce effective drainage. This system is for passive drainage only. Bubbling is evidence of air drainage from the pleural space. **B,** Three-bottle suction apparatus. The three-bottle system has a collection bottle, a water trap, and suction control bottle. It allows regulation of suction level by changing the water depth in bottle 3. There is a water seal so that suction can be turned off without concern of air leaking back into the pleural space. The exudates in bottle 1 can be evaluated and emptied independently. The water trap will bubble if air is evacuated from the pleural space.



If at any time negative pressure cannot be achieved despite continual aspiration, the tubing should be checked for air leaks, and all adaptors and three-way stopcocks should be checked and replaced in a sequential manner.

32.6 MAINTENANCE AND CARE

Strict aseptic care is required. Antibiotic prophylaxis is controversial and depends mostly on the circumstances in which the tube was placed and the animal's underlying disease.[1,20] Prophylactic antibiotics may be indicated in people if thoracostomy tubes are placed because of chest trauma.[21] Thoracostomy tubes increase the risk of nosocomial infections after thoracic surgery in humans.[22]

Bandages should be changed at least daily, and tubing should be wrapped to prevent accidental removal by the animal. A tubing clamp can be placed in addition to the 3-way stopcock if the tube is not being aspirated. It is essential that the animal be prevented from damaging the tube, and an Elizabethan collar may be required in some cases.

Animals with thoracostomy tubes need 24-hour monitoring. Respiratory rate and effort are checked on a regular basis, and other vital parameters are monitored based on the patient's problem(s). Analgesia is best provided by a combination of intravenous analgesia and administration of local anesthetics through the chest tube (see Chapter 164, Analgesia and Constant Rate Infusions).

32.7 REMOVAL

The decision to remove a chest tube depends on the rate of fluid production or air accumulation in the pleural space. As a general guideline, no air should be retrieved for 24 hours before tube removal. Tube removal can be considered if fluid production falls to less than 2 ml/kg per 24 hours.[8] In humans, thoracostomy tubes are removed if daily fluid aspiration is less than 150 to 200 ml.[2,23] Exemptions are septic exudates and the use of the thoracostomy tube as a device for lavage. Dogs with spontaneous pneumothorax requiring chest tubes have them for an average of 4.5 days (range 1 to 8 days).[11,24]

Thoracic radiographs are recommended before tube removal to ensure that the pleural space disease has truly been resolved. Tube occlusion or displacement can lead to negative aspiration results despite persistent pleural space disease.[2] Studies in humans recommend routine chest radiographs after thoracostomy tube removal only if clinical signs of respiratory distress are identified.[25]

For removal, the tube is smoothly and rapidly removed and a nonadherent pad with antibiotic ointment is pressed firmly over the exit site. A light bandage is applied and the incision is allowed to heal by second intention.

32.8 COMPLICATIONS

The most common complication of percutaneous thoracostomy is improper placement.[26] Other complications include hemorrhage, infection, visceral injury, and reexpansion pulmonary edema.[27] In human medicine, the complication rate is between 20% and 30% and depends on the experience of the operator.[28,29]

33 Chapter 33 Chest Wall Disease

Suzanne Donahue, VMD, DACVECC

33.1 KEY POINTS

- The chest wall is necessary for respiration and protection of the thoracic cavity.
- Diseases of the chest wall include congenital anomalies, neoplasia, trauma-induced abnormalities (rib fractures, flail chest, penetrating wounds), cervical spine disease, and neuromuscular disease.
- The history and physical examination can usually establish a diagnosis of chest wall disease. Thoracic radiographs may also be informative.
- Initial treatment is aimed at stabilizing the patient and providing mechanical ventilatory assistance if indicated. Medical or surgical management of underlying diseases may be necessary.

33.2 INTRODUCTION

Diseases of the chest wall must always be a differential for diagnosis of respiratory distress. Often a thorough history and physical examination will help to confirm a diagnosis and ensure appropriate and timely therapy.

33.3 CHEST WALL ANATOMY AND FUNCTION

The chest wall has two main functions. The bones of the chest wall (thirteen pair of ribs, thirteen vertebrae, and nine sternebrae) serve to protect the internal structures of the thorax. The muscles of the chest wall (mainly the diaphragm and the external and internal intercostal muscles), and the nerves that innervate them, are necessary for normal respiration to occur.

When the diaphragm is stimulated, it contracts and moves caudally in animals. At the same time, the intercostal muscles move the rib cage cranially and outward. When the chest wall moves outward, the lungs are “pulled” with it as negative pressure is generated within the pleural space. As the intrathoracic volume increases during inspiration, the pressure within the alveoli decreases slightly. Airway pressure becomes lower than atmospheric pressure, which causes air to flow into the lung. When the diaphragm and intercostal muscles relax during expiration, the elastic recoil of the lungs and chest wall compresses the lungs and expels the air. During heavy breathing, the abdominal muscles also assist with exhalation.

33.4 DIAGNOSIS OF CHEST WALL DISEASE

Diagnosis of chest wall disease is based mainly on history and physical examination. A hallmark of chest wall disease with a component of respiratory muscle paralysis is a paradoxical breathing pattern. This is characterized by decreased chest wall movement and inward movement of the abdominal wall during inspiration instead of the normal outward movement. Radiographs may be helpful when certain disease processes are suspected (rib fractures, congenital deformities, or neoplasia). Lastly, arterial blood gas changes indicating hypoventilation can also provide evidence of chest wall disease. In general, an arterial partial pressure of carbon dioxide ($PaCO_2$)

greater than 50 mm Hg is evidence of hypoventilation that may be due to several disease processes, including chest wall disease.

33.5 DISEASES OF THE CHEST WALL

33.5.1 Congenital

Congenital disease of the chest wall is rare. The most common abnormality is pectus excavatum, an inward concavity of the sternum and costal cartilages. Animals with this disease are often asymptomatic; however, respiratory distress can occur via either "restrictive ventilation or paradoxical movement of the deformity during inspiration."[1] Surgical management is indicated only if there is significant respiratory impairment.

33.5.2 Neoplasia

Neoplasia of the chest wall, although fairly common, does not often lead to respiratory distress. The main concern is whether the mass is benign or malignant. A biopsy is needed to determine treatment options. Common masses of the chest wall include lipoma, chondrosarcoma, osteosarcoma, fibrosarcoma, mast cell tumor, and hemangiosarcoma.[1] Surgical management, including aggressive resection, movement of the diaphragm cranially, mesh placement, or flap procedures may be necessary and may lead to respiratory difficulties postoperatively, especially in animals that require one or more concomitant lobectomies. Pain control is an important part of patient treatment in these cases (see Chapter 164, Analgesia and Constant Rate Infusions).

33.5.3 Rib Fractures

33.5.3.1 Trauma

Rib fractures are often significant from the standpoint of pain management. The patient may hypoventilate if severe discomfort is present during respiration. Although rib fractures do not routinely require stabilization, their presence should alert the clinician to the possibility of underlying soft tissue thoracic injury, including pulmonary contusions, diaphragmatic hernia, hemothorax, and/or pneumothorax. If the rib fractures are very unstable, they can cause further trauma to the surrounding tissues and intrathoracic structures (i.e., lungs), thus necessitating surgical intervention.[2]

33.5.3.2 Flail Chest and Intercostal Muscle Damage

Flail chest is defined as a "fracture of several adjoining ribs resulting in a segment of thoracic wall that has lost continuity with the rest of the hemithorax."[2] This results in the fractured segment moving paradoxically throughout respiration. During inspiration, as the chest wall moves outward, the flail segment collapses inward due to negative intrapleural pressure and vice versa.[2]

Respiratory distress often occurs in patients with flail chest. There are two are reasons for this. First, patients can hypoventilate purely because of pain. Second, many animals with flail chest have other lung injuries, such as pneumothorax, hemothorax, pulmonary contusions, or a diaphragmatic hernia, which can increase the degree of hypoxemia.

Management of flail chest can be purely medical or a combination of medical and surgical. Initially, the patient should be laid down on the side with the flail segment, or the chest can be wrapped. This reduces bulging of the segment during exhalation (although it will still be pulled inward with inhalation) to minimize pain and secondary trauma. If ventilation is severely impaired, intubation and manual ventilation may be lifesaving in that it may ensure that a tension pneumothorax is not present before positive-pressure ventilation is initiated (see Chapter 213, Basic Mechanical Ventilation). Aggressive analgesia is often helpful, although the animal should be monitored closely for respiratory depression and mechanical ventilation provided if necessary (see Chapters 164 and 213, Analgesia and Constant Rate Infusions and Basic Mechanical Ventilation, respectively).

Time and cage rest are often the treatment of choice. An external stabilization splint, which covers the affected and unaffected surrounding areas and is sutured to the chest wall, has been used to provide chest wall support. Whether or not to surgically stabilize the flail chest segment is controversial. Often the actual flail segment contributes very little to dyspnea, hypoxemia, or hypoventilation, and pain or coexisting disease is the primary cause of these abnormalities. However, surgically stabilizing the segment reduces pain and improves thoracic wall excursion and ventilation, and should be performed if anesthesia and surgery are required for other reasons. If the flail segment is displaced or adding to further lung dysfunction (laceration of the lung or vasculature by the flail segment), surgery is necessary (see Chapter 153, Thoracic Trauma).

Tearing of the intercostal muscles secondary to fractured ribs or a penetrating injury may cause a loss of chest wall rigidity and paradoxical movement of the affected area or flail segment. The degree of ventilatory impairment depends on the size of the destabilized area. This condition rarely causes direct respiratory impairment, but rather leads to pain and may be a sign of additional injuries.

33.5.3.3 Penetrating Wounds

If penetrating chest wall injuries allow air to enter into the pleural space, an open pneumothorax will develop. This should be closed manually to create an airtight seal and a chest tube should be placed, either at the site of the wound or a different location, in order to remove the air and reestablish negative pressure in the pleural space. A liberal amount of sterile ointment and an occlusive chest wrap can be used to cover the wound and maintain an airtight seal. As soon as the patient is stabilized, debridement and surgical repair should be performed. It is very important to monitor these patients closely because other internal organs could easily have been damaged as well, leading to continued pneumothorax, hemothorax, diaphragmatic hernia, or pulmonary contusions (see Chapter 153, Thoracic Trauma).

33.5.4 Cervical Spine Disease

Cervical spine diseases, such as cervical spine fractures or intervertebral disk disease, can cause significant hypoventilation. The exact mechanism is unknown, although there are many potential contributing factors. In dogs, the medullary respiratory center sends information via the reticulospinal tracts to the phrenic nerve and the segmental intercostal nerves. The phrenic nerve leaves the spinal cord between the fourth and sixth vertebral bodies and provides motor innervation to the diaphragm. The segmental intercostal nerves innervate the intercostal muscles and leave the spinal cord between C1 and T2. If these pathways are disrupted, ventilatory failure can ensue.[3] In cats, there is some evidence that afferent tracts to the respiratory center may be damaged during surgery on the cervical spine.[4]

33.5.5 Tick Paralysis

33.5.5.1 Neuromuscular Disease (see Chapter 101, Lower Motor Neuron Disease)

Tick paralysis is induced when an engorged female tick secretes a neurotoxin into the patient that either inhibits depolarization of motor nerves or blocks the release of acetylcholine. In the United States, the ticks most frequently involved are the American dog tick *(Dermacentor variabilis)* and the Rocky Mountain wood tick *(Dermacentor andersoni)*.[5] Signs typically develop 1 week after attachment of the tick. Patients often demonstrate marked ataxia of all four limbs, which progresses quickly to tetraparesis with generalized lower motor neuron symptoms. For an unknown reason, cranial nerve involvement is rare in the United States. If the tick is not found and removed, patients can progress to respiratory failure and ultimately death. Diagnosis is often made upon cessation of signs following tick removal. This often occurs within 24 hours, with a complete recovery by 72 hours.[5] If tick paralysis is suspected, but no ticks are found, rapid-acting insecticide solutions should be applied to the patient.

33.5.5.2 Acute Idiopathic Polyradiculoneuritis

Acute idiopathic polyradiculoneuritis, also known as coonhound paralysis, is seen primarily in hunting dogs that presumably have been exposed to raccoons, but it also has been seen in dogs with no raccoon exposure.[5] The disease occurs via immune-mediated demyelination and degeneration of axons of the ventral roots and spinal nerves.[5] This leads to an effective blockade of motor signals from the spinal cord to the muscles.

Clinical signs begin with pelvic limb paresis and hyporeflexia and can progress to tetraparesis within several days. The clinician will often detect diffuse hyperesthesia. If the disease is rapidly progressive, the patient may develop respiratory paralysis. Cranial nerve involvement is uncommon with coonhound paralysis. The clinical course tends to be approximately 3 to 6 weeks but can be significantly longer. Improvement usually begins by the third week.[5]

Diagnosis is based mainly on clinical suspicion. Coonhound paralysis is suspected when tick paralysis and botulism can be ruled out. The diagnosis can be supported by electromyelographic evidence of diffuse denervation of affected muscles.[5] Management is supportive and may be prolonged in severe cases. The prognosis is typically good if complications are prevented, but recurrences have been described.

33.5.5.3 Botulism

Botulism is seen when the preformed *Clostridium botulinum* toxin is ingested. There are several types of botulism toxin, but all cases reported in dogs have been the result of type C toxin,[5] which is known to inhibit the release of acetylcholine from nerve terminals.

Clinical signs occur within 1 week of ingestion. These include mild generalized weakness or, in more severe cases, tetraparesis and possible respiratory failure. Unlike coonhound paralysis, cranial nerve deficits can be seen with botulism. Duration of the disease is usually less than 2 weeks.[5]

Diagnosis is confirmed only by identification of the toxin in the serum, feces, or vomitus of the patient, or in the food or carrion that the patient ingested. Electromyelography may help to differentiate botulism from coonhound paralysis, but it is not definitive.

As for the other lower motor neuron diseases, management is largely supportive. There is an antitoxin available, but it needs to be administered before the toxin binds to receptors, which is not often possible.[5] Efficacy of antibiotics to manage *Clostridium* is unknown. Prognosis is generally good with aggressive supportive care and prevention of complications (e.g., aspiration pneumonia).

33.5.5.4 Fulminant Myasthenia Gravis

Myasthenia gravis occurs most commonly due to an autoimmune block, alteration, or destruction of the acetylcholine receptors at the neuromuscular junctions, but it can also be due to a congenital decrease in the number of these receptors on the postsynaptic membrane. Physical examination often reveals normal neurologic findings in the resting animal. With exercise, muscle weakness becomes apparent and will worsen with continued exertion. The limbs are most grossly affected. Evidence of regurgitation with or without aspiration pneumonia secondary to megaesophagus commonly is present.

A presumptive diagnosis is made based on exercise-induced weakness, a decreasing response to repetitive nerve stimulation, or a positive response to acetylcholinesterase drugs such as edrophonium.[5] A definitive diagnosis is made when acetylcholine receptor antibodies are detected in the serum. Muscle biopsy with special staining is also used to diagnose congenital myasthenia gravis.

Management entails the use of an anticholinesterase agent like pyridostigmine and, often, glucocorticoids (see Chapter 101, Lower Motor Neuron Disease). Management with azathioprine and mycophenolate mofetil has also proven useful and may minimize side effects of steroid administration.Thymectomy has also been described for patients that respond poorly to medical management, because thymoma has been found to cause myasthenia gravis.[5]

33.5.5.5 Coral Snake Envenomation

Bites from the coral snake *(Micrurus fulvius fulvius)* also lead to lower motor neuron disease. The venom from these snakes contains neurotoxic components, which leads to neuromuscular blockade. Clinical signs develop rapidly and, unfortunately, there is usually minimal to no local tissue reaction as is seen with other snake bites. Signs range from peripheral weakness to tetraparesis. In severe cases, paralysis of respiratory muscles occurs. Patients may or may not have signs of hemolysis.[6]

Management is mostly supportive, although antivenin can be used early in the disease process. Unfortunately, once signs are evident, efficacy of antivenin diminishes rapidly (see Chapter 101, Lower Motor Neuron Disease).[6]

34 Chapter 34 Nonrespiratory Look-Alikes

Kelly Hall, DVM

Justine A. Lee, DVM, DACVECC

34.1 KEY POINTS

- Respiratory distress, dyspnea, or tachypnea may occur as a result of disease processes not directly affecting the upper and lower airways, pulmonary parenchyma, pulmonary circulation, pleural space, and chest wall or diaphragm. Examples of nonrespiratory “look-alikes” (increased respiratory effort due to nonrespiratory causes) include respiratory compensation for metabolic acidosis, decreased oxygen content, pain, anxiety, stress, drugs, hyperthermia, hypovolemia, abdominal enlargement, metabolic derangements, and neurologic disease.
- Respiration is the only vital function with both automatic and voluntary components.
- The compensatory mechanism for metabolic acidosis is hyperventilation resulting in a respiratory alkalosis secondary to increased respiratory rate and depth.
- Decreased oxygen delivery to chemoreceptors due to a decrease in oxygen content (e.g., anemia, dysfunctional hemoglobin, pericardial tamponade, or a decrease in the partial pressure of oxygen in the plasma) or hypovolemia (e.g., decreased cardiac output) results in increased respiratory rate and depth.
- Pain, anxiety, and stress can affect the voluntary component of respiration, resulting in apparent dyspnea.
- When hyperthermia occurs, evaporative cooling via the respiratory tract results in tachypnea and a shallow breathing pattern.
- Disease processes affecting the nerves, muscles, or neuromuscular junctions to the intercostal muscles or diaphragm may result in an abnormal respiratory pattern.
- Brain lesions or drugs affecting areas that are responsible for respiratory signaling (e.g., medulla, cerebral cortex) will directly affect breathing rate and rhythm.
- Metabolic diseases, such as hyperadrenocorticism and hyperthyroidism, and severe biochemical derangements (e.g., potassium, calcium, glucose) affect the respiratory pattern as a result of altered respiratory mechanics, input to respiratory sensors, and compromise of respiratory muscles.
- Severe abdominal distention may cause pain, discomfort, decreased venous return to the heart, and metabolic acidosis, in addition to pushing the diaphragm cranially and inhibiting normal inspiratory movement.

34.2 INTRODUCTION

The “simple” job of the respiratory system, which is the delivery of oxygen to vasculature in the lungs and removal of carbon dioxide, is regulated by a complex system centered in the brain. The brain stem (medulla) generates signals transmitted to both the upper airway and main and accessory respiratory muscles to control the rate and pattern of breathing. Modification of the respiratory rate and pattern can be accomplished via afferent feedback from mechanoreceptors in the lung, airway, diaphragm, and chest wall, as well as chemoreceptors (monitoring pH and partial pressures of carbon dioxide [PCO_2] and oxygen [PO_2]) located centrally and peripherally. Additionally, the cortex and subcortex (supramedullary regions) can affect respiratory rate and pattern with volition, emotion, and onset of exercise.[1,2] In other words, respiration is the only vital function that has both an automatic (brain stem) and a voluntary (cortical) component.[3]

Because of the extensive network of input that can affect respiratory rate and pattern, patients with disease processes not directly affecting the upper and lower airways, pulmonary parenchyma, pulmonary circulation, pleural space, or chest wall may present with clinical signs of respiratory distress, dyspnea, or tachypnea. This becomes important to the veterinarian because patients with respiratory difficulty should be evaluated for both respiratory disease and nonrespiratory "look-alikes." Specific nonrespiratory look-alikes include respiratory compensation for a metabolic acidosis, a decrease in oxygen content (e.g., anemia, dysfunctional hemoglobin), pain, anxiety, stress, drug-induced difficulties, hyperthermia, hypovolemia, abdominal enlargement, metabolic disease, and neurologic disease. A concise history from the owner, a thorough physical examination, and appropriate diagnostic techniques should all be used concurrently to differentiate respiratory system disease from these nonrespiratory look-alikes. Multiple concurrent disease processes are common.

34.3 pH and pCO_2 RECEPTOR ACTIVATION

The most common acid-base abnormality in small animals is metabolic acidosis.[4] Metabolic acidosis is characterized by an increased hydrogen ion concentration, decreased pH, and decreased bicarbonate ion (HCO_3^-) concentration (see Chapter 59, Acid-Base Disturbances).[5] Metabolic acidoses most often result from a loss of bicarbonate-rich fluid from the body, increased hydrogen ion production, or decreased renal hydrogen ion excretion. In small animal medicine, the more common processes that cause metabolic acidoses are diabetic ketoacidosis, diarrhea-induced hyperchloremic acidosis, lactic acidosis, and uremic acidosis.[5] The normal compensatory mechanism for metabolic acidosis is to expel additional carbon dioxide via hyperventilation, as evidenced by a decrease in the partial pressure of carbon dioxide in the peripheral arterial blood ($PaCO_2$). This compensatory mechanism is initiated as a result of the increased number of hydrogen ions stimulating peripheral and central chemoreceptors, which in turn increases alveolar ventilation (hyperventilation).[5]

Canine patients with metabolic acidosis disorders may demonstrate increased respiratory depth and rate reflecting an attempt to normalize systemic pH by blowing off carbon dioxide. The expected compensatory respiratory response is a decrement in $PaCO_2$ by 0.7 mm Hg per 1 mEq/L decrease in plasma bicarbonate concentration.[5] Although data are limited, this respiratory compensation is less commonly observed in cats.[6]

141

142

Respiratory compensation may result in characteristic patterns such as Kussmaul respirations seen with diabetic ketoacidosis; this is clinically recognized as a deep, rhythmic breathing pattern.[5] Although this may not be classically seen in veterinary medicine, compensatory hypocapnia should be differentiated from underlying lung disease in these patients.

34.4 pO_2 RECEPTOR ACTIVATION

Oxygen-sensing receptors located in the carotid and aortic bodies are stimulated to increase respiratory rate and depth when inadequate oxygen is delivered to their sites. Under normal circumstances, central respiratory drive is modified primarily by changes in arterial PCO_2, which leads to an increase in the hydrogen ion concentration.

However, hypoxemia becomes the primary stimulation for ventilation when the partial pressure of oxygen in the peripheral arterial blood drops below 50 mm Hg (PaO_2 <50 mm Hg).[7]

Recall that the formula to determine arterial oxygen content (CaO_2) is:

$CaO_2 = (Hg \times SaO_2 \times 1.34) + 0.003 \times PaO_2$ and for oxygen delivery (DO_2) is:

$DO_2 = CaO_2 \times CO$ where Hg is the hemoglobin concentration (g/dl), SaO_2 is the percent oxyhemoglobin saturation of arterial blood, PaO_2 is the partial pressure of oxygen in the arterial blood (mm Hg), and CO is cardiac output (dl/min).[7]

Patients with anemia, hypovolemia, pericardial tamponade, or other types of blood flow obstruction (e.g., severe abdominal distention with gastric dilatation-volvulus) may appear tachypneic in an attempt to increase oxygen delivery. A decrease in oxygen delivery to chemoreceptors in the carotid and aortic bodies will stimulate an increase in respiratory rate and depth in order to deliver more oxygen to the alveoli for gas exchange. Clinically, this increase in respiratory rate and effort may result in a decrease in $PaCO_2$, even with coexisting pulmonary parenchymal disease, because carbon dioxide is 20 times more diffusible than oxygen, and is characterized by a steep dissociation curve.[7] Anemia, whether from decreased production, blood loss, destruction, or sequestration, will significantly affect oxygen-carrying capacity and the delivery of oxygen to PO_2 chemoreceptors. In animals with acute blood loss, cardiac output is increased in an attempt to increase oxygen delivery by increasing heart rate and stroke volume; this is seen clinically as signs of hypovolemic shock. In chronically anemic patients, compensation occurs via increases in cardiac output or changes in the affinity of hemoglobin for oxygen.[8]

Patients with altered hemoglobin-oxygen binding, including methemoglobinemia (e.g., acetaminophen toxicity) or carboxyhemoglobinemia (e.g., carbon monoxide poisoning, smoke inhalation), will have a decreased SaO_2. It is important to recognize that pulse oximetry is inaccurate with dysfunctional hemoglobin.

Finally, patients with underlying heart disease may have an increased respiratory rate and altered respiratory pattern due to a decrease in cardiac output. Clinically this should be distinguished from primary respiratory disease (e.g., pleural effusion, pulmonary edema), which may also be present. In summary, patients with decreased oxygen delivery from either anemia or hypovolemia may have a component of tachypnea or dyspnea from carotid and aortic receptor stimulation or from simultaneous anatomic respiratory disease.

34.5 CORTICAL MODIFICATION OF RESPIRATION

Dyspnea, the term used to characterize a subjective experience of breathing discomfort, may have a cyclic component when related to pain, stress, or anxiety.[3] The voluntary (cortical) component of respiratory control can be altered in situations that cause pain, stress, or anxiety (e.g., severe abdominal enlargement). Sympathetic stimulation (fight or flight) from pain, stress, or anxiety may result in hyperventilation and apparent dyspnea. The sympathetic response helps prepare the animal for immediate action by increasing oxygen delivery to the tissues and removing carbon dioxide generated with increased muscle activity.[9] When physical activity (fighting or escaping) does not occur, additional anxiety may result in hyperventilation.

Additionally, pain may limit chest expansion and cause anxiety, which may further increase respiratory distress (e.g., flail chest). Changes in the brain and spinal cord neurons result in central sensitization or a heightened perception of pain.[10] As a result, pain elicits the stress response, producing potentially detrimental physiologic effects such as increased sympathetic tone and vasoconstriction; this can lead to decreased oxygen delivery to tissues and compensatory increases in stroke volume and heart rate (resulting in increased cardiac output). This decreased venous blood flow can result in diminished pulmonary function, which can lead to atelectasis, hypoxemia, and ventilation-perfusion mismatch.[11]

Clinically, pain, stress, and anxiety are seen most commonly as tachypnea and panting. This may worsen respiratory distress or even mask underlying lung pathology; this can be seen in dogs with laryngeal paralysis that exacerbate their dyspnea and laryngeal swelling with the anxiety of dyspnea. Although blood oxygenation improves with oxygen supplementation, resolution of dyspnea frequently requires tranquilization (e.g., acepromazine), sedation (e.g., opioids), and/or analgesia.

34.6 THERMAL RECEPTOR CHANGES

An animal's primary method of thermoregulation is evaporative cooling from the respiratory tract through an increased respiratory rate. When body temperature is above the set-point of the hypothalamic thermoregulatory center, the animal begins to pant. The set-point of the thermoregulatory center is increased in disease (e.g., fever); as a result, cooling measures may not be stimulated with elevations in body temperature. μ-Opioids (e.g., morphine, fentanyl, meperidine, methadone, oxymorphone, hydromorphone) have a similar effect in that they may falsely decrease the thermoregulatory center's set-point, which may result in tachypnea when the body temperature is normal.[12] On the other hand, opioids may also have negative effects on the central respiratory center, resulting in respiratory depression and a decreased respiratory rate and effort. Hyperthermic patients or those treated with opioids may be tachypneic, and a thorough evaluation of the respiratory system should be conducted to ensure that underlying lung disease is not present.

34.7 PERIPHERAL NERVOUS SYSTEM DISEASE

Myasthenia gravis, botulism, polyradiculoneuritis (coonhound paralysis), and tick paralysis are all examples of neuromuscular junction diseases that can lead to hypoventilation and an abnormal respiratory pattern (see Chapters 33 and 101, Chest Wall Disease and Lower Motor Neuron Disease, respectively). Stimulation of the phrenic nerve results in contraction of the diaphragm, a subsequent increase in the thoracic cavity size, and expansion of the lungs to enable oxygen delivery to small airways and alveoli. With neuromuscular junction disease, signals from the phrenic nerve to the diaphragm are dysfunctional, resulting in hypoventilation that may lead to hypercapnia and hypoxemia. As a result, chest wall and abdominal wall muscles are recruited to assist in ventilation, causing an exaggerated respiratory pattern and increased abdominal effort. Similar clinical signs may be seen with spinal cord lesions at C1 to C5 or C6 to T2 (see Chapter 99, Spinal Cord Injury). Although increasing the inspired oxygen concentration with supplementation via mask, flow-by, or nasal cannula may mildly improve blood oxygen content, the patient will remain hypercarbic without ventilatory assistance. As a result, these patients frequently require positive-pressure ventilation until correction of the primary abnormality is achieved (see Chapter 213, Basic Mechanical Ventilation).

Drugs and medications that affect the neuromuscular junction may also result in hypoventilation. Paralytic agents (e.g., pancuronium, atracurium, vecuronium), which are nondepolarizing neuromuscular junction blockers, will cause respiratory paralysis. Pancuronium is used intraoperatively to help create muscle relaxation, particularly during orthopedic or ophthalmologic procedures. These patients must be manually or mechanically ventilated until the effect of the pancuronium is reversed or wears off (approximately 30 to 45 minutes). Reversal can be accomplished by administering an anticholinesterase agent (e.g., edrophonium, physostigmine, or neostigmine) with an anticholinergic agent (e.g., atropine or glycopyrrolate) (see Chapter 183, Neuromuscular Blockers).

34.8 CENTRAL NERVOUS SYSTEM DISEASE

As previously described, the respiratory drive originates in the medulla (brain stem). Additionally, chemoreceptors that monitor PCO_2 and pH are located centrally.[2] Finally, voluntary control of breathing occurs in the cerebral cortex. With central nervous system (CNS) disorders such as head trauma, patients may manifest abnormal respiratory patterns due to edema, bleeding, or increases in intracranial pressure affecting respiratory centers. Patients with space-occupying lesions in the CNS that affect respiratory centers may also have abnormal respiratory patterns. Because respiratory system controllers are located throughout the central nervous system (e.g., medulla, cortex, chemoreceptors in various locations), a thorough cranial and peripheral nerve examination should be completed to locate additional CNS abnormalities that may help the clinician localize the disease, formulate an appropriate diagnosis, and provide timely therapy.

34.9 METABOLIC DISEASE

Metabolic disease or electrolyte imbalances may result in nonrespiratory causes of tachypnea. Hyperadrenocorticism and hyperthyroidism can affect respiratory patterns because of altered respiratory mechanics or changes in respiratory sensor inputs. Significant alterations in calcium, potassium, or glucose concentrations may result in respiratory system muscle dysfunction (e.g., diaphragm, intercostal muscles, and accessory muscles).

Dogs with hyperadrenocorticism or those undergoing glucocorticoid therapy frequently are tachypneic at rest, which may be a result of respiratory muscle weakening, muscle wasting, and/or fat deposition within the chest wall. Additionally, hepatomegaly and abdominal fat deposition may cause increased pressure on the diaphragm, which contribute to the clinical signs.[13] These animals may also suffer from pulmonary thromboembolism secondary to a hypercoagulable state.

In cats with hyperthyroidism, increased carbon dioxide production due to an increased metabolic rate (necessitating an increase in respiratory rate and ventilation), respiratory muscle weakness from muscle wasting, or occasionally hypokalemia[13] resulting from a thyroid storm (see Chapter 72, Thyroid Storm). Cats may exhibit open-mouth breathing or have clinical signs of respiratory distress while maintaining normal oxygen levels. Underlying thyroid-induced cardiomyopathy with secondary congestive heart failure may also occur, and may result in primary respiratory disease (e.g., pulmonary edema, pleural effusion); this should be clinically distinguished from a thyroid storm or other causes of nonrespiratory look-alikes.

Severe hypokalemia (<2.0 mEq/L) may result in respiratory muscle weakness causing ineffective respiration, resulting in hypoventilation and hypoxemia. Such profound, severe hypokalemia is rarely seen in dogs and cats. Potential causes of hypokalemia include insulin administration, vomiting, chronic renal failure (cats), diabetic ketoacidosis, post-obstructive diuresis, and diuretic administration (see Chapter 55, Potassium Disorders).[14]

Hypocalcemia (or more specifically, a reduction in the biologically active form, ionized calcium) may also affect respiratory muscle function (see Chapter 56, Calcium Disorders). Conditions most commonly associated with clinically significant decreases in ionized calcium include acute or chronic renal failure, acute pancreatitis, and acute eclampsia (puerperal tetany) as seen in periparturient or nursing queens and bitches.[15]

Finally, hypoglycemia may alter respiratory muscle function and diminish proper signaling from the cortex and medulla to the respiratory system. Causes of hypoglycemia in dogs and cats include excess insulin (e.g., iatrogenic, insulinoma), severe liver disease (e.g., end-stage disease, portosystemic shunt, glycogen storage disease), insulin-like hormone–secreting tumors (e.g., hepatic carcinoma, hemangiosarcoma, leiomyoma, and leiomyosarcoma), metabolic disease (e.g., hypoadrenocorticism, growth hormone deficiency), neonatal and juvenile hypoglycemia (e.g., in toy breed puppies), sepsis, and, less commonly, pregnancy toxemia, polycythemia, and hunting dog hypoglycemia.[16]

Deficiencies in potassium, calcium, or glucose should be identified rapidly via diagnostic means such as blood gas analysis or glucometry in tachypneic patients to rule out nonrespiratory look-alikes. Appropriate, prompt therapy may lead to clinical improvement while the underlying disease process is identified and addressed.

34.10 CONCLUSION

In the emergency critical care setting, veterinarians are often presented with tachypneic, panting, or even apparently dyspneic patients. Approach to the patient with respiratory distress and compromise can be one of the most daunting tasks for a practicing veterinarian. Although there is no “cookbook” approach to the dyspneic patient, an appropriate diagnostic workup (including historical findings; clinical signs; a brief, yet focused physical examination; clinicopathologic data; pulse oximetry; chest radiography; blood gas analysis, etc.) is imperative. Although the goals of this chapter are not to discuss the approach to the dyspneic patient (see Chapter 9, Tachypnea and Hypoxemia), it is imperative that the clinician be cognizant of a rapid, plausible differential list that includes nonrespiratory look-alikes. Primary respiratory system diseases should be ruled out from nonrespiratory look-alikes, as these latter causes may mask underlying respiratory disease.

35 Chapter 35 Cardiogenic Shock

Andrew J. Brown, MA, VetMB, MRCVS, DACVECC

Deborah C. Mandell, DVM, DACVECC

35.1 KEY POINTS

- Cardiogenic shock is defined as inadequate cellular metabolism secondary to cardiac dysfunction, despite adequate intravascular volume.
- Clinical signs are consistent with global hypoperfusion. The aim of treatment is based on restoring cardiac output in order to normalize tissue perfusion and cellular metabolism.
- Systolic or diastolic dysfunction or arrhythmias can result in decreased stroke volume, forward flow failure, and cardiogenic shock.
- The most common cause of systolic dysfunction is dilated cardiomyopathy.
- Systolic dysfunction secondary to mechanical failure is less common. The causes include subaortic stenosis, hypertrophic obstructive cardiomyopathy, and acute mitral regurgitation secondary to ruptured chordae tendineae.
- Diastolic dysfunction can occur secondary to cardiac tamponade, hypertrophic cardiomyopathy, or tachyarrhythmias.
- Severe bradyarrhythmias such as third-degree atrioventricular block or sick sinus syndrome can lead to a severe decrease in cardiac output and thus cardiogenic shock.
- The prognosis for most forms of cardiogenic shock is guarded. A rapid diagnosis and appropriate therapeutic intervention(s) will enhance success.

35.2 INTRODUCTION

Cardiogenic shock is defined as inadequate cellular metabolism secondary to cardiac dysfunction when there is adequate intravascular volume. It is a serious life-threatening emergency and must be recognized, diagnosed, and treated as soon as possible.

The etiology of cardiogenic shock is wide ranging and varied. Consequently diagnostic modalities, case management, and definitive therapy vary with the cause. Diagnosis is based on clinical demonstration of shock along with evidence of cardiac dysfunction. Ultimately, the aim of treatment is based on restoring cardiac output in order to normalize tissue perfusion and cellular metabolism.

35.3 PATHOPHYSIOLOGY

Shock is defined as inadequate cellular energy production. It can have multiple classifications, such as distributive, metabolic, hypoxic, or cardiogenic. Decreased tissue perfusion and subsequent inadequate metabolism and energy production at the cellular level will occur when cardiac output is reduced. This occurs most commonly as a result of inadequate intravascular volume or hypovolemic shock (classified under distributive shock). In the face of adequate intravascular volume, but reduced cardiac output from cardiac dysfunction, a patient has forward failure. When forward flow failure is sufficient to cause inadequate tissue perfusion despite an adequate intravascular volume, the patient has cardiogenic shock. Heart failure can be classified as forward or backward ventricular failure. Backward flow failure occurs secondary to elevated venous pressures, and left ventricular failure (forward flow failure) occurs secondary to reduced forward flow into the aorta and systemic circulation.

Cardiac output is a product of stroke volume and heart rate (SV × HR). A decrease in either stroke volume or heart rate can therefore lead to a reduction in cardiac output. The normal physiologic response to a decrease in stroke volume is a compensatory increase in heart rate (and systemic vascular resistance) to maintain cardiac output. This is due to a baroreceptor-mediated sympathetic stimulation to preserve blood pressure and tissue perfusion. A decrease in stroke volume that cannot be reciprocally compensated for by a further increase in heart rate will lead to reduced cardiac output and forward flow failure. Similarly, forward failure may result from a severe decrease in heart rate without a primary decrease in stroke volume. Cardiogenic shock will ensue if the forward flow failure leads to decreased tissue perfusion that does not meet cellular energy demands.

Stroke volume is determined by preload, afterload, and contractility. Cardiogenic shock can ensue from alterations in any of these. For the purpose of this chapter, the cardiac cycle will be split into systole and diastole, and compromise to either phase may result in a decreased stroke volume and cardiogenic shock.

In addition to the reflex increase in heart rate, strategies exist within the body to ensure normal tissue perfusion. In response to cardiac dysfunction–induced hypotension, neurohormonal mechanisms (e.g., renin-angiotensin-aldosterone system) increase the effective circulating volume (see Chapter 6, Hypotension). This increases preload, stroke volume, and therefore cardiac output and enables the animal to maintain a normal blood pressure. As a result, forward failure in patients with chronic cardiac conditions is rare. Most patients deteriorate secondary to the increase in preload and subsequent congestive (backward) heart failure and pulmonary edema. Examples of this include chronic valvular disease in dogs and hypertrophic cardiomyopathy in cats. Some patients may suffer from concurrent forward and backward failure (e.g., dogs with dilated cardiomyopathy).

Patients that demonstrate an acute decrease in cardiac output do not have time to compensate and, as a consequence, abruptly develop cardiogenic shock (e.g., acute pericardial effusion with cardiac tamponade). These animals commonly have signs consistent with cardiogenic shock (forward failure) but may also have evidence of right-sided backward failure (ascites).

A sustained decrease in cardiac output will eventually lead to organ dysfunction. Reduced coronary blood flow may result in arrhythmias or decreased contractility and will exacerbate existing cardiac dysfunction. Inadequate renal perfusion will lead to acute renal failure, and decreased gastrointestinal perfusion may cause hemorrhagic diarrhea.

35.4 CLINICAL SIGNS AND DIAGNOSIS

Cardiogenic shock is an extreme manifestation of forward failure and clinical signs will reflect this state. Diagnosis is based on signs consistent with shock and cardiac dysfunction. It is important to realize that there is overlap among different classes of shock and that a definitive diagnosis can sometimes be difficult to ascertain.

Clinical signs are consistent with global hypoperfusion. A patient with cardiogenic shock will have a change in mentation manifested as depression, unresponsiveness, or disorientation. Peripheral extremities will be cold and the mucous membranes pale, with a prolonged capillary refill time due to intense vasoconstriction. The patient will often be tachypneic because of concurrent congestive heart failure (CHF) (pulmonary edema) or may have a compensatory respiratory alkalosis in response to a lactic acidosis. Parenchymal or pleural space disease secondary to backward failure may result in dyspnea and cyanosis.

The heart rate should be elevated in animals with cardiogenic shock unless a primary bradycardia is the cause of the cardiogenic shock or the patient is moribund. The tachycardia will be due either to an appropriate sympathetic response to hypotension or concurrent CHF, or can be a malignant arrhythmia (ventricular or supraventricular tachycardia) that is not allowing adequate diastolic filling and is the primary cause of cardiogenic shock. Correction of the malignant tachycardia in the latter case will likely improve stroke volume and cardiac output, whereas treatment of the compensatory tachycardia is contraindicated. This distinction can sometimes be difficult, and careful evaluation of the electrocardiogram and patient's volume status is necessary.

Careful auscultation of the heart and lungs should be performed. If the heart sounds are difficult to auscult, a pericardial effusion should be considered, although the clinician should not forget other causes of quiet heart sounds, including severe hypovolemia and obesity. If the patient has congestive heart failure, inspiratory crackles secondary to pulmonary edema may be heard on auscultation of the lungs, or the lungs may be quiet ventrally as a result of pleural effusion. A murmur or gallop may also be ausculted, and although extracardiac rule-outs for a heart murmur should be considered, this may provide further evidence for cardiac disease. “Synchronous” peripheral pulse palpation and cardiac auscultation should be performed to detect pulse deficits or arrhythmias.

Renal blood flow will be reduced with cardiogenic shock and may result in azotemia, with or without oliguria or anuria. Gastrointestinal tract perfusion will also be reduced and may lead to hemorrhagic diarrhea.

Venous blood gas analysis often reveals a metabolic acidosis. Inadequate cellular oxygenation may result in anaerobic metabolism and a lactic acidosis. Prerenal or renal azotemia may also contribute to the metabolic acidosis. The patient will usually have a compensatory respiratory alkalosis. If the patient has concurrent pulmonary edema the alveolar-arteriolar gradient (A-a gradient) will likely be increased on an arterial blood gas analysis (see Chapter 208, Blood Gas and Oximetry Monitoring).

An electrocardiogram should be performed on all patients that are in shock. Animals in cardiogenic shock may have a sinus tachycardia, bradyarrhythmia (e.g., AV block), or tachyarrhythmia such as atrial fibrillation or ventricular tachycardia. It is important to remember that patients with other causes of shock (e.g., distributive or hypoxic) can also have cardiac arrhythmias.

Chest radiographs should be performed when the patient is stable enough to withstand the stress of being held and may help to rule out cardiac disease as the primary cause of shock. There may be an abnormality in the cardiac silhouette and evidence of congestive or backward heart failure. Radiographic signs of CHF include enlarged pulmonary veins, an alveolar or interstitial pattern in the perihilar region (in dogs only; infiltrates are often patchy or diffuse in felines), or pleural effusion. However, it is important to remember that many animals in shock will have incidental cardiac disease that is not contributing to their morbidity. Information derived from radiographs and the electrocardiogram will not enable the clinician to definitively diagnose cardiogenic shock; rather, it should be interpreted in conjunction with clinical findings and results of other diagnostic tests.

Echocardiographic findings will vary depending on the underlying cause of cardiogenic shock. Congenital or acquired structural abnormalities, along with changes in cardiac chamber size or myocardial thickness, may be described. Pressure gradients, blood flow, and an assessment of systolic and diastolic function can be obtained. A diagnosis of cardiogenic shock may be made if there is evidence of systolic dysfunction in the presence of adequate end diastolic volume.

Even with advanced diagnostic imaging, the diagnosis of cardiogenic shock can still be difficult. A pulmonary arterial catheter (see Chapter 50, Pulmonary Artery Catheterization) can be placed to aid in both diagnosis and monitoring. A patient with cardiogenic shock will have a decreased cardiac output with an increase in the preload parameters of central venous pressure, pulmonary arterial pressure, and pulmonary arterial occlusion (wedge) pressure. This catheter can be helpful to obtain a diagnosis, guide therapy, and monitor the response to therapy.

35.5 SYSTOLIC DYSFUNCTION

Systolic dysfunction can result from a decrease in cardiac contractility or decreased flow through the left ventricular outflow tract (mechanical failure). The latter can result from a functional obstruction (e.g., aortic stenosis or hypertrophic obstructive cardiomyopathy) or severe retrograde blood flow (e.g., chordae tendineae rupture and acute, severe mitral regurgitation).

35.5.1 Failure of Contractility

35.5.1.1 Dilated Cardiomyopathy

The most common cause of cardiogenic shock resulting from systolic dysfunction is dilated cardiomyopathy (DCM) (see Chapter 38, Canine Cardiomyopathy). This condition is most commonly seen in dogs (Doberman 147 Pinscher, Boxer, Great Dane, Labrador Retriever, American Cocker Spaniel[1]) 148 and is rarely seen in cats (except those with taurine deficiency). A progressive decrease in myocardial contractility that can occur over months to years will result in a gradual decrease in stroke volume and forward failure. Activation of the renin-angiotensin system and sympathetic nervous system will stimulate renal retention of sodium and water. The increased intravascular volume results in increased in end-diastolic volume. Eccentric hypertrophy occurs secondary to cardiac myocardial stretch. These compensatory mechanisms will maintain cardiac output until the myocardial failure becomes so severe that the cardiac chambers cannot sustain further enlargement. Any further increase in intravascular volume will result in an increased end-diastolic pressure, leading to an increase in pulmonary capillary hydrostatic pressure and cardiogenic pulmonary edema in patients with left-sided heart failure or ascites in patients with right-sided heart failure.

Diagnosis of cardiogenic shock in dogs with DCM is made based on signs consistent with shock (see Clinical Signs and Diagnosis) and cardiac dysfunction. Chest x-ray films may reveal an enlarged heart along with evidence of CHF, if present. An electrocardiogram may reveal a sinus tachycardia or arrhythmias such as atrial fibrillation or ventricular tachycardia. However, it is important to remember that patients with shock from other causes (e.g., distributive or hypoxic) can also have cardiac arrhythmias.

An echocardiogram will demonstrate an enlarged and dilated heart with poor contractility. Valuable information can be gained from a pulmonary arterial catheter (see Chapters 50 and 203, Pulmonary Artery Catheterization and Hemodynamic Monitoring, respectively). This catheter will enable the clinician to measure cardiac output, as well as measure preload parameters such as central venous pressure, pulmonary arterial pressure, and pulmonary arterial occlusion (wedge) pressure. This can help in the diagnosis, prognosis, and treatment of these patients.

The aim of treating patients with systolic dysfunction is to maximize cardiac output by increasing stroke volume. Preload parameters should be monitored closely and fluids given only if necessary, or diuretics administered if the dog has congestive heart failure (see Chapter 180, Diuretics). Positive inotropic agents such as the β_1-adrenergic receptor agonist dobutamine (see Chapter 176, Vasoactive Catecholamines), phosphodiesterase inhibitors such as amrinone, pembendan, or cardiac glycosides such as digoxin (see Chapters 38 and 189, Canine Cardiomyopathy and Digoxin, respectively) can be titrated to optimize stroke volume. Optimal positive inotropic therapy has not been determined in human or veterinary medicine, and newer agents such as the calcium-sensitizing agent levosimendan are also being investigated.[2]

35.5.1.2 Sepsis

Studies in both humans and dogs have documented a dysfunctional myocardium in sepsis. Even during the hyperdynamic phase of septic shock (see Chapter 106, Sepsis) with increased cardiac output, a decrease in ejection fraction has been documented. A reduction in ventricular compliance, biventricular dilation, and a decrease in contractile function have been shown to contribute to the decrease in ejection fraction.[3] In an experimental model of septic shock, dogs in the hyperdynamic phase (with an increased cardiac output) had decreased contractility and left ventricular dilation.[3] Myocardial dysfunction peaks within days of the onset of sepsis, and has been shown to resolve within 7 to 10 days in patients who survive.[4] Low cardiac output is rare in patients with septic shock but is often due to end-stage decompensated myocardial depression.

35.5.1.3 Endomyocarditis

Endomyocarditis is a rare condition of cats that occurs several days following a routine procedure such as neutering (see Chapter 113, Endocarditis). Cats have normal myocardial function before the anesthesia and the procedure is usually uneventful, but rapid development of cardiac dysfunction, hypotension, pulmonary edema, and interstitial pneumonia develops. Although not well described, the endocardium is hyperechoic on ultrasonography, and histopathology reveals neutrophilic inflammation and fibroplasia.[5] Supportive care is recommended and, even with positive-pressure ventilation, the prognosis is poor.

35.5.1.4 Myocardial Infarction

Myocardial infarction is the number one cause of cardiogenic shock in humans, but is rarely seen in dogs (see Chapter 41, Myocardial Infarction).

35.5.2 Mechanical Failure

Cardiogenic shock resulting from mechanical failure is rare in dogs and cats. Forward flow can be reduced by an obstruction to the left ventricular outflow tract (e.g., aortic stenosis or hypertrophic obstructive cardiomyopathy) or due to severe acute retrograde blood flow as may occur with a chordae tendineae rupture.

Dogs with mitral endocardiosis and associated regurgitant flows typically have normal to increased myocardial contractility. However, when it is associated with chordae tendineae rupture, the acute and extensive mitral regurgitation will reduce forward flow sufficiently to result in cardiogenic shock and pulmonary edema.

35.6 DIASTOLIC FAILURE

Diastolic failure is due to inadequate ventricular filling. This can result from hypovolemia, a physical restriction (cardiac tamponade), inability of the myocardium to relax (hypertrophic cardiomyopathy), or inadequate time for filling (tachycardia). Diastolic failure will result in a decreased preload, and therefore a reduced stroke volume. If the animal is unable to maintain cardiac output with an increase in heart rate, cardiogenic shock ensues.

The most common cause of a decreased preload resulting in an inadequate cardiac output is hypovolemia. This is corrected by restoration of intravascular volume and is therefore not truly cardiogenic shock (see Chapters 10 and 65, Shock and Shock Fluids and Fluid Challenge, respectively).

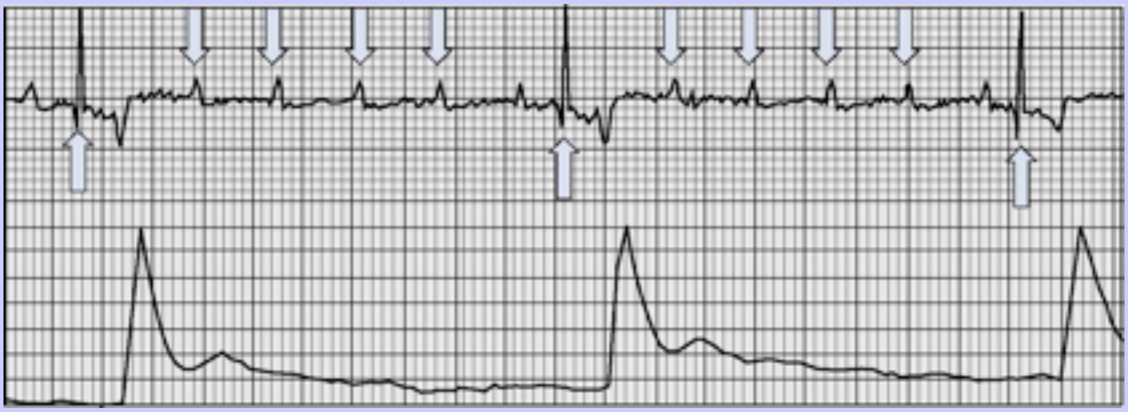
35.6.1 Cardiac Tamponade

Diastolic ventricular filling will be impaired because of the physical restriction that occurs with cardiac tamponade. Cardiac tamponade can occur secondary to pericardial effusion (see Chapters 43 and 44, Cardiac Tamponade and Pericardiocentesis and Pericardial Diseases, respectively). Effusions are most likely a result of neoplasia, but can also be secondary to a coagulopathy, trauma, atrial tear, or an idiopathic cause. The decreased diastolic ventricular filling will lead to a decrease in stroke volume and cardiac output. With the aim of maintaining normotension and tissue perfusion, a reflex tachycardia will ensue. 148 149 Eventually the increase in heart rate will not be sufficient to maintain an adequate cardiac output and the patient will become hypotensive. Cardiac auscultation will reveal quiet or absent heart sounds, leading to a high index of suspicion for a pericardial effusion; confirmation can be made quickly with ultrasonography. Despite the improved ability to visualize the heart in the presence of a pericardial effusion, a thorough echocardiogram should not be performed if a patient has cardiogenic shock. The reduced cardiac output will result in decreased tissue perfusion and a lactic acidosis. If the effusion is chronic, the patient may have decreased sodium and increased potassium concentrations from a reduced effective circulating volume-induced pseudo-hypoadrenocorticism. Because the systemic manifestations of this condition result from the decreased preload, increasing intravascular volume with a fluid bolus is warranted. However, emergency pericardiocentesis to allow for normal ventricular filling is also necessary to treat the cardiogenic shock. Pericardiocentesis in patients with coagulopathies or in dogs with a pericardial effusion secondary to an atrial tear is contraindicated, although the consequences of fulminant cardiogenic shock have to be weighed against the risk of exsanguination.

35.6.2 Hypertrophic Cardiomyopathy

Failure of normal end-diastolic volume can occur secondary to an intrinsic inability of the myocardium to relax (e.g., hypertrophic cardiomyopathy). Hypertrophic cardiomyopathy (see Chapter 37, Feline Cardiomyopathy) is the most commonly diagnosed feline cardiac disease and is characterized by concentric hypertrophy of the ventricular myocardium. Decreased end-diastolic ventricular volume due to the inability of the myocardium to relax leads to a decreased stroke volume and cardiac output. Activation of neurohormonal mechanisms will increase the intravascular volume to protect against hypotension and decreased tissue perfusion. Systolic function will normally remain adequate, and patients typically have backward (rather than forward) flow failure. However, cats with CHF that receive overzealous diuretic therapy can progress easily to hypovolemic (distributive) shock. In addition, cats with end-stage hypertrophic cardiomyopathy can also have severely impaired systolic function, leading to decreased stroke volume and cardiogenic shock. Treatment of cats with hypertrophic cardiomyopathy includes the use of β-blockers or calcium channel antagonists in an attempt to enhance lusitropy and diastolic filling (see Chapter 37, Feline Cardiomyopathy).

Figure 35-1 A lead II electrocardiogram with simultaneous arterial waveform of a patient with second-degree atrioventricular block. There are normal conducted QRS complexes *(up arrows)* with concurrent arterial pulses and nonconducted P waves *(down arrows)* with no associated cardiac output, as evidenced by an absence of an arterial pulse waveform.



35.6.3

Tachyarrhythmias

Inadequate ventricular filling occurs at elevated heart rates. End-diastolic volume is largely dependent on venous return, with atrial contraction contributing little to the normal preload. When patients become tachycardic (e.g., dogs with a heart rate over 200 beats/min), there is inadequate time for diastolic filling to occur before systole, and as a result end-diastolic volume and therefore stroke volume, are reduced. If the resultant cardiac output is compromised resulting in decreased perfusion with inadequate cellular metabolism, then the patient has cardiogenic shock. The most common cause of this malignant tachycardia is a supraventricular tachycardia (see Chapter 46, Supraventricular Tachyarrhythmias). This can be a result of primary cardiac disease or a cardiac manifestation of another systemic disease process. Therapy includes vagal maneuvers, calcium channel antagonists, and β-blockers to slow the heart rate, as well as management of the underlying condition (see Chapter 190, Antiarrhythmic Agents).

35.7

BRADYARRHYTHMIAS

Severe bradycardia can lead to such a decrease in cardiac output that cardiogenic shock ensues. The most common cause of this is severe high-grade second-degree AV block (Figure 35-1) or third-degree AV block. Animals with sick sinus syndrome can also be so severely affected that the patient can have decreased tissue perfusion and shock. In the case of third-degree AV block, AV nodal conduction does not occur and escape complexes from the bundle of His, bundle branches, or Purkinje fibers induce cardiac contraction. Extranodal heart rates are much slower than normal, with the bundle of His producing 40 to 60 beats/min, and ectopic beats from the bundle branches or distal Purkinje fibers producing 20 to 40 beats/min. Higher escape rates will be adequate for dogs at rest, but slower rates will result in a reduced cardiac output. An increase in stroke volume will occur secondary to an increased preload (due to the increased time for diastolic filling), but at low heart rates or during patient exertion, the cardiac output may be inadequate and cardiogenic shock will ensue.

Diagnosis can be made on the basis of the electrocardiographic evidence of severe second-degree or third-degree AV block or sick sinus syndrome, and other signs consistent with shock (see Clinical Signs and Diagnosis earlier in this chapter). Blood pressure may be normal, but it is important to remember that blood pressure does not equal flow. The origin of second-degree AV block can be vagally mediated or secondary to sinoatrial or AV nodal pathology. An atropine response test (0.02 to 0.04 mg/kg IV) is warranted in all cases. A β-agonist such as isoproterenol or dobutamine can be given as a constant rate infusion and will sometimes increase the heart rate sufficiently to treat the cardiogenic shock. If there is no response to medical therapy, the patient should have artificial cardiac pacing. This can be achieved by transthoracic pacing of the sedated patient, or an emergency temporary pacemaker can be placed. Intravenous fluids are contraindicated in these cases until a normal heart rate has been achieved, because preload is already increased, and a further increase in left ventricular filling pressures may result in congestive (backward) heart failure (see Chapter 45, Bradyarrhythmias and Conduction Abnormalities).

36 Chapter 36 Left Ventricular Failure

Dennis E. Burkett, VMD, PhD, DACVECC

36.1 KEY POINTS

- Clinical signs of congestive left heart failure are most commonly tachypnea, dyspnea, and coughing secondary to pulmonary edema.
- Cats with congestive left heart failure commonly develop pleural effusion.
- The primary aim of managing heart failure is to prevent edema and effusion.
- Most patients with acute left heart failure are brought to the hospital in severe or fulminant left heart failure and require intensive therapy with oxygen and intravenously administered furosemide or nitroprusside, with or without dobutamine.

36.2 BASIC TERMINOLOGY

- *Circulatory failure* is present when the delivery of oxygenated blood is insufficient to meet the metabolic requirements of the body's tissues. It may result from failure of any one or more of the various components of the circulation: the heart, the vascular bed, the blood volume, or the concentration of oxygenated hemoglobin (Hgb) in the blood.[1]
- *Heart failure* is the pathophysiologic state that results when the heart is unable to pump blood at a rate that will meet the metabolic demands of the tissues and maintain normal arterial or venous pressures at rest or with exercise.[1]
- *Myocardial failure* is heart failure caused by a defect in myocardial contractility (systolic pump failure). Myocardial contractility is depressed in dogs and cats with dilated cardiomyopathy, and this is the primary functional abnormality in these patients. Not all patients with heart failure, however, have decreased myocardial contractility. For example, dogs experiencing acute rupture of a chordae tendineae suffer heart failure even though myocardial contractility is normal. Other examples include pericardial effusion, constrictive pericarditis, and acute pulmonary thromboembolism.[1]
- *Congestive heart failure* is the clinical syndrome, not a disease, wherein abnormal cardiac function results in the accumulation and retention of sodium and water with the resulting signs of congestion and edema. Most, but not all, patients with heart failure develop systemic or pulmonary congestion. Congestive signs may be absent when heart failure develops suddenly and plasma volume is normal or reduced.[1]

36.3 LEFT VENTRICULAR FAILURE

Left ventricular failure is the classic type of cardiac dysfunction that clinicians usually think of when they think of heart failure. It can occur with or without signs of heart failure. Dogs with dilated cardiomyopathy apparently have left ventricular failure for years before showing clinical evidence of heart failure.[2] Experimental cats live for years with taurine deficiency and mild to moderate left ventricular failure without signs of heart failure.[3] 151

Left ventricular failure without heart failure can be detected by echocardiography and is seen as an increase in end-systolic left ventricular diameter and decreased excursions of the left ventricular free wall and interventricular septum from diastole to systole (decreased wall motion). Left ventricular failure is always severe in dogs and cats with dilated cardiomyopathy when clinical signs become obvious. Left ventricular failure can occur secondary to other chronic diseases that affect the left ventricle, such as aortic regurgitation and patent ductus arteriosus.[4]

36.4 OTHER CAUSES OF LEFT VENTRICULAR FAILURE

Left ventricular failure frequently is absent in other left ventricular diseases, although the patient has clinical signs of heart failure. Feline hypertrophic cardiomyopathy is the classic example in veterinary medicine. Cats with this disease can have heart failure but apparently have normal myocardial contractility and enhanced left ventricular performance because of an increase in myocardial mass. Signs of heart failure occur in this disease because the heart muscle is extremely thick and therefore stiff, causing an increase in the left ventricular diastolic pressure.

Mitral regurgitation in small dogs is another example of a disease in which left ventricular failure is not the prevalent problem.[5] In this disease the major factor leading to the signs of heart failure is massive regurgitation, or leakage, of blood into the left atrium rather than a decrease in myocardial contractility.

Patent ductus arteriosus does not result in clinically significant left ventricular failure in very young dogs but can cause signs of heart failure. Left ventricular failure develops if the lesion is left untreated for months to years.[4]

Signs of heart failure are divided into those referable to congestion and edema (congestive, or backward, heart failure), to inadequate blood flow (low-output, or forward, heart failure), or to markedly decreased blood flow and low blood pressure (cardiogenic shock).[6,7] Cardiogenic shock is rare in patients with chronic heart failure, although it can occur in those that are treated vigorously with diuretics and that stop eating and drinking and become markedly dehydrated. It is identified more commonly in patients with acute heart failure[4] (see Chapter 35, Cardiogenic Shock).

36.5 RIGHT-SIDED VERSUS LEFT-SIDED HEART FAILURE

In animals with heart failure, congestion develops as a consequence of excessive venous pressure caused by the combined effects of increased plasma volume (sodium and water retention) and decreased venous capacitance (venoconstriction). With impairment of the left side of the heart, pulmonary venous pressure increases, resulting in pulmonary edema (pulmonary capillary wedge pressure >25 mm Hg) and signs of respiratory distress (left-sided CHF). Conversely, with impairment of the right side of the heart, systemic venous pressures rise, resulting in hepatomegaly and ascites (central venous pressure >15 mm Hg, right-sided CHF).

Because the capacitance of the splanchnic veins and the systemic venous reservoir is large, a rather substantial increase in blood volume is required to raise pressures in this reservoir. As a result, right-sided congestive signs tend to develop slowly. By comparison, the capacitance of the pulmonary veins is small. Relatively small changes in blood volume or its distribution can cause a rapid rise in pulmonary venous pressure and resultant pulmonary edema. Sudden increase in sympathetic tone (with fear, anxiety, or exercise) constricts the splanchnic veins, causing a shift in the circulating blood volume from the systemic to the pulmonary venous reservoir. This is one reason for the often rapid onset of pulmonary edema in animals with left-sided heart failure.[1]

36.6 CONGESTIVE LEFT-SIDED HEART FAILURE

Congestion and edema in heart failure occur because of an increase in capillary hydrostatic pressure.[6] In left-sided heart failure, increased diastolic pressure in the left ventricle (and consequently an increase in diastolic left atrial pressure, because the left ventricle and the left atrium are essentially one chamber during diastole when the mitral valve is open) or high systolic and diastolic pressures in the left atrium and pulmonary veins result in increased pulmonary capillary hydrostatic pressure, leading to pulmonary edema. Increased left ventricular diastolic pressure generally is caused either by a marked increase in blood volume and venous return to the left heart that overwhelms the ability of the heart to distend or by a stiff left ventricle that cannot accept a normal venous return at a normal pressure, or by both. Clinical signs of congestive left-sided heart failure are tachypnea, orthopnea, dyspnea, and coughing, usually secondary to pulmonary edema[4] (see Chapter 21, Pulmonary Edema).

Poor cardiac output (blood flow into the aorta per unit time) results in poor tissue perfusion and can be caused by a myriad of abnormalities that affect the ability of the left ventricle to pump properly. Poor tissue perfusion caused by a decreased cardiac output causes clinical signs of fatigue, weakness, poor exercise tolerance, cold extremities, slow capillary refill time, poor mucous membrane color, and hypothermia.[6] All of the signs except exercise intolerance will not become evident until heart failure becomes severe.

Laboratory evidence of left ventricular failure consists of a decreased cardiac output, a widened arteriovenous oxygen difference (arterial-venous oxygen content), a decreased venous oxygen tension in a patient that is not hypoxemic or anemic, and azotemia and lactic acidosis if the cardiac output is severely depressed.[7] Decreased cardiac output results in decreased tissue oxygen delivery (tissue oxygen delivery = arterial oxygen content × cardiac output). Arterial oxygen content (ml O_2/100 ml blood) is determined by the following relationship:

$$[\text{Hgb}](\text{g}/100\ \text{ml blood}) \times \text{O}_2\ \text{saturation}(\%) \times 1.34(\text{ml O}_2/\text{g Hgb})$$

The calculated value indicates the number of milliliters of oxygen carried in a given quantity of blood.

If resting tissue oxygen consumption remains stable, the actively metabolizing cells in the body must extract more oxygen from the bloodstream to meet their needs when cardiac output is reduced. This results in a decreased amount of oxygen and partial pressure of oxygen at the end of a capillary bed and on the venous side. The oxygen tension at the end of the capillary bed is the critical factor that determines oxygen delivery to the mitochondria.[8]

In animals the normal value for end-capillary or venous oxygen tension is higher than 30 mm Hg.[8] If oxygen delivery decreases enough at rest because of decreased cardiac output, it can result in the end-capillary tension or venous oxygen tension decreasing below a critical level of 20 to 24 mm Hg. When the end-capillary partial pressure of oxygen is less than 20 to 24 mm Hg, oxygen delivery to mitochondria becomes inadequate. At this stage, cells must start relying on anaerobic metabolism, resulting in lactic acid production.[7–9]

If the patient is exercising, lactic acid production in skeletal muscle results in the feeling of fatigue and forces the patient to stop. Therefore signs of left-sided heart failure are best identified in a patient that has mild or moderate heart failure either by exercising the patient and measuring blood lactate concentration or venous oxygen tension from blood draining working skeletal muscle or by obtaining a history of the patient's exercise capabilities.[10] Patients with severe heart failure may have evidence of left-sided heart failure at rest.

36.7 MODERN CONCEPT OF HEART FAILURE

36.7.1 Backward Failure Hypothesis

According to this early view of heart failure, the clinical signs result from the following sequence of events. Some cardiac insult damages the heart, leading to reduced ejection of blood. As a result, ventricular end-diastolic volume and pressure increase. As a direct consequence, atrial pressure and volume increase, leading to elevation of venous volume and pressure behind the failing ventricle(s). This, in turn, leads to increased capillary hydrostatic pressure, transudation of fluid into the interstitium, and either systemic congestion or pulmonary edema. Some refer to this hypothesis as the *backs up and leaks out* theory of heart failure.[1]

36.7.2 Forward Failure Hypothesis

This view of heart failure was formulated some 50 years after the backward failure theory. According to this hypothesis, the clinical manifestations of heart failure occur as a result of inadequate delivery of blood to the arterial system such that there is diminished perfusion of vital organs such as the brain (leading to confusion), the muscles (leading to weakness), and the kidneys (leading to sodium and water retention). As a result of reduced renal perfusion, plasma volume and extracellular fluid accumulate, leading to congestion of organs and tissues.[1]

36.7.3 Modern Concept of Heart Failure

This view of heart failure incorporates elements of both of these hypotheses, but it also offers a more comprehensive view of the importance of various cardiac and systemic compensatory responses to declining cardiac output. The current working hypothesis explaining the genesis of heart failure emphasizes that many of the systemic responses evoked by developing heart failure are identical to those evoked by hemorrhage or hypovolemia. The body responds to declining cardiac output and reduced tissue perfusion by (1) retaining sodium and water in order to increase the blood volume, (2) increasing heart rate and contractility in order to augment cardiac output, and (3) inducing generalized vasoconstriction to maintain blood pressure and ensure perfusion of vital organs such as the brain and kidney.

These compensatory responses offer some advantages to patients with developing heart failure, but eventually they result in excessive sodium and water retention (leading to congestion and edema) as well as excessive vascular resistance (resulting in mismatching of afterload to contractility and declining cardiac output). A vicious cycle is established whereby the compensatory responses evoked by heart failure cause a progressive decline in cardiac function, which leads to further activation of the same deleterious compensatory responses. To a large extent, therapeutic strategies are designed to moderate the excesses of neurohormonal activation and to reestablish a more benevolent internal milieu.[1]

36.8 MEDICAL MANAGEMENT OF CONGESTIVE LEFT-SIDED HEART FAILURE

36.8.1 Goals of Treatment

The primary goal of treatment is to achieve a cure. When this is not possible, the goals of therapy are (1) to improve the quality of life (exercise capacity and comfort at rest) and (2) to increase survival time if the quality of life is acceptable to the owner. These goals are generally accomplished by improving pump function, resolving congestion, and reducing the work of the heart.[1]

The primary aim of treating heart failure is to prevent edema and effusion. A second goal is to increase cardiac output. Almost all medical heart failure treatments are palliative rather than curative. Consequently, most patients that develop heart failure die from heart failure, often within a relatively short time. Surgical or interventional procedures are curative for select abnormalities (e.g., patent ductus arteriosus) and for a very few select patients with select abnormalities (e.g., mitral regurgitation due to myxomatous mitral valve disease).

No studies have been performed in veterinary medicine to determine if any cardiovascular drug prolongs life, although angiotensin-converting enzyme (ACE) inhibitors have been shown to prolong the time until refractory heart failure or death occurs.[4] Certainly diuretics prolong life. Without them, most patients with severe heart failure would die before leaving the hospital. Studies to prove that diuretics improve quality of life and prolong life have not been done in dogs and cats. Even in humans no large, long-term clinical trial has been performed, primarily because the Food and Drug Administration has not required such studies for regulatory approval.[11]

ACE inhibitors have been shown to prolong life in humans with heart failure. However, this prolongation is modest, usually being measured in months rather than years. Digoxin has been shown not to prolong life in humans with heart failure.[12] Often of more importance is the effect that cardiovascular drugs have on the quality of a patient's life. Diuretics and ACE inhibitors definitely improve quality of life in dogs and cats with heart failure, although diuretics are much more efficacious.[4] Pimobendan produces substantial improvement in quality of life in many dogs and may also prolong survival in those with dilated cardiomyopathy.[13,14] When heart failure 152

153 becomes refractory to these drugs, others may help reduce edema formation and improve perfusion and so reduce clinical signs and increase comfort.

In human medicine, left-sided heart failure is often staged and therapy altered depending on the stage or class. The New York Heart Association developed a classification scheme that has been used in human medicine for decades. It is based primarily on exercise limitation and ranges from class I (no exercise limitation) to class IV (inability to carry on any activity without signs). Exercise limitation is not the primary clinical abnormality that is noted by most owners of animals with left-sided heart failure. Instead, they most commonly note tachypnea, dyspnea, and coughing, or combinations of these plus respiratory difficulty resulting from pleural effusion.

Consequently, the New York Heart Association scheme is not very useful for dogs and cats. For the purposes of deciding drug therapy and dosages, we prefer to categorize our patients simply into those with mild, moderate, or severe disease and mild, moderate, severe, fulminant, or refractory left-sided heart failure (Table 36-1).[4]

Table 36-1 Suggested Drug Regimens for Treating Heart Failure Caused by the Three Most Commonly Acquired Cardiac Diseases in Dogs and Cats

Type of Heart Failure	Mitral Regurgitation: Dog	Dilated Cardiomyopathy: Dog	Hypertrophic Cardiomyopathy: Cat
Chronic mild (mild pulmonary edema, ascites, mild pleural effusion)	1. Furosemide: 1 to 2 mg/kg PO q12-48h	1. Furosemide: 1 to 2 mg/kg PO q12-48h	1. Furosemide: 3 to 6 mg/cat PO q12-48h
	2. ACEI	2. ACEI	2. Diltiazem or β-blocker
		3. Digoxin	
Chronic moderate (as above but moderate)	1. Furosemide: 1 to 2 mg/kg PO q8-12h	1. Furosemide: 1 to 2 mg/kg PO q8-12h	1. Furosemide: 6 to 12.5 mg/cat PO q12-24h
	2. ACEI	2. ACEI	2. Diltiazem or β-blocker
	3. ± Digoxin	3. Digoxin	
Chronic severe (as above but severe)	1. Furosemide: 2 to 4 mg/kg PO q8-12h	1. Furosemide: 2 to 4 mg/kg PO q8-12h	1. Furosemide: 12.5 mg/cat q8-12h
	2. ACEI	2. ACEI	2. Diltiazem and/or β-blocker
	3. ± Low-salt diet	3. Digoxin	3. ± Low-salt diet
	4. ± Digoxin	4. ± Low-salt diet	4. ± ACEI
Acute severe (severe pulmonary edema or pleural effusion)	1. Furosemide: 4 to 6 mg/kg IV q1-4h	1. Furosemide: 4 to 6 mg/kg IV q1-4h	1. Pleurocentesis
	2. Oxygen	2. Oxygen	2. Furosemide: 2 to 4 mg/kg IV or IM q2-4h
	3. ± Nitroprusside	3. ± Nitroprusside	3. Oxygen
	4. ± Hydralazine	4. ± Dobutamine	4. Do not stress
	5. ± Nitroglycerin		
Acute fulminant (massive pulmonary edema or pleural effusion with severe dyspnea)	1. Furosemide: 6 to 8 mg/kg IV q1-2h	1. Furosemide: 6 to 8 mg/kg IV q1-2h	1. Pleurocentesis
	2. Oxygen	2. Oxygen	2. Furosemide: 2 to 4 mg/kg IV or IM q1-2h
	3. ± Nitroprusside	3. ± Nitroprusside	3. Oxygen
	4. ± Hydralazine	4. ± Dobutamine	4. Do not stress
	5. ± Nitroglycerin	5. ± Nitroglycerin	

Chronic refractory (signs of heart failure despite adequate dosages of standard drugs)	1. Furosemide: 4 mg/kg PO q8h	1. Furosemide: 4 mg/kg PO q8h	1. Furosemide: 12.5 to 18.5 mg/cat q8-12h
	2. ACEI	2. ACEI	2. Diltiazem and/or β-blocker
	3. Low-salt diet	3. Low-salt diet	3. Low-salt diet
	4. ± Thiazide diuretic	4. Digoxin	4. ACEI
	5. ± Hydralazine	5. ± Thiazide diuretic	5. ± Thiazide diuretic
	6. ± A nitrate	6. ± A nitrate	6. ± A nitrate

Modified from Kittleson MD: Pathophysiology and management of heart failure. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.

ACEI, Angiotensin-converting enzyme inhibitor; *IM,* intramuscular; *IV,* intravenous; *PO,* per os.

The drugs and dosages in this table are presented as guidelines only. Drug choices must be tailored to the individual patient. *Acute:* patients that usually have been showing clinical signs for 24 hours or less and are not on current medications; *chronic:* patients showing clinical signs usually for days to weeks or patients that are being treated and now demonstrate clinical signs; ±, the drug may be used in this situation.

All patients with left-sided heart failure have severe disease. We further subdivide left-sided heart failure into acute and chronic left-sided heart failure. Most patients with this condition are brought for treatment in severe or fulminant left-sided heart failure and require intensive therapy with oxygen and intravenously administered furosemide or nitroprusside, with or without dobutamine (see Chapters 176, 178, and 180, Vasoactive Catecholamines, Antihypertensives, and Diuretics, respectively). Cats with left ventricular failure commonly develop pleural effusion, and thoracocentesis is essential to stabilize them (see Chapter 31, Thoracentesis).

Chronic left-sided heart failure is much more common than acute left-sided heart failure in veterinary medicine, 153
although patients often have signs compatible with acute decompensated left-sided heart failure. This is because 154
dogs and cats commonly hide their clinical signs or the clinical signs go unnoticed until they are severe. Chronic left-sided heart failure is graded according to the severity of the pulmonary edema on thoracic radiographs in dogs and on the severity of pulmonary edema or pleural effusion in cats.

Increasing severity of chronic left heart failure is managed with escalating dosages of furosemide, whereas an ACE inhibitor is administered at a fixed dosage. The role of pimobendan is being defined. It is approved for use in dogs with atrioventricular valvular insufficiency or dilated cardiomyopathy in the United States. Pimobendan is indicated in dogs and cats with left heart failure resulting from myocardial failure. Digoxin may also be used, depending on the underlying disease and the stage of left-sided heart failure, although it is used more frequently as an antiarrhythmic than a positive inotropic agent (see Chapter 189, Digoxin). Refractory left-sided heart failure resulting from dilated cardiomyopathy is managed by adding pimobendan, if it is not already being used, or a thiazide diuretic. The same drugs or a potent arteriolar dilator, such as hydralazine or amlodipine, may be used in dogs with refractory severe mitral regurgitation secondary to myxomatous mitral valve disease. Spironolactone is also commonly used. Although its efficacy is questionable, there is little doubt that it is safe.[4]

37 Chapter 37 Feline Cardiomyopathy

Jonathan Abbott, DVM, DACVIM (Cardiology)

37.1 KEY POINTS

- Myocardial disease accounts for almost all acquired cardiac disorders in the cat.
- Cardiomyopathy, defined as a heart muscle disease that is associated with cardiac dysfunction, is an important cause of both morbidity and mortality in the cat.
- The most common forms of feline cardiomyopathy result in impaired ventricular filling.
- Clinical signs are associated with congestive heart failure (CHF) or systemic thromboembolism.
- Diagnostic imaging, through radiography and echocardiography, is vital to the diagnostic approach.
- Urgent medical management of CHF secondary to feline cardiomyopathy primarily consists of supportive care and interventions that decrease ventricular filling pressures.

37.2 INTRODUCTION

Heart muscle disease is an important cause of morbidity and mortality in the cat. The various forms of myocardial disease account for virtually all acquired cardiac disorders in this species; disease that is primary to valvular structures, the pericardium, or specialized conduction system is uncommon. The nomenclature of myocardial disease is potentially problematic but evolving. Most recently, cardiomyopathy has been defined as a heart muscle disease that is associated with cardiac dysfunction.[1] Myocardial diseases generally are defined by morphopathologic features or, when it is known, cause. Based on this classification scheme, there are four basic types of cardiomyopathy: (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy (HCM), (3) restrictive cardiomyopathy (RCM), and (4) arrhythmogenic right ventricular cardiomyopathy.[1] All of these forms are observed in the cat.[2-6]

Heart muscle diseases that are associated with a known causal agent, hemodynamic abnormality, or metabolic derangement are known as specific cardiomyopathies.[1] In the cat, the most important disorders in this category are thyrotoxic cardiomyopathy and hypertensive HCM.[7] In general, these secondary cardiomyopathies seldom result in clinical signs and are reversible when the underlying disorder resolves.[8,9]

This chapter addresses the clinical picture and therapy of cardiomyopathy that develop as a result of abnormalities that are primary to the myocardium. HCM is the most common heart disease in the cat and therefore is emphasized.

37.3 ETIOPATHOGENESIS

HCM is a primary heart muscle disease in which ventricular hypertrophy develops in the absence of a hemodynamic or metabolic cause.[10] Although systolic dysfunction and wall thinning occasionally develop in patients with long-standing HCM, the disorder generally is characterized by hypertrophy of a nondilated ventricle.[10] It is accepted that HCM in humans is a genetic disease, and this disorder has been associated with more than 200 mutations of genes that encode sarcomeric proteins. The mutation responsible for familial HCM in Maine Coon Cats has been identified.[11,12] This finding and the occurrence of HCM in related purebred and mixed breed cats, support a genetic basis.[13-15]

Feline RCM is a disorder in which impaired ventricular filling occurs in the absence of myocardial hypertrophy or pericardial disease. The structural features of RCM are varied and diagnostic criteria are not rigidly defined. The term generally is applied when there is atrial enlargement associated with a ventricle that has a normal or nearly normal appearance.[7] The cause of feline RCM is not known. Endomyocardial fibrosis and myocardial functional deficits that impair relaxation are the presumed explanations for diastolic dysfunction and resultant atrial enlargement. It is possible that some examples of RCM represent the sequelae of endomyocardial inflammation.[4]

37.4 PATHOPHYSIOLOGY

37.4.1 Diastolic Dysfunction

The ability of the ventricle to fill at low diastolic pressures depends on the rate of the active, energy-requiring process known as *myocardial relaxation,* as well as on mechanical properties that determine chamber compliance.[16] Impaired myocardial relaxation and diminished chamber compliance alter the pressure-volume relationship so that diastolic pressures are high when ventricular volume is normal or small. High diastolic pressures are reflected upstream, potentially resulting in atrial enlargement and venous congestion. In cases in which the end-diastolic volume is diminished, stroke volume may also be reduced. Therefore diastolic dysfunction can explain subnormal cardiac output as well as venous congestion.

Diastolic dysfunction is the predominant pathophysiologic mechanism responsible for clinical signs in HCM and RCM.[7] With regard to HCM, intrinsic functional deficits of the cardiomyocytes and ischemia related to hypertrophy and abnormalities of the intramural coronary arteries are responsible for impaired myocardial relaxation. Hypertrophy and fibrosis stiffen the ventricle and explain diminished chamber compliance. The basis of cardiac dysfunction in feline RCM has been defined incompletely, although endomyocardial fibrosis likely plays an important role.

Systolic anterior motion (SAM) of the mitral valve is echocardiographically detected in approximately 65% of cats with HCM.[2] The precise pathogenesis has been the subject of debate, but it is likely that abnormal drag forces are responsible for systolic movement of the valve leaflets toward the septum.[17] Abnormal papillary muscle orientation and dynamic systolic ventricular performance provide a structural and functional substrate that predisposes to SAM.[18] Movement of the mitral leaflets toward the septum results in dynamic—as opposed to fixed—left ventricular outflow tract obstruction and, usually, concurrent mitral valve regurgitation. It is relevant that SAM is a labile phenomenon. Decreases in preload and afterload or increases in contractility may provoke or augment SAM.[19] The prognostic relevance of SAM in feline HCM has not been defined. Outflow tract obstruction due to SAM has been associated with poor prognosis in humans with HCM.[20] Interestingly, the results of two retrospective studies of feline HCM suggest that SAM confers a more favorable prognosis than does its absence.[2,21] Possibly this finding reflects the limitations of retrospective evaluation of a referral population but it is nonetheless interesting. SAM is likely the most important cause of cardiac murmurs in cats with HCM.

37.5 CLINICAL PRESENTATION

37.5.1 Patient History and Physical Findings

Clinical manifestations of feline cardiomyopathy result from CHF and arterial thromboembolism (ATE). Diagnosis and management of ATE are discussed elsewhere in this volume.When CHF is present, the observation of tachypnea or respiratory distress most commonly prompts the pet owner to seek veterinary evaluation. Cats with heart failure seldom cough. Nonspecific clinical signs such as lethargy, depression, and inappetence often are observed in patients with cardiomyopathy. Although the causative disorder is usually chronic, the onset of clinical signs associated with CHF is typically sudden.

Retrospectively evaluated case series have identified an association between the administration of glucocorticoids and the development of CHF in cats.[21,22] Some affected cats may have had preexisting but clinically silent HCM, but this has not been established. This association is relevant, because the long-term prognosis for cats with glucocorticoid-associated CHF may be better than for those with CHF from more typical causes.[22]

Patients with CHF often are depressed, and hypothermia commonly is observed. The heart rates of cats with heart failure differ little from those of healthy cats,[23] although bradycardia is occasionally evident. Many cats with HCM have a systolic murmur associated with SAM. The prevalence of murmurs in cats with other forms of heart disease is lower.[5] A gallop rhythm is a subtle but important auscultatory finding. The third and fourth heart sounds are seldom audible in healthy cats. In general, auscultation of a gallop sound signifies diminished ventricular compliance in association with high atrial pressures. A gallop sound more specifically identifies cats with heart disease than does a murmur. It is important to recognize that the prevalence of murmurs in echocardiographically normal cats is not inconsequential. Because of this, the finding of a cardiac murmur is sometimes incidental to a clinical picture that results from noncardiac disease.

Crackles are sometimes heard in feline patients with cardiogenic edema, but it is likely that the auscultation of adventitious pulmonary sounds has low sensitivity and specificity for pulmonary edema. Patients in which pleural effusions are responsible for respiratory distress generally have quiet heart sounds as well as diminished, dorsally displaced bronchial tones.

155
156

37.5.2 Electrocardiography

In the absence of arrhythmias, the diagnostic utility of electrocardiography in the assessment of cats with cardiomyopathy generally is low. Electrocardiographic evaluation of cats with clinical signs resulting from feline cardiomyopathy generally reveals sinus rhythm, although pathologic tachyarrhythmias sometimes are observed. The heart rates of cats with heart failure seldom are higher than is normal, and bradycardia resulting from a slow sinus rate or AV conduction disturbances is occasionally evident.

37.5.3 Radiography

In the cat, radiographic patterns of specific chamber enlargement are relatively indistinct. Because of this, it is seldom possible to draw conclusions regarding atrial or ventricular size, but rather, it is apparent only that the silhouette is enlarged. Radiographic cardiomegaly usually is evident when respiratory signs result from feline cardiomyopathy. Cardiogenic pulmonary edema in the cat typically is patchy but distributed diffusely through the lung (Figure 37-1). Fairly often the pulmonary arteries and veins are prominent if not obscured by infiltrates. Pulmonary edema is the most common manifestation of congestion in patients with HCM, but some cats develop large pleural effusions associated with HCM or other types of feline cardiomyopathy. Curiously, cats sometimes develop large pleural effusions as a result of cardiac diseases that affect primarily the left ventricle.

37.5.4 Echocardiography

Definitive antemortem diagnosis of feline cardiomyopathy requires echocardiographic evaluation. HCM is characterized echocardiographically by ventricular hypertrophy in the absence of chamber dilation. It is generally accepted that the end-diastolic thickness of the interventricular septum or left ventricular posterior wall is less than 6 mm in healthy cats, and measurements that exceed this figure suggest hypertrophy.[2] Left atrial enlargement resulting from diastolic dysfunction and sometimes concomitant mitral valve regurgitation is often present (Figure 37-2). This finding is clinically important, because respiratory signs rarely result from cardiomyopathy in patients with normal atrial size. It is important to know that echocardiographic pseudohypertrophy can result from hypovolemia. When this is the case, atrial dimensions typically are small.

37.5.5 Systemic Blood Pressure

Systemic blood pressure is related to both tissue perfusion and vascular resistance. Serial evaluation of blood pressure is potentially useful in the treatment of critically ill patients with feline cardiomyopathy. Because abnormal ventricular loading conditions associated with systemic hypertension may result in compensatory hypertrophy, feline HCM is a diagnosis of exclusion. Systemic blood pressure can be measured by direct puncture of a peripheral artery but more often is estimated using indirect methods. In the cat, the Doppler technique is likely to be superior to the oscillometric method.[24] Accuracy of indirect blood pressure estimation is critically dependent on technique, and results must be interpreted in context of the inherent limitations of the method and the clinical scenario. Repeatable measurements of systolic blood pressure in excess of 180 mm Hg are compatible with a diagnosis of hypertension.

37.6 DIAGNOSTIC APPROACH

The therapeutic approach to feline cardiomyopathy is best formulated based on the results of diagnostic evaluation (Figure 37-3). Clinical signs of tachypnea and respiratory distress should be investigated radiographically. When physical and radiographic findings suggest that cardiac disease is responsible, echocardiographic evaluation is indicated. When the clinical picture is complicated by arrhythmias, the patient also should be evaluated electrocardiographically. However, it is important to recognize that feline patients in respiratory distress are fragile. Sometimes the risks associated with restraint for diagnostic evaluation cannot be justified, and empiric diuretic therapy should be considered. When empirical therapy is contemplated, it is important that the presumptive diagnosis is plausible based on signalment, history, and physical findings. Furthermore, an understanding of the expected response and a willingness to adapt to changing clinical circumstances is essential.

Sometimes it is possible to perform an abbreviated echocardiographic examination while the patient is sternally recumbent, minimally restrained, and receiving supplemental oxygen. In these circumstances, it is not always important to characterize definitively the nature of the myocardial disease. Documentation of left atrial enlargement provides indirect evidence of elevated filling pressures from which it can reasonably be surmised that the clinical signs result from congestion. In most circumstances, the absence of left atrial enlargement suggests that respiratory signs are not the result of cardiac disease. It is important to note that patients who have suffered ATE often exhibit tachypnea that presumably is a manifestation of pain. In this patient population, tachypnea is inconsistently associated with congestion and it is therefore appropriate to obtain thoracic radiographs before administering diuretics to patients with ATE.

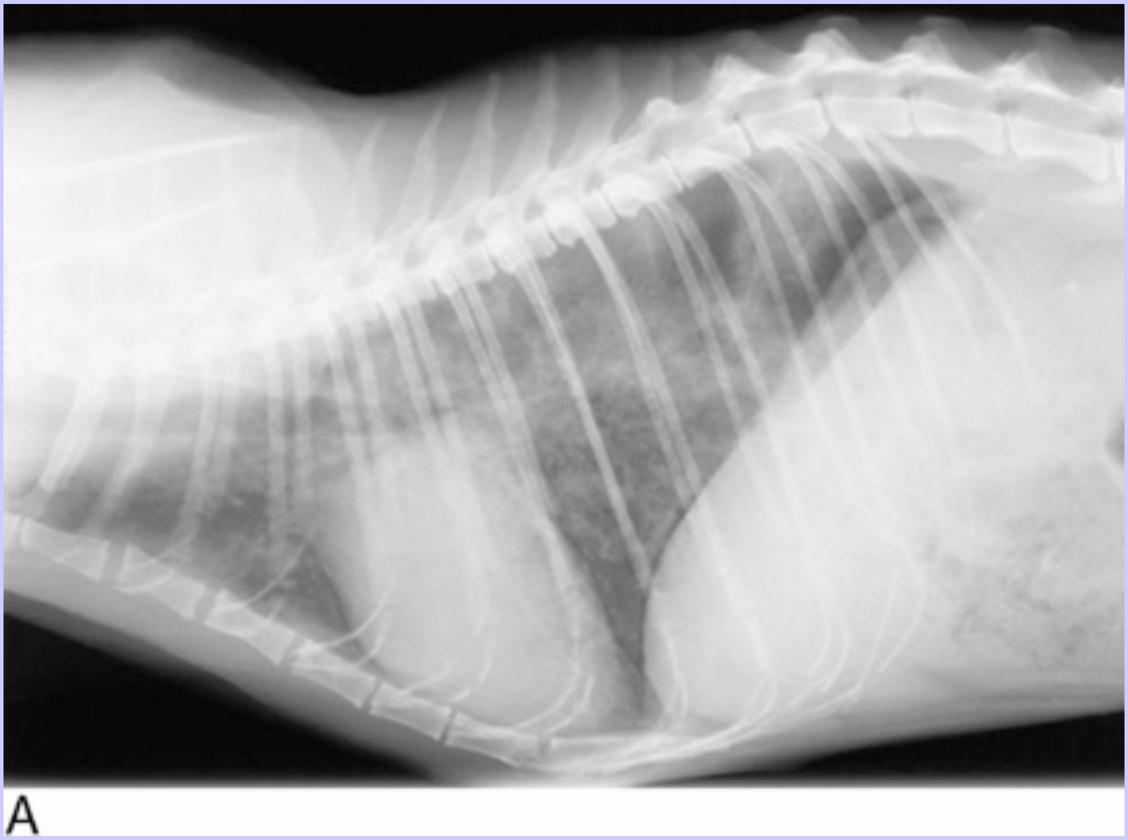
37.7 THERAPEUTIC APPROACH

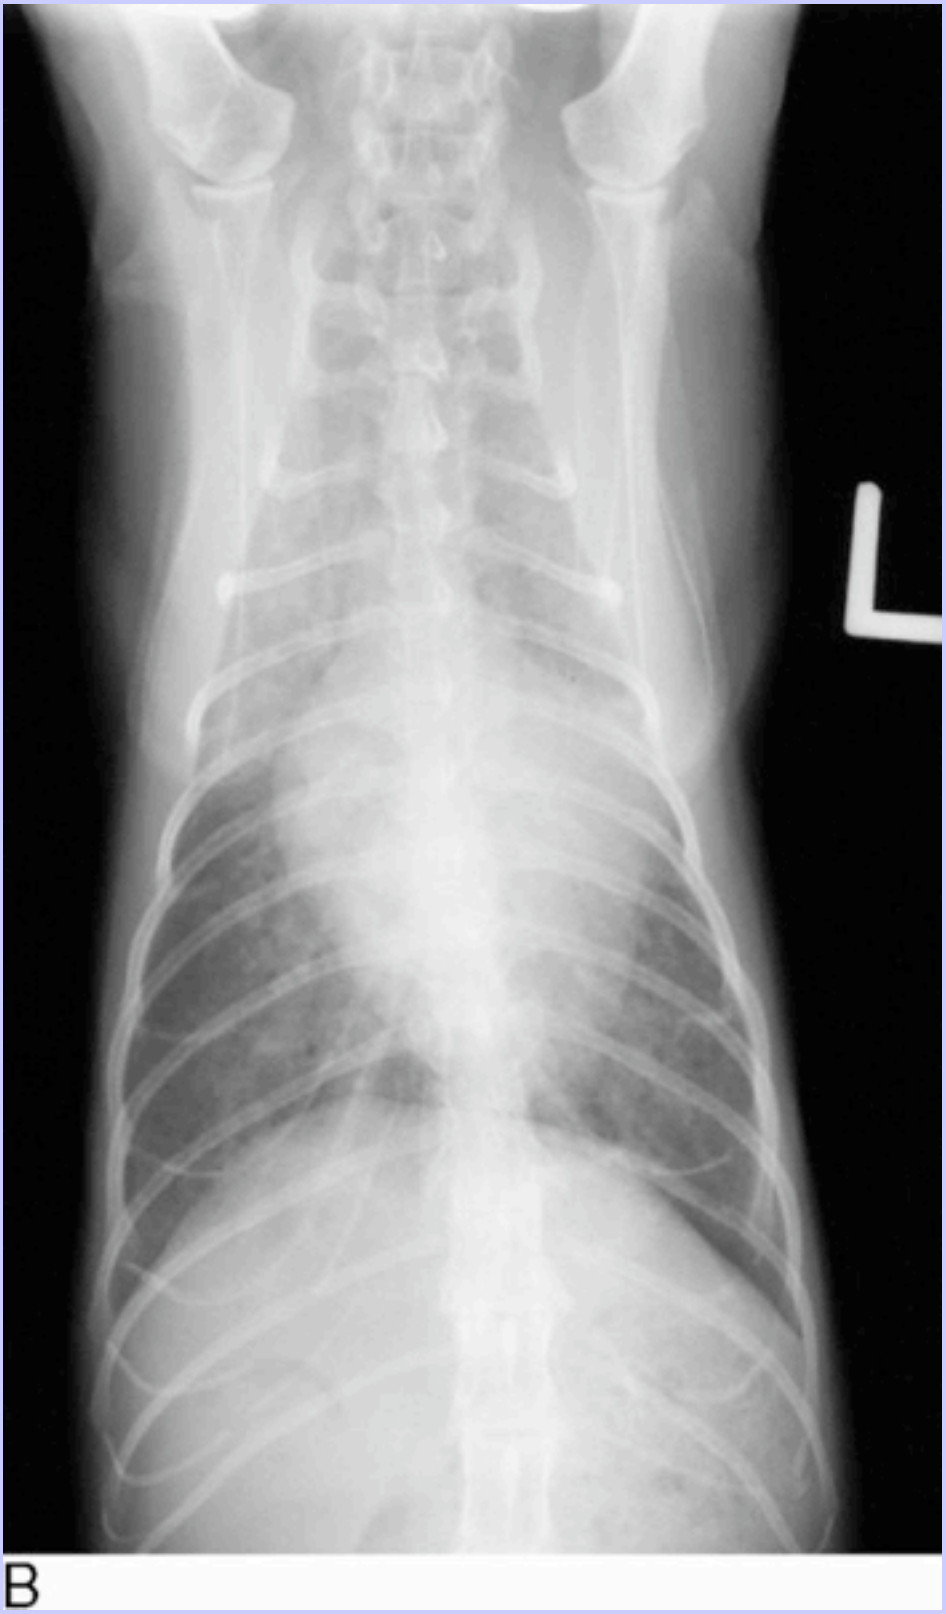
37.7.1 Management of Acutely Decompensated Heart Failure

Heart failure is a syndrome that results from impaired filling or emptying of the heart. Clinical findings may reflect congestion, diminished cardiac output, or both. In veterinary patients it is necessary to use objective rather than subjective markers of disease and, therefore, feline heart failure can be defined as pulmonary edema or pleural effusion that is caused by heart disease.

General supportive measures are indicated for feline heart failure. Indirect heat sources should be used when hypothermia is present. Supplemental oxygen can be administered by mask, nasal insufflation, or via an oxygen administration cage. Most patients that respond to medical therapy for cardiogenic edema do so promptly, so mechanical ventilation generally is not required but can be considered for patients with marked respiratory distress. Pleurocentesis should be performed when physical or radiographic findings confirm that a large pleural effusion is responsible for respiratory distress. Intravenous fluids should be administered to patients with frank congestion sparingly and only if required as a vehicle for drug therapy. In animals with congestive failure, infusion of fluid further increases venous pressures but does not improve cardiac performance.

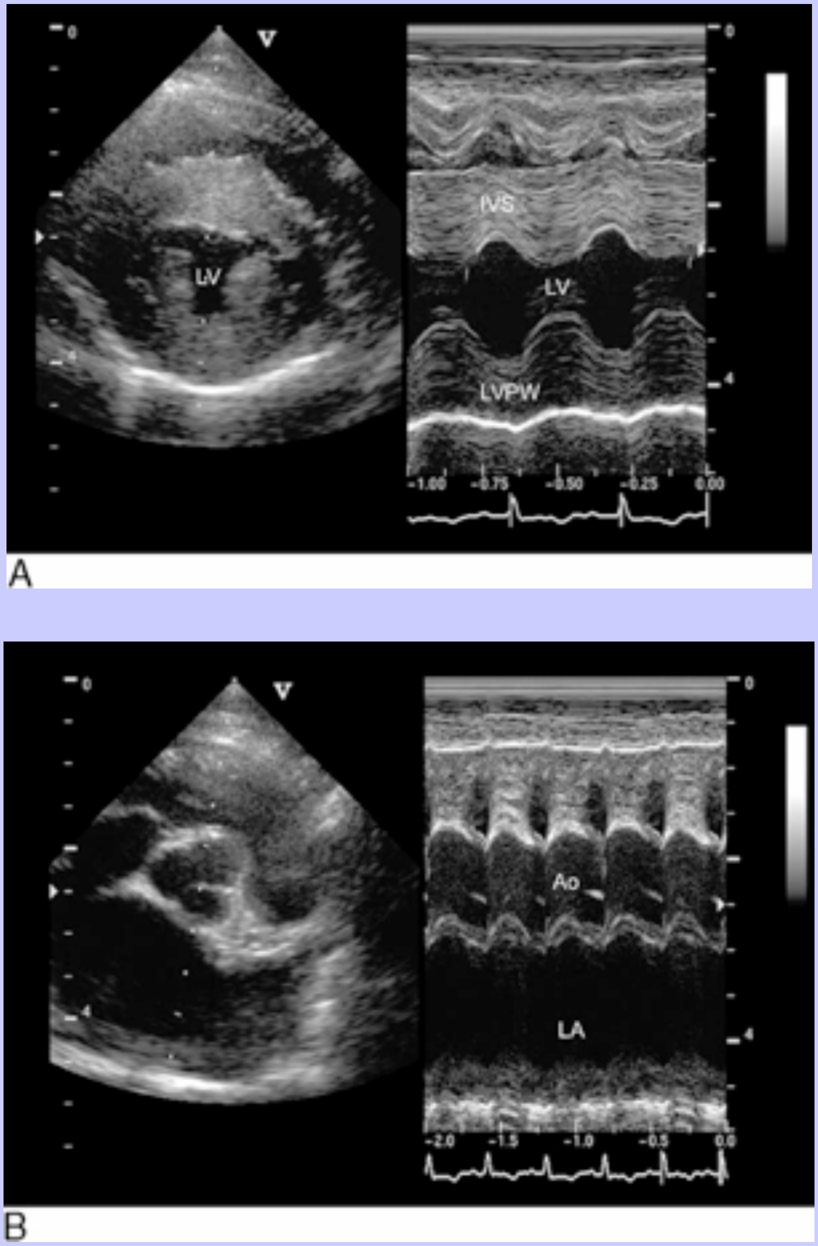
Figure 37-1 Lateral **(A)** and ventrodorsal **(B)** radiographic projections of the thorax of a cat with heart failure due to hypertrophic cardiomyopathy. The cardiac silhouette is enlarged and there are patchy interstitial and alveolar densities distributed throughout the lung.





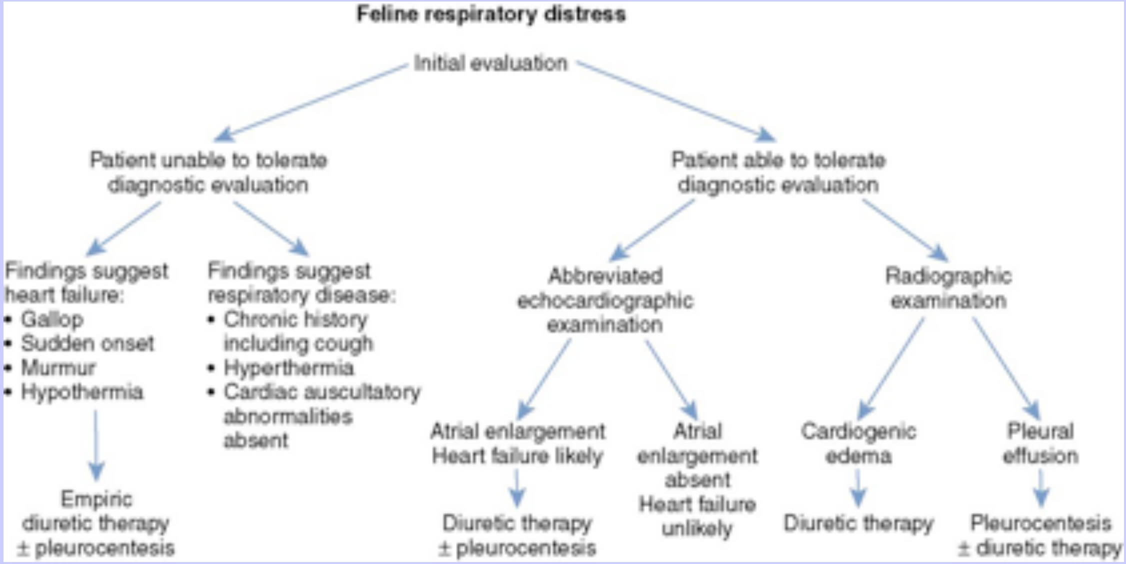
L
B

Figure 37-2 Echocardiographic images obtained from a cat with heart failure due to hypertrophic cardiomyopathy. There is moderate left ventricular hypertrophy **(A)** and left atrial enlargement **(B)**. Static two-dimensional, right parasternal short-axis images and related M-mode echocardiograms are shown for each image plane. *Ao,* Aorta; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *LVPW,* left ventricular posterior wall.



When cardiogenic pulmonary edema is present, diuretic therapy is indicated. Furosemide is a high-ceiling loop diuretic that increases urine production and therefore reduces intravascular volume and venous pressures. Furosemide can be administered intravenously, intramuscularly, or orally. During acute decompensation, the intravenous route is preferable, but intramuscular administration is appropriate when resistance to manual restraint or other factors make intravenous administration difficult or impossible. Generally, the initial dosage is relatively high, perhaps 2 to 4 mg/kg.[25] The patient is then carefully observed for 40 to 60 minutes. If there is a decrease in respiratory rate or effort, a lower dose is administered. The dosage and interval for furosemide should be determined by clinical response. Frequent administration of low doses (0.5 to 1 mg/kg IV q1h) until respiratory signs resolve may provide a means to prevent excessive diuresis. Constant rate infusion of furosemide may accomplish the same objective, although the utility of furosemide infusion has not been specifically evaluated in the cat. If there is no change or if there is deterioration of clinical status after administration of two or three doses of parenteral furosemide, reevaluation of the presumptive diagnosis and therapeutic approach is indicated.

Figure 37-3 An algorithm that outlines one approach to the problem of feline respiratory distress; case management is determined by the tolerance of the patient and the availability of diagnostic modalities. When possible, the therapeutic approach is optimally determined by diagnostic data. It should be emphasized that these are only guidelines and that it can be difficult or impossible to distinguish cardiac and noncardiac causes of respiratory distress based only patient history and physical findings (see text for details).



Feline respiratory distress
Initial evaluation
Patient unable to tolerate diagnostic evaluation
Patient able to tolerate diagnostic evaluation
Findings suggest heart failure:
• Gallop
• Sudden onset
• Murmur
• Hypothermia
Findings suggest respiratory disease:
• Chronic history including cough
• Hyperthermia
• Cardiac auscultatory abnormalities absent
Abbreviated echocardiographic examination
Radiographic examination
Empiric diuretic therapy ± pleurocentesis
Atrial enlargement Heart failure likely
Atrial enlargement absent Heart failure unlikely
Cardiogenic edema
Pleural effusion
Diuretic therapy ± pleurocentesis
Diuretic therapy
Pleurocentesis ± diuretic therapy

It is noteworthy that the clinical profile of heart failure resulting from feline cardiomyopathy is similar to that of feline endomyocarditis.[4] The latter is an idiopathic disorder that is associated with pneumonitis. Patients typically are brought for evaluation of respiratory distress that develops soon after a stressful event, such as surgical sterilization or onychectomy. Because respiratory signs associated with this disorder are apparently not cardiogenic, diuresis is unlikely to improve clinical status.

Nitroglycerin (NG) is an organic nitrate that is sometimes used with furosemide as an adjunctive therapy that may further reduce ventricular filling pressures.[25] NG causes venodilation as well as dilation of specific arteriolar beds, including those of the coronary circulation. In veterinary medicine, NG is used principally as a venodilator that increases venous capacitance, therefore causing a decrease in ventricular filling pressures. Thus the hemodynamic effect of NG is similar to that of diuretic therapy; it is primarily a preload-reducing intervention. The efficacy of NG in feline patients has not been established. NG is most commonly administered using a transdermal cream that is applied to the pinnae or inguinal area. In humans, absorption of transdermal NG depends on the surface area of the skin to which it is applied. The dosage in feline patients is based on anecdotal evidence, but ⅛ to ¼ inch of the transdermal cream has been suggested.

Preload reduction is used for heart failure because it may effectively eliminate clinical signs of congestion. However, preload reduction generally does not improve cardiac performance. Indeed, aggressive reduction in filling pressures can decrease stroke volume, potentially resulting in hypotension. This is particularly relevant in the discussion of feline cardiomyopathy because the disorders that most commonly cause heart failure in the cats result in diastolic dysfunction. Patients with diastolic dysfunction develop congestion when ventricular volumes are normal or small. This partly explains the sensitivity of feline patients to diuretic therapy.

Patient monitoring is an important aspect of critical care. In the management of feline cardiomyopathy, the vital signs are perhaps the most important. It is useful to record body weight, body temperature, heart rate, and respiratory rate at frequent intervals. Other parameters including hematocrit, total serum protein values, blood urea nitrogen concentration, and systemic blood pressure may provide useful ancillary information.

Diastolic dysfunction resulting from HCM or RCM is the most common cause of feline heart failure. Other than furosemide, for which efficacy is assumed, no medical interventions have demonstrated efficacy for this syndrome. Based on this, the use of cardioactive ancillary therapy during acute decompensations is difficult to justify. An exception to this might be the use of antiarrhythmic agents for tachyarrhythmias that contribute to congestive signs. Primarily, the management of acutely decompensated feline cardiomyopathy consists of supportive care and judicious lowering of ventricular filling pressures.

37.7.2 Management of Chronic Heart Failure

Long-term therapy for feline myocardial disease is best guided by echocardiographic findings. Management of diastolic dysfunction traditionally has been with drugs that slow heart rate or speed myocardial relaxation or both. β-Adrenergic antagonists such as atenolol are believed to indirectly improve ventricular filling by lowering heart rate. It is likely that slowing the heart rate is beneficial when tachycardia contributes to diastolic dysfunction. Furthermore, if diastolic function is markedly impaired, myocardial relaxation may be incomplete, even when the diastolic interval and heart rate are normal. Additionally, slowing the rate may improve coronary perfusion, which presumably is abnormal in cats with HCM. Still, elevated filling pressures resulting in congestion at rest are the most obvious cause of clinical signs in HCM, and it is likely that abnormal ventricular stiffness related to hypertrophy and fibrosis is at least partly responsible. It is therefore unclear whether heart rate reduction in patients in which heart rate initially is normal can decrease venous pressures. Relevant studies are lacking and the optimal heart rate for patients with heart failure due to feline HCM is not known. β-Adrenergic antagonists may have a particular role when dynamic left ventricular outflow tract obstruction is caused by SAM and when tachyarrhythmia complicates the clinical picture.

Diltiazem is a benzothiazepine calcium channel antagonist. It is has only a modest slowing effect on heart rate but is believed to speed myocardial relaxation. The latter effect may serve to reduce ventricular filling pressures. Additionally, diltiazem may dilate coronary arteries and improve diastolic function by improving coronary perfusion. In general, diltiazem has little effect on outflow tract obstruction due to SAM.

Enalapril, an angiotensin-converting enzyme (ACE) inhibitor, also has been used in long-term management of feline HCM.[26,27] By interrupting the enzymatic conversion of angiotensin I to angiotensin II, this agent has diverse neuroendocrine effects. ACE inhibitors are vasodilators, although this effect is relatively weak. Most patients with HCM have normal or hyperdynamic systolic performance, and arteriolar dilation confers no obvious mechanical advantage. In contrast to patients with systolic dysfunction and chamber dilation, a reduction in afterload is unlikely to increase stroke volume simply because the ventricle empties almost completely in any case. Indeed, vasodilators generally are contraindicated in human HCM primarily because of the concern that vasodilation will provoke or worsen SAM.[28] The potential but theoretical benefits of ACE inhibition relate primarily to the neuroendocrine effects of these drugs. The resultant decrease in aldosterone activity might be beneficial by decreasing the renal retention of salt and water. Additionally, aldosterone and angiotensin II have been implicated as trophic factors that might be relevant to the development of hypertrophy and fibrosis.[29,30]

Unfortunately, little is known of the efficacy of ancillary therapy for feline cardiomyopathy. In a small, open-label clinical trial, the effects of diltiazem, propranolol, and verapamil on cats with pulmonary edema due to HCM were compared.[31] Diltiazem was the most efficacious of the three. However, this trial did not include a placebo group. A multicenter, randomized, placebo-controlled trial that was designed to evaluate the relative efficacy of atenolol, diltiazem, and enalapril in feline patients with CHF due to HCM or RCM has been completed.[32] The results of this study have been presented but are not yet published. The primary end point of the trial was recurrence of congestive signs, and none of the agents were superior to placebo in this regard. Patients that received enalapril remained in the trial longer than those receiving the alternatives, although this result did not achieve statistical significance. Interestingly, patients receiving atenolol fared less well than did those in the placebo group. The finding that atenolol may harm cats with pulmonary edema was possibly unexpected but is consistent with the result of the only comparable study in which propranolol administration was associated with decreased survival.[31] Studies have not addressed the effect of multivalent therapy; it is possible that β-blockers or other agents are beneficial when used in combination with furosemide and an ACE inhibitor. Regardless, based on these as yet unpublished data, the use of enalapril with furosemide seems a reasonable, initial approach to the long-term management of feline patients with CHF resulting from diastolic dysfunction.

38 Chapter 38 Canine Cardiomyopathy

Robert Prošek, DVM, MS, DACVIM (Cardiology)

38.1 KEY POINTS

- Primary cardiomyopathies, by definition, are idiopathic diseases that are not the result of an identifiable systemic disorder or any type of congenital or acquired heart disease.
- Myocardial diseases resulting from a well-defined disease process are appropriately referred to as *secondary myocardial diseases,* and these need to be considered before the diagnosis of a primary cardiomyopathy.
- Dilated (congestive) cardiomyopathy (DCM) is the most common form of primary myocardial disease in dogs and is characterized by chamber dilation and decreased contractility.
- Large and medium sized dogs are typically affected by DCM.
- Atrial fibrillation is common and often is one of the first abnormalities detected in giant breeds with DCM such as Great Danes, Irish Wolfhounds, and Newfoundlands.
- Breed variations in canine DCM should be considered in Cocker Spaniels, Dalmatians, Boxers, Doberman Pinschers, Portuguese Water Dogs, and the giant breeds.
- Boxers with arrhythmogenic right ventricular cardiomyopathy often have syncope and, as the name states, arrhythmias (ventricular).
- Myocardial failure that leads to congestion is an emergency that requires a low-stress environment, oxygen, diuretics, vasodilators, and inotropic support.

38.2 INTRODUCTION

Primary myocardial diseases, or “true” cardiomyopathies, are those conditions that predominately affect the heart muscle, that are not the result of other congenital or acquired valvular, pericardial, vascular, or systemic diseases, and whose causes are unknown. The most common form of myocardial disease in the dog is dilated cardiomyopathy (DCM), but arrhythmogenic right ventricular cardiomyopathy (ARVC) (in Boxers) and hypertrophic cardiomyopathy (HCM) are also reported. There is increasing breed-specific information about canine DCM, especially in Doberman Pinschers, Dalmatians, Portuguese Water Dogs, Cocker Spaniels, and the giant breeds, which should be considered in diagnosis and treatment. Secondary myocardial diseases resulting from well-defined disease processes are listed in Box 38-1 and should be considered before making the diagnosis of a primary cardiomyopathy. Diagnostic and treatment techniques often are tailored to each patient and breed, with emphasis on control of a stable rhythm, prevention of congestive heart failure (CHF), and improvement in quality and length of life.

38.3 DILATED CARDIOMYOPATHY

DCM is characterized by chamber dilation and impaired systolic and often diastolic function of one or both ventricles. It is an adult-onset disease, with the exception of the Portuguese Water Dog in which the young are affected (2 to 32 weeks old). Generally, it is a disease of large and medium-sized dogs with increased incidence in the Doberman Pinscher, Great Dane, Irish Wolfhound, and American Cocker Spaniel in North American surveys, but European studies show an increased incidence in the Airedale Terrier, Newfoundland, English Cocker Spaniel, and Doberman Pinscher.[1]

  - Lyme disease, trypanosomiasis

* Conditions discussed in this chapter.

38.3.2 Physical Examination

Often a soft grade 1 to 3 of 6 systolic left or right apical murmur is noted and is a result of either mitral or tricuspid valve insufficiency, respectively. Auscultation may also reveal a chaotic rhythm of atrial fibrillation or an irregular rhythm due to atrial or ventricular premature beats. With right-sided CHF the following may be noted: jugular pulses or distention or both, muffled heart and ventral lung sounds with pleural effusion (pleural fluid line), and hepatomegaly due to congestion with or without ascites. With left-sided CHF, examination will often reveal pulmonary crackles or rales, hypokinetic femoral pulses, pulse deficits with ventricular premature beats, or atrial fibrillation. Peripheral edema is rare. Finally, albeit rare, cardiogenic shock may be present as a result of decreased arterial blood pressure (usually blood pressure is normal as a result of vasoconstriction and neurohormonal activation). 160 161

38.3.3 Thoracic Radiography

Thoracic radiographs should be examined for generalized cardiomegaly and signs of CHF. Signs of left-sided heart failure include interstitial or alveolar pulmonary edema and moderate to severe left atrial enlargement.

Right-sided failure results in pleural effusion, enlarged caudal vena cava, hepatomegaly, and ascites (Figure 38-1).

38.3.4 Electrocardiography

The electrocardiogram (ECG) should be examined for sinus tachycardia, possibly with atrial or ventricular premature beats, atrial fibrillation, and ventricular tachycardia, especially in Boxers and Doberman Pinschers. Prolonged or increased voltage QRS complexes suggestive of left ventricular enlargement or low-voltage QRS complexes with pleural effusion may be noted.

38.3.5 Routine Blood Tests

Routine blood work findings are usually normal unless severe heart disease is present. Prerenal azotemia, high alanine aminotransferase levels, and electrolyte abnormalities may be evident in cases of severe heart disease. Hyponatremia and hypochloremia, if noted with CHF, are associated with a poorer prognosis. Hypokalemia, metabolic alkalosis, and prerenal azotemia may also be the result of diuretic therapy for heart disease.

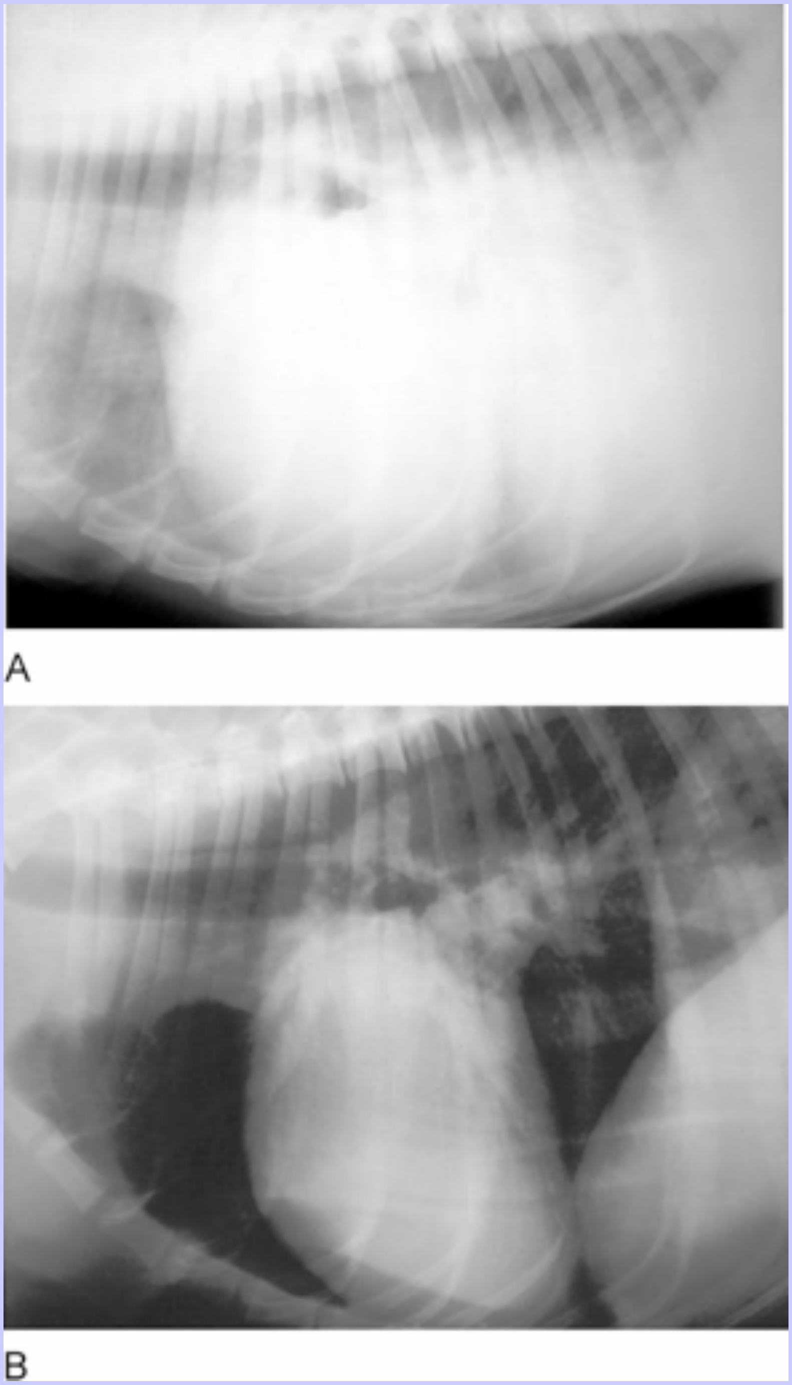
38.3.6 Effusion Analysis

Peritoneal or pleural effusion in dogs with DCM is usually a modified transudate (nucleated cell count <2500/ml, total protein <4.0 g/dl), but on occasion a chylous effusion is found.

38.3.7 Echocardiography

Ventricular and atrial dilation are common with reduced myocardial systolic function (reduced left ventricular fractional shortening percentage [FS%] and ejection fraction). Increased E-point septal separation is also common with ventricular dilation.[2] Doppler studies confirm evidence of mitral and tricuspid regurgitation, low-velocity transaortic flow, diastolic ventricular dysfunction, and possible pulmonary hypertension (due to severe left-sided heart failure). Pleural effusion can also be noted along with mild pericardial effusion due to CHF. Remember, most DCM cases with CHF should have moderate to severe atrial enlargement, and low FS% is not pathognomonic for DCM; many normal hearts contract more in apical-to-basilar direction, and this motion is not accounted for by the FS% (Figure 38-2).

Figure 38-1 Lateral radiographs of a Doberman Pinscher with dilated cardiomyopathy. **A,** On presentation. **B,** Same patient after 36 hours of aggressive treatment of congestive heart failure (furosemide, O^2, nitroprusside, dobutamine).



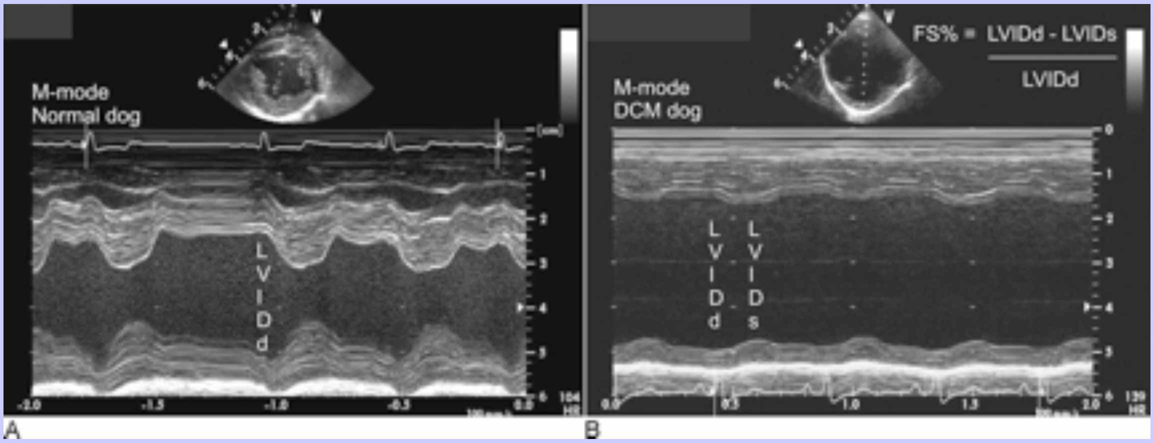
38.4 ACUTE TREATMENT OF CONGESTIVE HEART FAILURE

Acute treatment of CHF is summarized in Box 38-2. CHF failure is discussed further in Chapter 36.

38.5 LONG-TERM TREATMENT OF DILATED CARDIOMYOPATHY

Pleurocentesis and abdominocentesis should be performed as needed to relieve clinical signs.

Figure 38-2 **A,** Example of a normal dog M-mode and **(B)** an M-mode from a dog with dilated cardiomyopathy. Dog in *B* would have a decreased fractional shortening percentage based on left ventricular internal dimension in diastole – left ventricular internal dimension in systole divided by left ventricular internal dimension in diastole = LVIDd –LVIDs/LVIDd.



38.5.1 Box 38-2 Guidelines for Acute Management of Congestive Heart Failure

- Minimize stress and ensure absolute rest.
- Pleurocentesis as needed for pleural effusion (therapeutic and diagnostic).
- Oxygen supplementation.
- If pulmonary edema: Furosemide 2 to 6 mg/kg IV or IM initial dose, then 1 to 2 mg/kg q2-3h as needed for resolution of pulmonary edema, then q8-12h for the first 3 days).
- 2% Topical nitroglycerin: 1 to 2 inches q8h.
- Life-threatening arrhythmias (see Chapters 47 and 48, Ventricular Tachyarrhythmias and Myocarditis, respectively).

- Sodium nitroprusside: 2.0 μg/kg/min. If mean BP remains > 70 mm Hg increase incrementally to 4 μg/kg/min until patient is stabilized or mean pressure falls below 70 mm Hg (rate >10 μg/kg/min rarely needed); extremely effective with furosemide in managing pulmonary edema.
- Dobutamine (if severe heart failure or cardiogenic shock; ECG monitoring needed): start at 2.5 to 5 μg/kg/min, increase q3-4h by 2.5 μg/kg/min until heart rate increases excessively (>180 beats/min or >10% rise from baseline); maximum infusion rate 15 μg/kg/min. If ventricular ectopy develops, reduce rate.
- Other options for positive inotropic support include amrinone, milrinone, and pimobendan.

Note: Management should be individually tailored, based on treatment history, clinical picture, complicating arrhythmias, and concurrent diseases.

ECG, Electrocardiogram.

38.5.2 Diuretics

Diuretics are administered as needed to control edema. Furosemide is given at 1 to 4 mg/kg PO q8-24h, spironolactone at 1 to 2 mg/kg PO q12h, with or without hydrochlorothiazide 2 to 4 mg/kg PO q12h. The author often uses a combination of spironolactone-hydrochlorothiazide (Aldactazide) at 1 mg/kg PO q24h in refractory cases to decrease the number of drugs the owner has to administer (see Chapter 180, Diuretics).

38.5.3 Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors are initiated early in the therapeutic regimen, and possible drug selection includes enalapril (0.5 mg/kg PO q12-24h), benazepril (0.25 to 0.5 mg/kg PO q12-24h), and lisinopril (0.5 mg/kg PO q24h).

38.5.4 Digoxin

Digoxin is administered to improve systolic function and to slow ventricular rate in animals with supraventricular tachyarrhythmias (0.003 mg/kg PO q12h, adjusting dosage based on blood levels) (see Chapter 189, Digoxin).

38.5.5 Novel Therapy

These therapies maybe used after careful consideration of the benefits and risks involved; consultation with a cardiologist may be warranted. β-Blockers may be considered to blunt cardiotoxic effects responses of the sympathetic nervous system; however, heart failure must be well controlled and the dosage titrated slowly with careful monitoring. Carvedilol (0.5 mg/kg PO q12h; start with ¼ to ½ of a 3.125-mg tablet initially) or metoprolol (0.5 to 1 mg/kg PO q8h) can be used with caution. Pimobendan (0.25 mg/kg PO q12h) is a calcium sensitizer and a phosphodiesterase inhibitor recently approved for treatment of DCM.

38.5.6 Diet

It is important to keep patients eating an adequate level of protein, eliminate high salt–containing snacks, and in cats offer a sodium-restricted commercial diet (not at the expense of anorexia) such as Purina CV or Hills H/D.

38.5.7 Supplements

Taurine (500 mg PO q12h) is started while waiting for taurine blood levels, especially in Cocker Spaniels. Omega-3 fatty acids may improve appetite and reduce cachexia (EPA 30 to 40 mg/kg PO q24h; DHA 20 to 25 mg/kg PO q24h). Consider l-carnitine (110 mg/kg PO q12h) in American Cocker Spaniels not responding to taurine and in Boxers.

38.6 TREATMENT OF ARRHYTHMIAS

Please see Chapters 46 and 47, Supraventricular Tachyarrhythmias and Ventricular Tachyarrhythmias, respectively.

38.7 BREED VARIATIONS WITH DCM

38.7.1 Cocker Spaniels

DCM in some Cocker Spaniels is associated with low plasma taurine levels, and supplementation with taurine and l-carnitine (see earlier section for dosing) appears to improve myocardial function.[3] Normal plasma taurine levels should be over 50 ng/ml. Additional measures should be used to address complications such as arrhythmias and CHF and might be withdrawn gradually pending response to taurine (usually 3 to 4 months).

38.7.2 Doberman Pinschers

Typically considered the poster child for DCM, the Doberman Pinscher does have some unique manifestations that are important for the clinician to recognize. About 25% to 30% of Dobermans Pinschers have ventricular arrhythmias without the classic ventricular dilation seen with DCM and CHF.[4] These patients are brought in most commonly for syncope or for arrhythmias noted on routine physical examinations. Sudden death is of great concern in this breed and successful treatment of ventricular arrhythmias is imperative (see Chapter 47, Ventricular Tachyarrhythmias).

The author finds the most successful treatment consists of sotalol alone or in combination with mexiletine. A Holter monitor should be used on syncopal Dobermans Pinschers to identify the causative arrhythmia (occasionally syncope due to bradycardia in this breed)[5] and to monitor success of treatment. Dobermans Pinschers with more than 50 ventricular premature complexes (VPCs) per 24 hours, or with couplets or triplets are suspected for development of DCM. The rest of the Dobermans Pinschers have left or biventricular failure, or both, and often have atrial fibrillation. Atrial fibrillation and bilateral CHF appear to be poor prognostic signs,[6] but outlook is also affected by treatment used and client and patient compliance.

38.7.3 Dalmatians

Male dogs appear to be overrepresented in Dalmatians with DCM. All dogs in one study had left-sided heart failure with no evidence of right-sided CHF or atrial fibrillation. Dalmatians fed a low-protein diet for prevention or treatment of urate stones that develop signs consistent with DCM should be switched to a balanced protein diet.[7] Otherwise, treatment is the same as for any dog with left-sided heart failure.

38.7.4 Great Danes and Irish Wolfhounds

Atrial fibrillation is the most common finding and in some cases develops before any other evidence of underlying myocardial disease.[8] Affected dogs commonly are presented in for weight loss and loss of full exercise capacity, with occasional cough. Progression of the disease is relatively slow, especially in the Irish Wolfhounds.[8] An X-linked pattern of inheritance is suspected in some families of Great Danes, with male dogs being overrepresented.[9]

38.7.5 Portuguese Water Dogs

A juvenile form of DCM has been reported in Portuguese Water Dogs. Affected puppies die from CHF at an average age of 13 weeks after rapid disease progression.[10]

38.8 ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN BOXERS

In affected Boxer dogs, approximately one third have predominately left-sided failure, another one third are brought in for syncope or collapse secondary to a rhythm disturbance, and the remaining one third are asymptomatic but have rhythm disturbances (primarily ventricular arrhythmias). Atrial fibrillation occurs less frequently in Boxers than in other breeds, and cardiomegaly usually is less marked on radiographic evaluation. The pathology of Boxer dog cardiomyopathy closely resembles that seen in humans with ARVC. Similarities between the populations include etiology, clinical picture, and histopathology of fibrous fatty infiltrate of the right ventricular free wall and septum.[11] ARVC appears as an autosomal dominant trait with variable penetrance in Boxers.[12]

38.8.1 Electrocardiography

Ventricular premature beats typically have a left bundle branch block morphology in leads I, II, III, and aVF, consistent with right ventricular origin. As in the Doberman Pinschers, a Holter monitor is helpful in quantifying the VPCs and diagnosing the cause of syncope or collapse (Figure 38-3). More than 100 VPCs in a 24-hour period, periods of couplets, triplets, or runs of ventricular tachycardia may be diagnostic in a symptomatic Boxer.

38.8.2 Treatment of Arrhythmogenic Right Ventricular Cardiomyopathy

Treatment of arrhythmias is based on clinical signs and generally is considered for animals that experience more than 500 to 1000 VPCs per 24 hours, runs of ventricular tachycardia, or evidence of R-on-T phenomenon. The author prefers sotalol (1.5 to 3 mg/kg PO q12h) with the combination of mexiletine (5 to 8 mg/kg PO q8h) in life-threatening ventricular arrhythmias in Boxers[13] (see Chapter 48, Myocarditis). Another study found that treatment with sotalol or mexiletine-atenolol was well tolerated and efficacious in Boxer dogs with ventricular arrhythmias.[14] If CHF is present, or echocardiographic ventricular and atrial dilation are noted, treatment is the same as outlined earlier for other breeds. Additionally, supplementation with L-carnitine (110 mg/kg PO q12h) might be considered, because a family of Boxers showed an improvement in systolic function with this drug.[15]

38.9 HYPERTROPHIC CARDIOMYOPATHY IN DOGS

HCM is a condition characterized by idiopathic hypertrophy of the left ventricle. The term is applied appropriately only in circumstances in which a stimulus to hypertrophy can not be identified. HCM has been recognized in only a small number of dogs and can be assumed to be an uncommon disorder.[16,17] A heritable form of hypertrophic obstructive cardiomyopathy has been described in Pointer dogs.[16] The cause of HCM in dogs is unknown. A genetic cause has been identified in most human patients,[18] but the precise pathogenic mechanism of hypertrophy remains a mystery. As with DCM, there may be more than one form (cause) of HCM.

38.9.1 Pathologic Features

The left ventricle is either symmetrically or asymmetrically hypertrophied (concentric hypertrophy), and the left atrium is dilated. Left ventricular mass is increased (heart weight–to–body weight ratio). When dynamic outflow tract obstruction is present, there is fibrosis of the anterior leaflet of the mitral valve, and a fibrous endocardial plaque on the ventricular septum opposite the mitral valve is noted. Myocardial fiber disarray, which characterizes the human form of this disease,[18] does not appear to be consistently present in affected dogs.

38.9.2 Important Differentials for Concentric Hypertrophy of the Left Ventricle

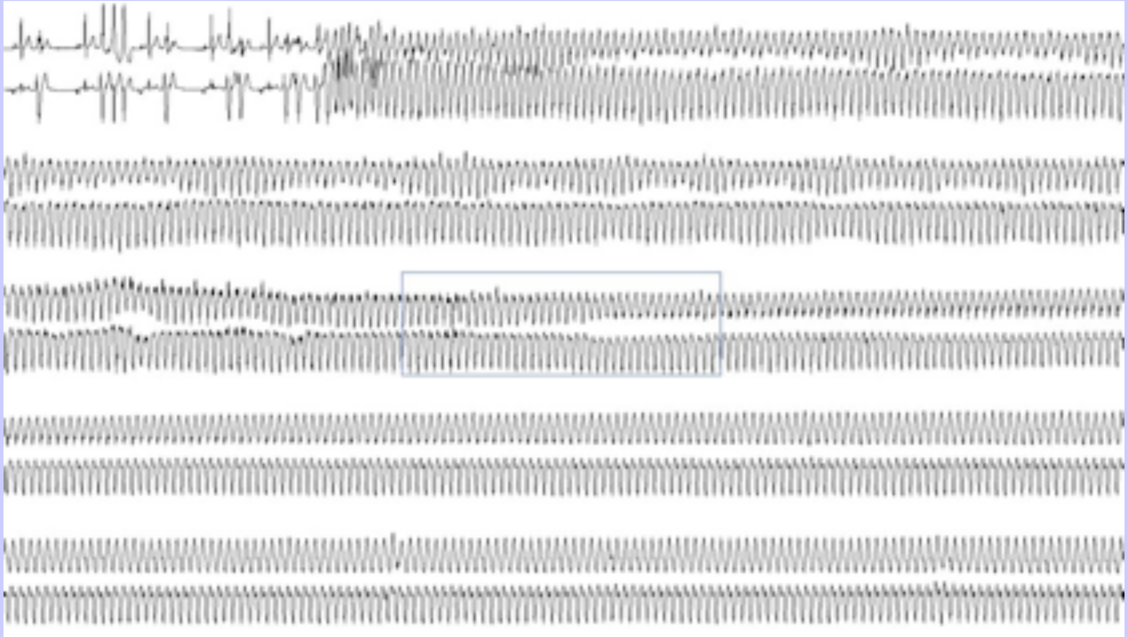
HCM and its variant hypertrophic obstructive cardiomyopathy are infrequent in dogs, and patients should be evaluated for other causes of concentric hypertrophy such as subvalvular or valvular aortic stenosis and systemic hypertension.

38.10 UNCOMMON MYOCARDIAL DISEASES OF DOGS

38.10.1 Duchenne Cardiomyopathy

Duchenne muscular dystrophy is an inherited neuromuscular disorder with an X-linked pattern of inheritance. Dystrophin, a cytoskeletal protein of the plasma membrane, is absent or defective in dogs and humans with Duchenne muscular dystrophy.[19,20] The disorder has been described best in Golden Retriever dogs.[19] Signs of skeletal muscle dysfunction predominate in most affected dogs. Some affected dogs develop deep and narrow Q waves in leads II, III, aVF, CV_6LU, and CV_6LL, and may manifest a variety of ventricular arrhythmias. Echocardiography demonstrates hyperechoic areas (fibrosis and calcification) in the left ventricular myocardium as a sequela to myocardial necrosis.[19,20] Some affected dogs develop myocardial failure resembling DCM.

Figure 38-3 Sustained ventricular tachycardia in a Boxer dog wearing a Holter monitor (24-hour recorder).



38.10.2 Atrioventricular Myopathy

Atrioventricular myopathy (silent atria, persistent atrial standstill) is a progressive idiopathic myocardial disease of dogs that may or may not be associated with a poorly characterized form of shoulder girdle skeletal muscular dystrophy. The unique features of this disorder include the marked degree of myocardial destruction and fibrosis, and the characteristic bradyarrhythmia(s) that result. Pathologic studies often reveal dilated, thin, almost transparent atria with little or no visible muscle. Involvement of the ventricles, especially the right ventricle, occurs somewhat later and is more variable. Histologic findings include variable amounts of mononuclear infiltration, myofiber necrosis and disappearance, and extensive replacement fibrosis. In dogs with muscular dystrophy, changes in skeletal muscle include muscle atrophy, hyalinized degenerated muscle fibers, and mild to moderate steatosis.[21,22] A similar cardiac disorder has been observed in human patients with Emery-Dreifuss (scapulohumeral) muscular dystrophy.

The most commonly affected dogs are English Springer Spaniels and Old English Sheepdogs. Affected dogs usually are brought in for weakness, collapse, or syncope caused by severe bradycardia. Less commonly, dogs have signs of right ventricular or biventricular CHF. Soft murmurs of atrioventricular valve insufficiency are audible in many cases. The most common ECG abnormality is persistent atrial standstill, but complete heart block and other rhythm and conduction disturbances may occur. Atrial enlargement is often found on thoracic radiographs, and generalized cardiomegaly is present in some dogs. Dilated, immobile atria can be identified by 164 echocardiography 165 or fluoroscopy. The clinical course usually is characterized by declining contractility, progressive ventricular dilation, and eventual heart failure. Management of the bradyarrhythmia by artificial pacemaker implantation usually results in immediate improvement in signs, but most dogs eventually develop refractory myocardial failure.[22]

38.10.3 Toxic Myocardial Disease

Doxorubicin (Adriamycin) and other anthracycline antibiotics can cause myocardial failure, typically after the administration of high cumulative doses (usually more than 200 to 300 mg/m^2 doxorubicin). Inasmuch as cardiac toxicity is irreversible, prevention is advised by avoiding high cumulative doses. Dexrazoxane, a cyclic derivative of ethylenediaminetetraacetic acid, protects against cardiomyopathy induced by doxorubicin and other anthracyclines, the main drawback for its use being expense.[23]

39 Chapter 39 Valvular Heart Disease

Aaron C. Wey, DVM, DACVIM (Cardiology)

39.1 KEY POINTS

- Myxomatous valvular degeneration is the most common acquired cardiovascular disorder encountered in canine patients.
- The clinical picture of patients with valvular heart disease in the emergency setting is typically that of cardiogenic pulmonary edema (left-sided congestive heart failure).
- Virtually all patients with acquired degenerative valve disease that have congestive heart failure will have an audible cardiac murmur in the left apical position. If the patient does not have a murmur, other diagnoses should be considered.
- Radiographic and physical examination findings provide a working diagnosis for the treatment of most patients with valvular heart disease. Echocardiography is helpful but not essential for empiric emergency treatment.
- Goals of emergency therapy are to relieve symptoms of congestion, improve forward cardiac output, and improve tissue oxygenation and nutrient delivery.

39.2 INTRODUCTION

Acquired degenerative valvular disease is the most common cardiovascular disorder identified in small animals, accounting for approximately 75% of cardiovascular disease seen in dogs.[1] The condition may also be referred to as *myxomatous valvular degeneration (MVD), mitral valve prolapse, or valvular endocardiosis*. Because the mitral valve is most frequently affected, the condition is often referred to as *mitral valve disease*. This latter designation is technically incorrect, and the condition may affect all four cardiac valves.[2] For the purpose of this discussion, *myxomatous valvular degeneration* will be used to describe the condition.

MVD most frequently affects canine patients, although it may occur in any mammalian species. Feline patients rarely are affected. In the dog, small breeds are over-represented. Breeds commonly associated with the disease include the Poodle, Miniature Schnauzer, Chihuahua, Cocker Spaniel, Dachshund, Cavalier King Charles Spaniel, Lhasa Apso, Shih Tzu, and terrier breeds.[2,3] However, the differential should not be excluded in large-breed dogs with a heart murmur in the left apical position. The disease typically is seen in elderly patients, but some breeds are known to develop MVD relatively early in life (Cavalier King Charles Spaniel).[4] A male predisposition has been suggested.[7]

39.3 PATHOLOGY

The exact cellular and hormonal mechanisms that result in MVD are unknown. One attractive theory suggests that collagen degeneration and collagen synthesis are imbalanced. This is supported by the observation that chondrodystrophic breeds with other connective tissue disorders (collapsing trachea, intervertebral disk disease) frequently develop MVD.[2] Neurohormonal factors have been implicated, including serotonin and nitric oxide, but the exact role of these hormonal messengers in the development and progression of the disease is unknown.[11-13] A common misconception is that previous or chronic vegetative endocarditis from periodontal disease contributes to MVD, but evidence to support this hypothesis is lacking.

Detailed descriptions of the histologic changes that accompany MVD are beyond the scope of this discussion, and the readers are referred to other sources for this information.[3,5,6] Grossly, the changes are evident as valve thickening and elongation, which subsequently alter the normal coaptation of valve leaflets and may result in valve prolapse. The myxomatous changes have been characterized into classes of severity that are useful in a research setting, but these designations rarely are used clinically.[5]

If the degenerative changes or valve prolapse are significant, they result in a valve regurgitation that increases atrial pressure and decreases forward cardiac output (in the case of atrioventricular valve regurgitation). The degree of valvular insufficiency is dependent on the regurgitant orifice area, the pressure gradient across the valve, and the duration of systole (for the atrioventricular valves) or diastole (for the semilunar valves). In response to the decreased forward cardiac output and increased atrial pressure, several compensatory mechanisms are activated (see Pathophysiology) that result in eccentric hypertrophy (dilation) of the cardiac chambers on either side of the insufficient valve. The valve annulus then enlarges, causing further displacement of the leaflets and more regurgitation. In contrast to diseases with primary myocardial failure (i.e., dilated cardiomyopathy), ventricular function usually is maintained until late in the course of MVD, and patients frequently are symptomatic before severe myocardial failure develops. Large breed dogs may develop myocardial failure sooner during the course of the disease for reasons that are not completely understood, although increased wall stress due to a larger ventricular diameter may be a factor.[3] Many patients with MVD have a long preclinical phase before the onset of clinical signs. In these patients the murmur of valvular regurgitation frequently is identified during routine physical examination or when the patient is seen for an unrelated problem. The factors that result in progression from the asymptomatic stage to overt signs of heart failure in some dogs but not others are not completely understood.

39.4 PATHOPHYSIOLOGY

A detailed description of the pathophysiology of heart failure is presented elsewhere in this text (see Chapter 36, Left Ventricular Failure), but a brief description is presented here. Decreased forward stroke volume and decreased mean arterial pressure results in neurohormonal activation: increased sympathetic tone, activation of the renin-angiotensin-aldosterone system, and a change in the concentration of numerous other neurohormones (endothelin 1, tumor necrosis factor-α, nitric oxide).[9,10] The net result of these changes is vasoconstriction, sodium and water retention, and an increased forward cardiac output and blood pressure. This is accomplished though increased contractility (sympathetic stimulation), volume expansion, and eccentric hypertrophy. Other neurohormonal mechanisms may be activated to modulate this response (i.e., natriuretic peptide production secondary to increased atrial pressure and stretch), but these measures frequently are overwhelmed or downregulated with chronically altered cardiac output. Chronic activation of the renin-angiotensin-aldosterone system and sympathetic nervous system occurs at the expense of circulating volume and atrial pressure, which is ultimately transmitted to the pulmonary or systemic venous system. Capillary hydrostatic pressure eventually overcomes other forces in Starling's law (interstitial hydrostatic pressure and capillary oncotic pressure) that help to maintain a balance in movement of fluid across the capillary membrane, and fluid transudation results. Initially the pulmonary and systemic lymphatic systems accommodate the extra fluid transudation, but these systems eventually become overwhelmed, and overt pulmonary edema or third-space fluid accumulation result (congestive heart failure). Additional complications particular to MVD such as rupture of chordae tendineae may also occur. This may be well tolerated with a minor chord but may result in a large increase in regurgitant orifice area and left atrial pressure with acute pulmonary edema. Rarely, left atrial rupture occurs secondary to endothelial tearing at the site of impact of a high-velocity regurgitant jet. This complication results in acute tamponade (see Chapter 43, Cardiac Tamponade and Pericardiocentesis), collapse, and frequently death.

39.5 HISTORY AND PHYSICAL EXAMINATION

Patients with MVD frequently have a history of a cardiac murmur that was identified during a routine physical examination. The murmur is often chronic, although it may be a new finding in the case of chordal rupture. The intensity of the murmur has been correlated with the severity of regurgitation.[8] The patient may be brought in for evaluation of a cough, dyspnea, exercise intolerance, syncope, or collapse. Physical examination findings with left-sided heart failure are attributable to pulmonary edema: dyspnea, orthopnea, cyanosis, and abnormal lung sounds. It should be noted that all patients with pulmonary crackles do not have cardiogenic pulmonary edema, although soft crackles may be present. Tachyarrhythmias (sinus tachycardia, atrial premature contractions, or atrial fibrillation) may also be noted. Right-sided heart failure may result in the accumulation of pleural effusion or ascites, with decreased ventral lung sounds or abdominal distention, respectively. Jugular distention or pulsation should be visible in patients with right heart failure. An S_3 gallop sound may be detected with careful auscultation at the left sternal border in a patient with severe valvular disease.[8] Femoral pulses usually are strong until late in the course of the disease unless acute chordal or left atrial rupture occurs. With left atrial rupture, patients demonstrate symptoms of cardiac tamponade (see Chapter 43, Cardiac Tamponade and Pericardiocentesis).

39.6 LABORATORY EVALUATION

Laboratory findings for patients with MVD often are nonspecific. The complete blood count may be normal or may demonstrate a normochromic, normocytic nonregenerative anemia. A stress leukogram (neutrophilia, monocytosis, lymphopenia, eosinopenia) frequently is present in patients with congestive heart failure. The biochemical profile may be normal or may demonstrate abnormalities consistent with other diseases of aged patients (e.g., chronic renal failure, hepatopathies). Blood gas analysis may reveal varying degrees of hypoxemia with metabolic acidosis secondary to peripheral vasoconstriction and poor perfusion (lactic acidosis).

Research has identified several biochemical markers that may aid in the assessment of the patient with heart failure. The concentration of natriuretic peptides (ANP, BNP) is known to increase in congestive heart failure (CHF), and several studies have demonstrated that these hormones are sensitive and specific in differentiating patients with cardiogenic edema from those with dyspnea of other causes.[14] Human “bedside” analyzers for B-type natriuretic peptide are available and may eventually be included in the veterinary emergency hospital laboratory. Cardiac troponins (particularly cardiac troponin I, or cTnI) have also been investigated as blood-based biomarkers for heart disease in dogs and may be clinically applicable in the future for patients with MVD.[15,16]

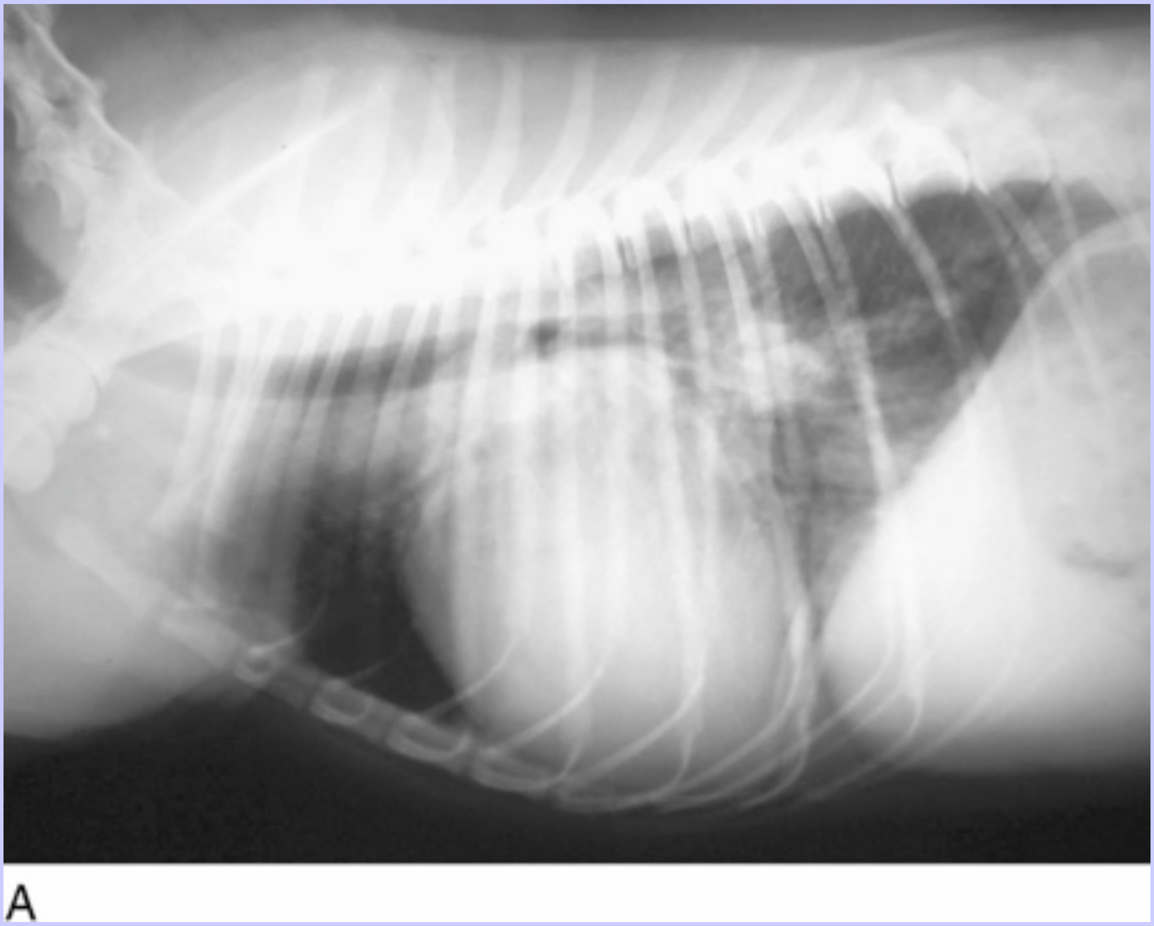
39.7 ELECTROCARDIOGRAPHIC FINDINGS

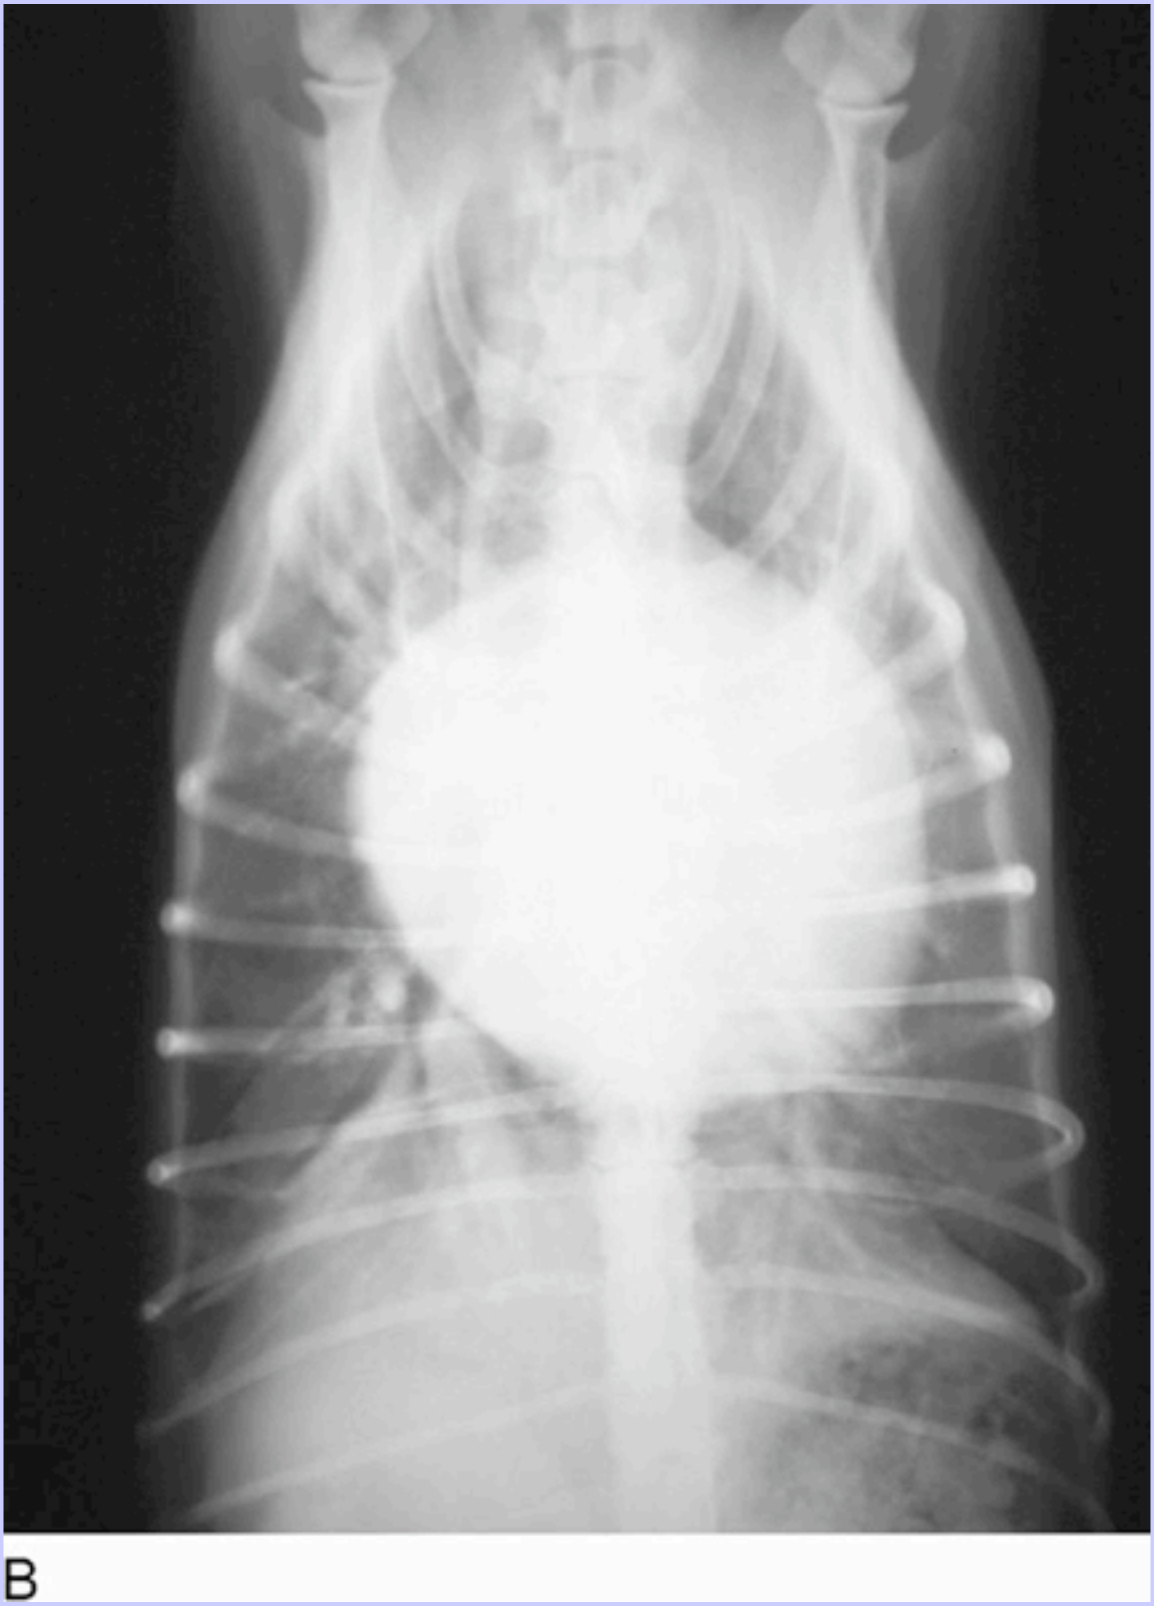
The electrocardiogram is not a sensitive or specific diagnostic test for MVD. However, it should be performed in any patient with an arrhythmia or tachycardia. The most common rhythm changes seen in patients with MVD are sinus tachycardia, atrial premature contractions, and atrial fibrillation. Ventricular ectopy is unusual in the typical small breed dog with MVD but may occur with hypoxia, other organ system failure, or in large breeds. Other abnormalities that may be identified in canine patients include P mitrale (P wave width >40 msec), P pulmonale (P wave height >0.5 mV), or evidence of left ventricular enlargement (R wave amplitude >2.5 mV or duration >60 msec). Severe cardiac disease may be present with normal electrocardiographic findings, and the absence of these electrocardiographic changes should not be interpreted by the clinician as an indicator of normal cardiac chamber size or function.

39.8 RADIOGRAPHIC FINDINGS

The radiographic findings in canine patients with MVD and congestive heart failure CHF are illustrated in Figures 39-1 and 39-2. Left-sided heart enlargement is apparent as loss of the caudal cardiac waist (left atrial enlargement) and a tall cardiac silhouette (left ventricular enlargement). These changes result in dorsal deviation of the trachea and carina. Pulmonary venous congestion may be evident in the cranial lobar vessels on the lateral projection and the caudal lobar veins on the orthogonal projection. Dorsoventral positioning provides better visualization of the caudal pulmonary vasculature and is less stressful for the dyspneic patient than ventrodorsal positioning. Ventrodorsal positioning should be used in patients with pleural effusion for better visualization of the heart and accessory lung lobe.[17] In patients with significant tricuspid regurgitation, the heart may have changes consistent with right-sided heart enlargement (reverse “D” on dorsoventral films, increased sternal contact on lateral films). Frequently patients with advanced valvular disease will have global or generalized cardiomegaly. Pulmonary edema in the dog initially is identified as a mild, perihilar or central interstitial infiltrate. As the severity of the infiltrates increases in canine patients, they generally progress in a caudal and dorsal distribution but may be multifocal. In cases with right-sided heart failure or biventricular disease, pleural fissure lines or overt effusion may be visible and there may be a loss of serosal detail in the cranial abdomen.

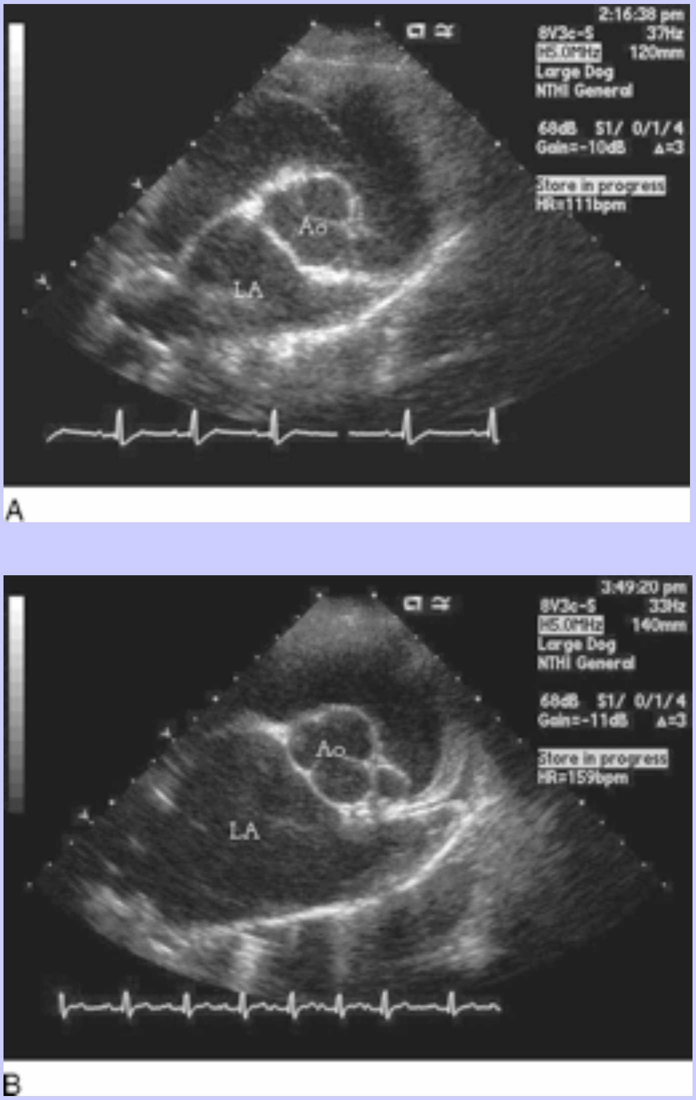
Figure 39-1 Right lateral **(A)** and dorsoventral **(B)** radiographs of a dog with myxomatous valvular degeneration and severe mitral regurgitation. **A,** Severe left-sided heart enlargement is visible as an increase in overall heart size (vertebral heart score 13.0) with a tall cardiac silhouette (left ventricular enlargement) and loss of the caudal cardiac waist (left atrial enlargement). Pulmonary venous distention is visible (cranial lobar veins), and there is a hilar and caudal pulmonary interstitial pattern. The liver is enlarged. **B,** Severe generalized cardiomegaly is present with an enlarged left atrium. The pulmonary vasculature is prominent (caution must be taken in interpreting venous distention in the right caudal lobar veins because of the caudal vena cava). An interstitial pattern is visible in the caudal lung fields.





B

Figure 39-2 Right parasternal short-axis echocardiographic views of the aorta and left atrium in a normal dog **(A)** and a dog with myxomatous valve disease **(B).** The ratio of the cross-sectional dimensions of the left atrium and aorta *(LA/Ao)* should be ≤1.5 in normal dogs. In *B,* severe left atrial enlargement is present with an LA/Ao >2.0, suggestive of severe mitral regurgitation and elevated left atrial pressure. In the emergency setting, this finding may be used to support a diagnosis of congestive heart failure. The patient in *B* also has a small volume of pericardial effusion delineating the borders of the left auricle and the right ventricular outflow tract.



39.9 ECHOCARDIOGRAPHIC FINDINGS

Although echocardiography is not essential in generating an emergency medical treatment plan for patients with valvular disease, ultrasound machines are being used increasingly in the emergency setting. Echocardiography can help gauge disease severity, identify ruptured chordae tendineae, quantify pleural or pericardial effusion, confirm the diagnosis when radiographs are inconclusive, and guide therapy (i.e., thoracentesis). The classic findings in a patient with MVD affecting the mitral valve include left ventricular and left atrial dilation, hyperdynamic left ventricular wall motion, and thickened mitral valve leaflets. For the emergency veterinarian, evaluation of left atrial size is the easiest assessment and has been reviewed elsewhere.[18] In general, patients in left heart failure secondary to MVD will have a left atrium-to-aorta ratio ≥2.0 (see Figure 39-2). If this criterion is not met, other diagnoses should be considered for interstitial pulmonary infiltrates (pulmonary hypertension or thromboembolism, primary lung diseases). Other echocardiographic findings that may be identified include valve prolapse, leaflet flail (protrusion of the leaflet margin into the atrium during systole), and ruptured chordae tendineae. If available, color and spectral Doppler evaluation can confirm valve insufficiencies and offer subjective information regarding the severity of the regurgitant lesion. In patients with left atrial rupture, pericardial effusion and a pericardial thrombus may be identified. Although M-mode and spectral Doppler echocardiography offer many techniques for evaluating cardiac function in patients with MVD, these techniques are highly dependent on sonographer experience and are beyond the scope of this text. The reader is referred to other texts for descriptions of these techniques.[3,6]

39.10 EMERGENCY MANAGEMENT

As with any cause of heart failure, ideal therapy would be to reverse or correct the underlying disease. Although this is not possible in the emergency setting for a patient with MVD, several hemodynamic variables can be manipulated to improve cardiovascular function and relieve clinical signs. The goals of emergency therapy for the patient in heart failure secondary to MVD are to relieve signs of congestion, improve forward cardiac output, and improve tissue oxygenation and nutrient delivery.

39.10.1 Congestive Signs

Congestive signs can be relieved by reducing the hydrostatic pressure in the pulmonary or systemic venous system. This may be accomplished by reducing circulating volume or by venodilation. Relief of congestion usually is accomplished with diuretics to decrease intravascular volume. Furosemide is used most frequently (2 to 8 mg/kg in dogs or 1 to 4 mg/kg in cats IM or IV). A dosage-dependent venodilator effect has been observed with intravenous administration in humans.[19] A protocol for constant rate infusion of furosemide has been investigated in normal dogs and is more effective than intermittent bolus injection.[20] Other loop diuretics (bumetanide) may have greater potency but are not widely used in veterinary medicine. Oral diuretics are not ideal because of the likelihood of impaired gastrointestinal absorption and a relatively slow onset of action. In patients with refractory edema, moderate restriction of fluid intake may also be helpful in reducing congestive signs. Side effects of diuretic therapy include prerenal azotemia, electrolyte disturbances (hypokalemia, hyponatremia, others), and acid-base derangements (metabolic alkalosis). Overzealous administration of diuretics or restriction of fluids can result in uremia, dangerous reductions in circulating plasma volume, and poor tissue perfusion.

Vasodilators are not universally effective in veterinary patients, and their use should be considered adjunctive to diuretic therapy or oxygen administration. Topical nitroglycerin ointment (⅛ to ¼ inch q6h on the inner pinnae) is used most frequently. This modality increases venous capacitance in normal dogs,[21] but oral nitrates have minimal effect in normal dogs or dogs with CHF.[22]

39.10.2 Cardiac Output

Arterial vasodilators are helpful in reducing regurgitant fraction and increase forward cardiac output. Hydralazine (0.5 to 2.5 mg/kg PO q12h) has been advocated in this setting for patients with refractory heart failure.[3] Side effects of this therapy include emesis and hypotension. Amlodipine (0.2 to 0.4 mg/kg PO q12h) may also be useful and generally has fewer side effects than hydralazine. Enalapril is not a potent vasodilator in dogs and cats and generally is not recommended for emergency management of CHF. More aggressive approaches for improving forward cardiac output can be employed using an intravenous vasodilator in conjunction with a positive inotrope. This combination should be used only in settings where invasive blood pressure monitoring is available. Intravenous nitroprusside (1 to 2 μg/kg/min titrated upward to a target blood pressure) can be administered alone or in conjunction with either dopamine or dobutamine (2.5 to 10 μg/kg/min) to improve forward cardiac output and reduce capillary hydrostatic pressure. Arterial pressures should be maintained above 80 mm Hg (mean) with this regimen and can be adjusted quickly because of the short half-life of these medications. Potential complications of this therapy include severe hypotension and cyanide toxicity (with expired solutions or ≥3 days after mixing). Oral positive inotropic agents rarely are used in the emergency setting. Digoxin and other digitalis glycosides have a long half-life that limits their usefulness for acute therapy. This can be overcome with intravenous administration or oral drug loading, but these approaches may result in toxicity (see Chapters 85 and 189, Digoxin Overdose and Digoxin, respectively). Pimobendan is a new phosphodiesterase inhibitor with both positive inotropic and vasodilatory properties that has significant benefits in the management of CHF.[23,24] This drug recently has been approved for use in the United States, with a recommended oral dosage of 0.1 to 0.3 mg/kg PO q12h.

39.10.3 Tissue Oxygenation

Oxygen therapy should be considered essential for the patient in heart failure from any cause. Increasing the fraction of inspired oxygen will help improve blood oxygen content, but the impaired pulmonary function caused by edema necessitates that oxygen be used in conjunction with the therapies described above. Detailed guidelines for administration of oxygen are given elsewhere in this text (see Chapter 19, Oxygen Therapy).

39.10.4 Arrhythmia Management

Arrhythmias may be present in patients with MVD and complicate medical management. Isolated atrial or ventricular premature contractions rarely require therapy, but atrial fibrillation and ventricular or supraventricular tachycardia should be identified and addressed. These frequently result in a rapid heart rate that decreases diastolic filling and affects forward cardiac output. Tachyarrhythmias may also decrease systolic function and result in myocardial failure if they are chronic (tachycardia-induced cardiomyopathy). Pharmacologic management of these arrhythmias is discussed elsewhere in this text (see Chapters 46 and 47, Supraventricular Tachyarrhythmias and Ventricular Tachyarrhythmias, respectively). Direct current cardioversion may be employed for rhythms that are refractory to medical management (see Chapter 53, Cardioversion and Defibrillation).

39.10.5 Monitoring

Successful treatment of a patient with CHF from MVD requires monitoring of volume status, renal function, acid-base balance, and blood pressure. When patients are admitted in an emergency setting, a complete blood count, biochemical profile, urine specific gravity and thoracic radiographs should be obtained before initiation of therapy (condition permitting). Twelve to 24 hours after initiation of therapy, a blood gas analysis, biochemical profile with electrolytes, and thoracic radiographs should be repeated. If a patient develops significant azotemia (blood urea nitrogen >50 mg/dl, creatinine ≥2.5 mg/dl), dehydration, alkalosis, or electrolyte disturbances, diuretic therapy should be modified and alternative modalities employed.

39.11 LONG-TERM THERAPY

In general, the goals of long-term therapy for MVD mirror those of the emergency setting but with orally administered medications. The precise timing for initiation of therapy before the onset of CHF is a subject of much debate because clinical trials have demonstrated variable results with the early use of angiotensin-converting enzyme (ACE) inhibitors.[29,30] The initial treatment of patients with MVD and CHF should include a diuretic at the lowest effective dosage and an ACE inhibitor. A balanced low-salt diet should also play an integral role in the management of a patient's congestion and may reduce the dosage of diuretics required to control signs of edema. As heart failure progresses or complications such as atrial arrhythmias or systolic dysfunction develop, digoxin is often added to this regimen. Adjunctive therapies (potassium gluconate and cough suppressants) are used on a case-by-case basis. When patients develop edema that is refractory to this therapy, additional diuretics (spironolactone), positive inotropic agents (pimobendan where available), and vasodilators (amlodipine, hydralazine) are used in various combinations depending on the patient's coexisting disease states, ventricular function, and tolerance of therapy. For patients whose disease is refractory to medical therapy, surgical intervention is a newer therapeutic modality that is offered at selected teaching institutions.[25-27]

39.12 PROGNOSIS

In general, MVD carries a more favorable prognosis than many other cardiovascular diseases. The condition has a long (1 to 2 years) preclinical phase when patients have an excellent quality of life with few clinical signs. When CHF signs develop, the prognosis worsens. Medical therapy may offer patients the possibility of approximately 1 year of good-quality life after the onset of CHF.[28] Patients with ruptured major chordae tendineae or a ruptured left atrium have a poor or grave prognosis. When patients decompensate while receiving long-term oral medications, aggressive parenteral therapy can still offer the possibility of partial recovery and return to life at home with oral medication.

39.13 INFECTIOUS ENDOCARDITIS

This condition is presented here because of the similar hemodynamic changes that develop with valve regurgitation caused by vegetative lesions, but the condition is not typically associated with MVD. With the exception of one case report,[31] no published data are available that would suggest that MVD predisposes dogs to bacterial endocarditis. For detailed descriptions of this disease the reader is referred to other texts.[32,33]

Bacterial infection of valvular structures in the heart is a rare cause of CHF in domestic animals. In dogs and cats, the aortic and mitral valves are affected most frequently, and the tricuspid and pulmonic valves are rarely affected.

The condition is identified rarely in the cat and infrequently in the dog, and large breed males are overrepresented. The most common causative agents in the dog include *Staphylococcus* spp, *Streptococcus* spp, and *Escherichia coli,* although many more agents have been identified. *Bartonella* species are emerging as important causes of culture-negative endocarditis in dogs and humans.[34] Physical examination findings may mimic those of a patient with degenerative valve disease, but a spectrum of other clinical findings should alert the clinician to the possibility of vegetative endocarditis: fever, hemogram results consistent with sepsis, coagulopathies, lameness, and evidence of multiorgan involvement or failure (septic emboli). Secondary immune-mediated disorders (e.g., glomerulonephritis) are also common sequelae. A portal of entry for the bacteria is not often identified, and other predisposing factors (e.g., indwelling catheters) should be considered for patients with endocarditis. Patients with endocarditis frequently have acute valvular regurgitation, and the classic radiographic appearance of the heart in a patient with MVD may not necessarily be present. Echocardiography plays a more important role in the management of vegetative endocarditis than of MVD by confirming the presence of vegetative lesions, characterizing the severity of the valve damage, and offering a prognosis. Definitive diagnosis is often elusive, and criteria have been defined to help remedy this problem. Management of patients with vegetative endocarditis should include an effort to identify the causative agent (blood cultures, urine culture, and culture of open wounds or indwelling catheters), culture and sensitivity–directed intravenous antibiotic therapy, and supportive care for other organ systems that may be affected by septic embolization. If sensitivity data are not available, broad-spectrum intravenous antibiotics should be used. Frequently antibiotics are required for long periods (>6 weeks). Therapy for CHF should be identical to that described for other types of valvular heart disease discussed in this chapter and elsewhere.

40 Chapter 40 Myocardial Contusion

Adam J. Reiss, DVM, DACVECC

40.1 KEY POINTS

- Myocardial injuries often are overlooked in the trauma patient.
- The most common physiologic consequence of myocardial injury in dogs and humans is arrhythmias.
- Arrhythmias associated with myocardial injury may be delayed in onset up to 48 hours.
- Holter monitoring or continuous electrocardiographic (ECG) monitoring should be considered in high-risk patients.
- Troponins, cardiac-specific proteins, are an effective biomarker of myocardial injury in dogs.
- Normal ECG findings and cardiac troponin I levels on admission in traumatized human patients are an efficient way to rule out myocardial injuries and arrhythmias associated with trauma.
- Management of myocardial injuries is aimed toward maintaining optimal cardiac output and suppressing life-threatening arrhythmias.
- The class I antiarrhythmic agents, including lidocaine and procainamide, are used commonly to manage ventricular ectopy associated with myocardial injury.

40.2 INTRODUCTION

Traumatic myocarditis is a controversial subject. Much of the controversy in human studies revolves around a lack of consistent evidence that this injury has any effect on patient outcome and the expense associated with diagnostic testing, cardiac monitoring, and prolonged hospital stays.[1] Additional controversies associated with this injury revolve around its name, incidence, and how it is diagnosed. What appears to be agreed on consistently in the literature is the basic definition of this injury and that there is lack of an antemortem diagnostic gold standard. Direct visualization of the heart or histologic examination of damaged myocardium are considered the current diagnostic gold standard.[2]

The term *traumatic myocarditis* has been used frequently in veterinary literature to describe an assumed myocardial injury associated with arrhythmias in patients suffering from blunt thoracic trauma.[3] This term is used interchangeably with myocardial injury in this chapter.

40.3 INCIDENCE

Blunt thoracic trauma has been reported to result in myocardial injuries in 8% to 95% of human patients.[3-10] Reported variations in the frequency of myocardial injuries of dogs are similar to those described in humans. Several studies (three prospective, two retrospective) have examined the prevalence of traumatic myocarditis in the dog and report a range from 10% to 96%.[4,11-14] Variations in study design as well as disagreements regarding terminology, diagnostic modalities, and criteria used to identify myocardial injuries in humans and dogs contribute to the wide range in the reported frequency of this type of injury in both the human and veterinary literature.[2,3,7,13-21] The authors of these studies do agree, however, that myocardial injuries are easily overlooked.[18]

[*] References 2, 3, 7, 13–17, 20, 21.

40.4 ETIOLOGY, MECHANISM OF INJURY, AND PATHOPHYSIOLOGY

Thoracic trauma is common in dogs injured by automobiles, animal attacks (bites, kicks), and falls from a height.[2,3,11-13,19-21] Because of the elastic nature of the thoracic cage, blunt trauma may subject the myocardium to compressive and concussive forces.[13,14,22-24] The most common mechanism of myocardial injury in the dog is that secondary to lateral chest compression.[22,24] In addition to potential concussive injury from forceful contact with the ribs, sternum, and vertebrae when rapid acceleration or deceleration occurs, it has been proposed that distortion of the thoracic cage results in a rise in intrathoracic and intracardiac pressures, causing shearing stresses within the myocardium powerful enough to result in contusions.[6]

In vivo studies performed in dogs to mimic blunt chest trauma have correlated histopathologic areas of myocardial injury with areas of injury found during echocardiographic examination. Experimental trauma delivered to the left side of the chest resulted in abnormalities that were located primarily in the craniolateral wall of the left ventricle, and right-sided chest trauma produced septal and right ventricular wall damage.[6]

Gross pathologic findings in the traumatized heart have been characterized by localized edema, ecchymosis, and intramyocardial hematoma formation. Myocardial injuries were often transmural, with the epicardial surface being more severely affected.[6]

Arrhythmias and conduction defects are the most commonly reported consequences of myocardial injuries in humans and dogs.[7,11,22-27] One proposed proarrhythmic mechanism of myocyte trauma is the lowering of the ratio of effective refractory period to action potential duration and an increase in the resting membrane potential (less negative) in damaged myocardial cells. Additionally it is proposed that myocyte injury results in alterations of sodium and calcium currents across cell membranes, increasing the availability of intracellular calcium, resulting in increased sensitivity to depolarization.[3] These proposed intracellular derangements secondary to trauma can 171 potentiate 172 arrhythmogenesis.[3] Arrhythmias become apparent when the injured myocardium becomes the site of the most rapid impulse formation, overcoming the sinus node as the dominant (overdrive) pacemaker. The injured myocardium becomes the new overdrive pacemaker, propagating the arrhythmia by depolarizing the sinus node before it has a chance to fire and recapture the cardiac rhythm.[3]

Isolated rabbit hearts have been subjected to injury during high-resolution mapping of epicardial excitation to identify the origin of arrhythmias in injured myocardium. The results of this study identified reentry as the mechanism of arrhythmia due to myocardial contusion. The authors found that the site of impact became electrically silent (temporarily), resulting in a fixed and functional conduction block that caused reentry initiation.[28]

Traumatized patients may also develop arrhythmias associated with metabolic acidosis, hypoxia, electrolyte imbalance, intracranial injuries, and catecholamine release.[23,25-27,29] These physiologic aberrations all promote alterations in membrane transport and permeability of cations (sodium, potassium, and calcium), which lead to a decrease in resting membrane potential, as described earlier, contributing to aberrant depolarization and arrhythmias.[3,23,25]

The most frequently reported arrhythmias secondary to canine myocardial injuries include premature ventricular contractions, ventricular tachycardia, and nonspecific ST segment elevation or depression.[6,22-27,29] Less commonly reported arrhythmias reported in dogs with chest trauma include atrial fibrillation, sinus arrest with ventricular or junctional escape complexes, and second-degree and third-degree atrioventricular block.[7,12,22,27]

40.5 DIAGNOSIS

Although uncommonly performed in the live patient, gross or histologic examination of the heart remains the diagnostic gold standard for myocardial contusions.[2,17,30] Because of the impracticality of visualizing the heart or performing myocardial biopsy, an understanding of the mechanism of injury, an awareness of associated injuries, and a high index of suspicion for myocardial injury are essential in making a diagnosis.[10] Emergency clinicians should consider myocardial injury in all traumatized dogs that have the following injuries: (1) fractures of extremities, spine, or pelvis, (2) external evidence of thoracic trauma, (3) radiographic evidence of chest trauma such as pulmonary contusions, pneumothorax, hemothorax, diaphragmatic rupture, and rib or scapular fractures, and (4) neurologic injury.*

Dogs with any of these injuries should have a lead II electrocardiograph (ECG) performed and, depending on the patient's condition and the clinician's index of suspicion, the ECG should be repeated intermittently (i.e., every 2 to 24 hours). ECG abnormalities commonly are delayed in onset for up to 48 hours after blunt chest trauma, so in cases in which there is a high index of suspicion for myocardial injury ECG monitoring should be considered for that time frame.[22,23,25] Holter monitoring is the most sensitive and least invasive indicator of arrhythmias in dogs with suspected myocardial injuries. However, the lack of immediate Holter interpretation (rapid turnaround time) may limit the practical application of this modality for veterinarians.[12] Other forms of continuous ECG monitoring, such as single patient monitors and telemetry, would likely provide a similar advantage over intermittent ECGs without the delays in interpretation encountered with Holter monitoring.[18]

An echocardiogram should be considered in severely traumatized dogs with a poor response to resuscitative efforts and evidence of thoracic injuries even if no ECG abnormalities are present. Transthoracic echocardiography in the dog can be used to identify and localize both structural and functional abnormalities of injured myocardium due to blunt chest trauma. The echocardiographic features of myocardial injuries in the dog include (1) increased end-diastolic wall thickness, (2) impaired contractility, indicated by wall motion abnormalities and decreased fractional shortening, (3) increased echogenicity, and (4) localized areas of echolucency consistent with intramural hematomas.[6]

Serum myocardial isoenzyme analysis (cardiac troponins T and I [cTnT and cTnI]) has been used to diagnose myocardial injury in dogs and humans. The skeletal isoforms of the troponin proteins expressed are different from those in cardiac muscle.[19,31] The troponin structure is highly conserved across many differing species, allowing for veterinary application of tests currently in use at human care facilities.[32]

Troponin testing is based on immunologic detection of the cardiac-specific isoforms of troponin T and troponin I.[31] In both human and dogs, detectable levels appear in the circulation within 4 to 6 hours of cardiac myocyte injury, and serum elevations may be present for up to 7 days.[7,19,32] In a comparison of multiple myocardial enzyme and protein markers and ECG to detect myocardial injury in traumatized dogs, cTnI was the most sensitive indicator of this type of injury.[2] One of the most important findings of the many human studies investigating the clinical use of cardiac troponins appears to be the negative predictive values for cardiac complications in trauma patients. In human trauma patients a normal cTnI level in combination with a normal ECG tracing on arrival has a negative predictive value of 100% for myocardial injuries, allowing these patients to avoid intensive cardiac monitoring and even be discharged safely in the absence of other significant injuries.[33] Because of the controversies and difficulty diagnosing myocardial injuries in dogs, veterinarians should consider using these two tests to rule out this disease in a quick and practical manner. Although there are no studies confirming this hypothesis in dogs, clinicians could consider performing a baseline ECG and cTnI measurement within 4 hours of injury. Extrapolating from human findings, dogs with a combination of normal ECG findings and cTnI levels (normal <0.03 to 0.07 ng/ml[34]) would be less likely to develop arrhythmias and therefore would not require intensive cardiac monitoring. A positive finding on either test would suggest the possibility of myocardial injury and would indicate continuous ECG monitoring in those dogs.

* References 2, 12, 22, 25, 29, 30.

40.6 TREATMENT

Treatment of myocardial injuries typically is aimed at suppressing potentially life-threatening arrhythmias and maintaining adequate tissue perfusion.[30] Antiarrhythmic therapy is not recommended if arterial pulse quality is good and synchronous on auscultation, mean arterial pressure is higher than 75 mm Hg, mucous membranes are pink, capillary refill time is 2 seconds or less, and the patient has no clinical signs of weakness or cardiopulmonary distress.[30] Antiarrhythmic therapy should be considered when properly stabilized patients (i.e., received adequate fluids, electrolytes, oxygen, pain control) develop arrhythmias such as multiform premature ventricular complexes, ventricular tachycardia, and the R-on-T phenomenon.[23,26,27,30] Treatment is imperative when arrhythmias are accompanied by clinical evidence of decreased cardiac output such as hypotension, weakness, pale mucous membranes, delayed capillary refill time, collapse, or syncope.[23,26,30] Additionally, treatment is indicated when an arrhythmia has a sustained (>15 to 30 seconds) ventricular rate that exceeds 140 to 180 beats/min in the dog.[12,23,26]

Lidocaine (2 mg/kg IV bolus) is the agent of choice for traumatized dogs suffering from ventricular ectopy fulfilling the criteria described in the previous paragraph.[30] Intravenous boluses of lidocaine may be repeated every 10 to 20 minutes until a cumulative dose of 8 mg/kg is given. A constant rate infusion (CRI) of 40 to 80 μg/kg/min may be initiated to maintain a cardiac rate and rhythm that provides appropriate tissue perfusion.[23,30] Additional boluses of lidocaine are often required to suppress arrhythmias while steady-state blood levels are achieved by the CRI. The upper end of the recommended dosages of lidocaine may cause vomiting or seizures, so administration should be slowed or temporarily discontinued if these signs develop.[23,30,35]

If lidocaine does not resolve ventricular ectopy, procainamide may be administered intravenously or intramuscularly (6 to 15 mg/kg q4-6h).[23,30] If repeated boluses of procainamide are required to suppress arrhythmias, a CRI (10 to 40 μg/kg/min) may be started. Oral procainamide (sustained release formulation 20 mg/kg q8h) may be initiated if continued management is required and oral medications can be tolerated. Potential side effects of procainamide administration include hypotension and atrioventricular conduction block.[23,35] Additional oral arrhythmia management options include tocainide (10 to 20 mg/kg PO q8-12h) and mexiletine (4 to 8 mg/kg PO q8h).[23] The reported side effects of tocainide include nausea, vomiting, and anorexia; although less frequently observed, complications associated with mexiletine include excitement or depression.[35]

β-Blockers (propranolol, metoprolol, atenolol, sotalol) should be considered cautiously when traumatized dogs with ventricular ectopy are unresponsive to class I antiarrhythmic agents, have been treated appropriately for shock and pain, and are not receiving positive inotropic medications.[30,35] An ultrashort-acting intravenous β-blocker, such as esmolol, may be used to test the efficacy of β-blockers in managing ventricular arrhythmias that have not responded to other medications.[26] The potential for serious side effects such as atrioventricular block, hypotension, bronchoconstriction, and decreased cardiac contractility must be considered when using β-blockers. [23,35]

Arrhythmias secondary to myocardial trauma that do not fulfill the stated guidelines for management are likely to be self-limiting and resolve within 3 to 10 days.[30] The end point of therapy is not necessarily complete resolution of the arrhythmia; appropriate therapeutic response includes reduction of the heart rate (<140 beats/min) and the return of adequate tissue perfusion.[30] In most cases antiarrhythmic therapy can be discontinued within 48 to 72 hours; however, it is recommended that intermittent ECG monitoring continue up to 1 week after discharge.[30] Medications being used to suppress arrhythmias should be discontinued a minimum of 24 hours before reexamination.[30] The most sensitive way to detect complete resolution of arrhythmias after discontinuing antiarrhythmic medications is continuous ECG (Holter) monitoring.[12] If some form of continuous monitoring is not available, intermittent lead II ECG monitoring can be performed to ensure that the arrhythmia has resolved and it is safe to discontinue therapy. If the arrhythmia persists, long-term oral therapy may be initiated.[30]

If a dog with a suspected myocardial injury must undergo anesthesia, agents that are least likely to induce arrhythmias, such as acepromazine, butorphanol, isoflurane, and glycopyrrolate, should be used.[3,23] Halothane, atropine sulfate, and the thiobarbiturates should be avoided because they are reported to exacerbate arrhythmias and to sensitize the heart to catecholamine-induced arrhythmias.[23,25]

40.7 SUMMARY

Although myocardial injuries may cause significant alterations in cardiac function in the traumatized dog, they are often overlooked in the face of severe trauma. Ventricular arrhythmias are the most common abnormalities caused by blunt myocardial injury. Although ECG monitoring traditionally has been used to diagnose myocardial injuries, the onset of arrhythmias associated with these injuries is often delayed, making recognition difficult. Arrhythmias may be secondary to alterations in transport of cations, such as calcium, potassium, and sodium, across the membranes of injured myocytes, resulting in a decrease of resting membrane potential, aberrant firing of injured cells, and loss of organized myocyte depolarization or reentry mechanisms.

The medical community has yet to provide a prospective study that investigates the need for therapeutic intervention of traumatic myocardial injuries in humans or dogs. Although newer noninvasive tests for myocardial injuries such as troponin levels may assist in diagnosing these injuries, they have not yet proven to be the single noninvasive diagnostic modality to detect myocardial injury.[18] In the real world of veterinary practice, continuous ECG monitoring has been shown to be a sensitive, noninvasive indicator of arrhythmias in traumatized dogs and should be considered in dogs with suspected myocardial injuries.[12]

A human study may have inadvertently stumbled upon an approach that makes more sense than those previously discussed, ruling out this disease rather than ruling it in. This study showed that in traumatized patients a combination of normal ECG and cTnI findings on admission had a 100% negative predictive value for cardiac complications, meaning that none of the patients with these test results developed arrhythmias requiring intervention.[33] These findings may be helpful in determining the need for continuous ECG monitoring in canine patients with suspected myocardial trauma and should be considered for further investigation in dogs.

41 Chapter 41 Myocardial Infarction

C. Kate Meier, DVM

Mark A. Oyama, DVM, DACVIM (Cardiology)

41.1 KEY POINTS

- Myocardial infarction is relatively uncommon in small animal patients.
- Myocardial infarction can be associated with primary cardiovascular disease or can be secondary to other systemic disease processes.
- Antemortem diagnosis is challenging and is based on certain clinical pathologic derangements and electrocardiographic (ECG) and echocardiographic changes.
- Management is largely supportive to help maintain cardiac perfusion, suppress arrhythmias, and manage the underlying causes of the infarction or ischemia.

41.2 INTRODUCTION

Myocardial infarction is the end result of either acute or chronic myocardial ischemia. Myocardial ischemia differs slightly from myocardial hypoxia in that ischemia results in a stasis of waste products of cellular metabolism in addition to a lack of oxygen delivery, leading to cellular damage above and beyond that from hypoxemia.[1] Myocardial infarction is a pathologic diagnosis and, depending on whether it is acute or chronic, is characterized by loss of normal cardiac myocyte structure (i.e., myocytolysis, coagulative necrosis, inflammatory cell infiltration, and fibrosis). Myocardial infarction has a host of causes and is a leading cause of cardiovascular disease and death in humans.[2] The vast majority of myocardial infarction in people stems from coronary artery disease and atherosclerosis, both of which are relatively uncommon in the veterinary patient population. In dogs, collateral circulation of the coronary arterial supply is relatively extensive,[1] so the probability of irreversible myocardial ischemia from any one coronary arterial occlusion may be lower in this species.

The clinical manifestations of myocardial ischemia and infarction in veterinary patients can range from nonspecific symptoms to severe life-threatening arrhythmias and congestive heart failure. Thus, clinical suspicion of myocardial infarction should lead to aggressive management and supportive care. Prognosis depends on the severity of clinical signs, presence of concurrent disease, and response to initial therapy.

41.3 ASSOCIATED DISEASE PROCESSES

Multiple extracardiac disease processes have been associated with myocardial infarction in dogs and cats. In theory, any disease that induces a hypercoagulable state or thromboembolic complications can increase the risk of myocardial infarction. These include, but are not limited to, neoplasia, immune-mediated hemolytic anemia, trauma, heatstroke, loss of antithrombin III through renal or gastrointestinal disease, excess circulating corticosteroids (exogenous or endogenous), systemic inflammatory response syndrome, and sepsis. Atherosclerosis, a primary risk factor for infarction in humans, has been documented in dogs with hypothyroidism and diabetes mellitus.[3,4] In one study of 21 dogs with pathologically confirmed atherosclerosis, all had disease of the coronary arteries as well as fibrotic changes in the myocardium.[3] In another study, 20 of 30 dogs with atherosclerosis had coronary artery involvement.[4] Not all dogs with coronary atherosclerosis had clinical signs suggestive of cardiovascular disease, and of seven dogs that had ECG monitoring, only four had abnormalities.[3] This suggests that not all myocardial infarctions are clinically apparent.

Myocardial infarction can also be associated with primary cardiovascular disease. Bacterial endocarditis has been associated with myocardial infarction because emboli are showered from an infected valve and may lodge in the coronary arterial circulation.[5,6] Feline hypertrophic cardiomyopathy can lead to myocardial infarction through several different mechanisms. First, an increased oxygen demand of the hypertrophied ventricle can lead to chronic myocardial ischemia, especially in the endocardium. It has been hypothesized that this myocardial ischemia or infarction may lead to fatal ventricular arrhythmias and sudden death in some cats with hypertrophic cardiomyopathy. Second, decreased oxygen delivery to the hypertrophied ventricle results in proliferative remodeling of the coronary arterioles and obliteration of the vessel lumen.[7,8] Furthermore, cats with hypertrophic cardiomyopathy develop diastolic dysfunction, which leads to elevated left ventricular filling pressures and eventual left atrial dilation. It is thought that left atrial dilation, via altered hemodynamics and blood pooling, is a predisposing factor for thrombus formation, and this may lead to microthrombi that embolize to the coronary circulation, and result in myocardial infarction. Lastly, cats with significant hypertrophic cardiomyopathy may be persistently tachycardic, and as the ratio of time spent in systole versus diastole increases, diastolic flow into the coronary circulation is impaired, leading to myocardial hypoxia. Dogs with subaortic and pulmonic stenosis are thought to be at higher risk for myocardial infarction for reasons similar to those in cats with hypertrophic cardiomyopathy.[9-11] Dogs with cardiac neoplasia and chronic valvular disease also can have myocardial infarction.[11,12]

41.4 HISTORY AND CLINICAL SIGNS

Clinical signs in dogs and cats with myocardial infarction range from nonspecific to sudden death.[13] In one study, the most common initial signs in dogs and cats with histopathologically confirmed acute myocardial infarction were lethargy and inappetence.[14] In another study, 20% of dogs with infarctions experienced sudden death as the first manifestation.[15] The lack of specificity of clinical signs can make myocardial infarction difficult to diagnose. If present, more specific signs, such as dyspnea, collapse, and syncope, are largely attributable to and compatible with primary cardiac disease. These commonly are seen with many forms of nonischemic organic heart disease, so further investigation is necessary to evaluate specifically for myocardial infarction.

41.5 PHYSICAL EXAMINATION

The most commonly reported physical examination findings in dogs with myocardial infarction are dyspnea, tachycardia, arrhythmias, cardiac murmurs, and signs attributable to other concurrent systemic disease. Information is limited in cats; however, dyspnea and tachycardia have been reported. Dyspnea often is related to congestive heart failure (i.e., pulmonary edema or pleural effusion) or pulmonary thromboembolism. Arrhythmias can range from single premature supraventricular and ventricular beats to supraventricular tachycardias, atrial fibrillation, and ventricular tachycardia. The rhythm likely is determined by the location and extent of damaged myocardium. Murmurs, if present, probably arise from primary cardiac disease, rather than from myocardial infarction per se.

41.6 DIAGNOSTIC WORKUP

In veterinary patients, antemortem diagnosis of myocardial infarction is challenging because there are no established diagnostic criteria. The diagnostic workup typically includes diagnostic imaging in addition to clinicopathologic, and electrophysiologic tests. Clinicopathologic diagnostics include a complete blood count, serum chemistry panel, urinalysis, thyroxine level, coagulation panel, D-dimer levels, thromboelastography, and cardiac troponin I (cTnI) levels. Common derangements include elevated aspartate aminotransferase, alanine aminotransferase, creatine kinase, and cTnI values. Coagulation parameters outside of the reference ranges may increase the index of suspicion.

Because of a high degree of sensitivity and specificity, cTnI is considered a gold standard test in the diagnosis of myocardial infarction in humans. cTnI values above the 99% reference limit and accompanied by pathologic ECG changes or appropriate clinical signs (i.e., angina, syncope) are indicative of recent infarction.[16] In dogs with experimentally induced myocardial infarction, cTnI values are elevated dramatically, up to 150 times the upper reference range, and can remain up to 25 times the upper reference range for 4 days or longer.[17] Elevated cTnI values have been reported in normal dogs and cats, as well as in patients with a variety of naturally occurring heart diseases (i.e., dilated cardiomyopathy, hypertrophic cardiomyopathy, subaortic stenosis, mitral valve disease).[18-24] In many of these cases, mild elevations of cTnI likely reflect myocardial hypoxia and ischemia secondary to underlying disease, rather than myocardial infarction per se. We postulate that antemortem diagnosis of acute myocardial infarction in veterinary species would involve greatly elevated cTnI values detectable within 24 hours of the index event. In theory and in the absence of repeated infarction events, cTnI values should slowly decrease back toward baseline over several days to weeks. Additional clinical pathologic abnormalities associated with underlying disease processes, such as proteinuria and azotemia in animals with glomerular and tubular renal disease, or low thyroxine in dogs with hypothyroidism, may also be present.

An ECG should be performed in any animal in which myocardial infarction is suspected. The most common arrhythmia is sinus tachycardia, followed by ventricular tachycardia, atrial fibrillation, and ventricular premature complexes. Elevation or depression of the ST segment, prolonged QT interval, or T wave abnormalities may also suggest myocardial hypoxia or ischemia. Based on a very limited number of reports, ECG findings in cats may include ventricular premature complexes and atrial fibrillation.[14,25] As opposed to humans, strict ECG criteria for diagnosis of myocardial infarction in veterinary species do not exist.

Diagnostic imaging, including thoracic radiographs and echocardiography, should be performed in animals with suspected myocardial infarction. Thoracic radiographs may show cardiomegaly associated with primary cardiac disease. Signs of congestive heart failure may be present, including pulmonary venous congestion, pulmonary edema, or pleural effusion. Echocardiography can detect underlying cardiac disease that may predispose to myocardial infarction (i.e., hypertrophic cardiomyopathy, subaortic stenosis). Cardiac ultrasonography may detect regional or global hypokinesis, regional myocardial hyperechogenicity, poor systolic function, and cardiac chamber enlargement or aneurysms. Visualization of intracardiac thrombi heightens the suspicion for myocardial infarction. Confirmation of myocardial infarction is made postmortem via gross and histopathologic examination.

41.7 TREATMENT

Treatment of myocardial infarction is predominantly supportive. Control of arrhythmias with appropriate antiarrhythmic agents, diuresis for congestive heart failure, and oxygen therapy form the basis of treatment. 175 Administration of β-blockers and angiotensin-converting enzyme inhibitors is common in humans with acute 176 myocardial infarction and helps reduce myocardial oxygen demands and ameliorate pathologic remodeling. The benefit of these treatments in dogs and cats is unknown; however, β-blocker use should probably be limited to patients with adequate systolic function. In humans, the use of fibrinolytics, such as tissue plasminogen activator, is generally reserved for the acute period (within 12 hours after the primary event) and is accompanied by a small risk for cerebral hemorrhage and other bleeding complications (see Chapter 188, Thrombolytic Agents). Antiplatelet and antithrombin therapy with aspirin or heparin may be helpful, particularly in patients with intracardiac thrombi (see Chapter 187, Anticoagulants). Recognition and management of any underlying disease process are indicated, including thyroid supplementation for hypothyroid dogs, regulation of diabetes mellitus, and control of any systemic inflammation or disease that may be precipitating a hypercoagulable state.

41.8 PROGNOSIS

Prognosis for animals with severe acute myocardial infarction is poor. Because diagnosis is difficult, it is likely that myocardial infarction is an under recognized phenomenon in the veterinary patient population. The prognosis is largely dependent on the severity of clinical signs, the underlying disease process, and the response to therapy.

42 Chapter 42 Hypertensive Crisis

Scott Brown, VMD, PhD, Diplomate (ACVIM)

42.1 KEY POINTS

- Emergency antihypertensive therapy is indicated only when there is end-organ damage likely to produce significant permanent abnormalities without rapid lowering of blood pressure (BP).
- Diagnosis and management of hypertension must be based on measurement of the patient's BP following a standard protocol, and a thorough physical examination should be performed concurrently to assess end-organ damage.
- The primary goal of emergency antihypertensive therapy is to reduce the magnitude, severity, and likelihood of further end-organ damage.
- To resolve a hypertensive crisis, systolic BP should be lowered to 110 to 150 mm Hg, generally within 4 to 12 hours, using parenteral or oral pharmacologic agents.

42.2 RATIONALE FOR EMERGENCY MANAGEMENT

Elevations of systemic arterial BP can injure tissues, referred to as *end-organ damage*. The end organs affected by elevated BP include the kidney, cardiovascular system, eye, and brain. A hypertensive crisis mandating emergency therapy occurs whenever there is end-organ damage that is likely to produce significant permanent abnormalities unless BP is lowered immediately. In veterinary patients, the end organs affected by this type of damage are usually the eyes and brain (Table 42-1).

42.3 END-ORGAN DAMAGE

42.3.1 Ocular

Ocular lesions are observed in many animals with systemic hypertension; reported prevalence rates are as high as 100%.[1-6] The syndrome of hypertensive ocular injury is most often termed *hypertensive retinopathy*. [2,4,7,8] Sudden onset of blindness, intraocular hemorrhage, and retinal detachment are the most common indications for emergency lowering of BP. Other ocular lesions associated with high BP include retinal vessel tortuosity, edema, and retinal degeneration. Effective antihypertensive management can lead to retinal reattachment, although restoration of vision is not common and subsequent retinal degeneration leading to blindness may occur. Hypertensive ocular injury has been reported at systolic BP as low as 168 mm Hg,[3] and there is a substantially elevated risk of occurrence when systolic BP exceeds 180 mm Hg, particularly when this occurs suddenly.[6,8]

42.3.2 Neurologic

Neurologic clinical signs are frequently in hypertensive dogs and cats. Signs include altered mentation, disorientation, lethargy, seizures, balance disturbances, head tilt, nystagmus, behavioral abnormalities, and focal neurologic defects. Hypertensive encephalopathy[9] is a complication justifying rapid lowering of BP that has been reported in dogs[5] and cats,[4,7,10,11] occurring as a well-described entity in humans characterized by white matter edema and vascular lesions.[12] Hypertensive encephalopathy also occurs after renal transplantation in humans[13] and is a cause of otherwise unexplained death in cats.[10] Hypertensive encephalopathy is more likely to occur with a sudden rise of BP or a systolic BP that exceeds 180 mm Hg.[14] This syndrome, in its early phases, is rapidly responsive to lowering of BP.[10,14] Hemorrhagic and ischemic stroke are observed in dogs and cats, and these conditions may generally be distinguished from hypertensive encephalopathy by virtue of their slow and incomplete response to lowering BP. Before treating hypertension in the patient with evidence of intracranial disease, a Cushing reflex in response to increased intracranial pressure must be distinguished from neurologic injury secondary to hypertension (see Chapter 100, Intracranial Hypertension).

42.3.3 Renal

In the kidney, hypertensive injury generally manifests as an enhanced rate of decline of renal function, early renal death, and proteinuria. Proteinuria is a marker of hypertensive nephropathy in humans,[15] and severity was directly related to degree of elevation of BP in an experimental study of chronic kidney disease in cats.[14] Malignant hypertension is a syndrome of severe, progressive elevations of BP causing end-organ damage that is often associated with kidney disease and is a recognized cause of rapidly progressive renal injury in rats and people, necessitating quick reductions in BP. However, hypertensive damage to the canine and feline kidneys is almost always a slow and insidious process requiring weeks to years to fully manifest, and is thus rarely a rationale for emergency therapy in dogs and cats.

Table 42-1 Hypertensive End-organ Damage

End Organ	Hypertensive Injury	Clinical Findings	Can this damage be a rationale for emergency antihypertensive therapy?
Eye	Retinopathy	Acute blindness, retinal detachment, or hemorrhage	Yes
	Choroidopathy	Vitreal hemorrhage or hyphema	
Brain	Encephalopathy	Central neurologic symptoms of acute onset	Yes
	Stroke		
Kidney	Progression of chronic kidney disease	Serial increases in serum creatinine concentration	Generally, no
		Proteinuria	
Heart and vessels	Cardiac failure	Left ventricular hypertrophy	Generally, no
		Systolic murmur	
		Arrhythmias	
		Evidence of cardiac failure	

42.3.4 Cardiovascular

Cardiac changes in hypertensive animals may include systolic murmurs and cardiac gallops[16] and left ventricular hypertrophy.[1,4,16,17] Although cats with previously undiagnosed hypertension may unexpectedly develop signs of congestive heart failure after receiving fluid therapy, heart failure and other serious complications are infrequent[4,7,18] and slow to develop. Although vascular injury within the eye or central nervous system is a rationale for emergency therapy, cardiac changes rarely mandate rapid reductions in BP.

42.4 PATIENTS AT RISK FOR HYPERTENSION

There are at least two primary indications for evaluating BP in a patient. First, BP should be measured in patients with clinical abnormalities consistent with hypertensive end-organ damage; the presence of unexplained clinical findings that are associated with systemic hypertension should lead to BP measurement at the time of diagnosis. For emergency treatment, this generally includes clinical signs of hypertensive retinopathy or hyphema and unexplained intracranial neurologic signs (e.g., seizures, altered mentation, focal neurologic deficits). A second indication for BP measurement is the presence of diseases or conditions casually associated with secondary hypertension (e.g., chronic kidney disease, feline hyperthyroidism, diabetes mellitus, and hyperadrenocorticism) or the use of therapy that may elevate BP (e.g., sympathetic agonists or intensive fluid therapy). A thorough physical examination, including funduscopic evaluation, cardiac auscultation, and neurologic examination, should concurrently be performed in these at-risk populations to assess for end-organ damage. Abnormalities of the urinary (e.g., microalbuminuria, proteinuria, azotemia, or structural changes in the kidney) and cardiovascular (e.g., unexplained left ventricular hypertrophy, gallop rhythm, arrhythmia, or systolic murmur) systems also indicate BP measurement.

42.5 MEASUREMENT OF BLOOD PRESSURE

Diagnosis and treatment of hypertension must be based on the patient's BP. It can be measured directly by an intraarterial means[19] or indirectly by devices employing a compressive cuff. Arterial puncture by needle or catheter has been used in veterinary medicine.[7] Radiotelemetric implants have been employed in laboratory studies of hypertension in dogs[20] and cats,[14,21-24] and this technology may yet prove to be a clinically useful approach. However, indirect devices are generally more clinically acceptable and in much wider use[9,25-32] (see Chapters 49 and 203, Arterial Catheterization and Hemodynamic Monitoring, respectively).

Diagnosis and treatment of hypertension generally are based on systolic BP. This is largely because the risk of end-organ damage is most closely related to systolic BP in humans and rats. Furthermore, some devices commonly used in veterinary medicine do not provide reliable measurements of diastolic BP. Although isolated diastolic hypertension (elevated diastolic with normal systolic BP) occurs in dogs and cats, animals with end-organ damage necessitating rapid BP reductions should be expected to exhibit elevations of both systolic and diastolic BP.

To obtain reliable values, it is important to follow a standard protocol. The BP may be affected by stress or anxiety associated with the measurement process,[22] and these changes may result in a false diagnosis of hypertension.[33] This anxiety-induced, artifactual elevation of BP is often referred to as *white-coat hypertension,* a reference to the white coat of the medical professional measuring BP. A measurement session consisting of three to seven consecutive indirect measurements should be obtained before initiation of antihypertensive therapy. Although the general rule is to conduct at least two measurement sessions separated by 30 minutes or more before initiating therapy, the presence of ocular or neurologic end-organ damage constituting an emergency is an exception to this rule.

42.6 TREATMENT OF THE EMERGENCY HYPERTENSIVE PATIENT

Before making a decision to treat high BP as a hypertensive crisis, careful evaluation of the patient and appropriate selection of agents are mandatory.

42.6.1 Decision to Treat

High BP measurements alone do not constitute an emergency. Emergency antihypertensive therapy is indicated only when two conditions have been met.

First and foremost, there is end-organ damage likely to produce significant permanent abnormalities without rapid lowering of BP (i.e., hypertensive neurologic or ocular injury).

Second, the degree of BP elevation places the patient at moderate or severe risk of sustained or worsening injury in these end organs.[9] High BP measurements can be caused by measurement artifact (i.e., stress-induced, or white-coat, hypertension), occur in association with other disease processes that may elevate BP (i.e., secondary hypertension), or occur in the absence of evidence for other potentially causative disease processes (i.e., idiopathic hypertension). A decision to use antihypertensive therapy should be accompanied by identification and treatment of conditions that may complicate therapy, generally those that cause secondary hypertension.

Table 42-2 ACVIM System for Classification of Systolic Blood Pressure Levels in Dogs and Cats Based on Risk for Further End-organ Damage[9]

Risk Category	Systolic Blood Pressure (mmHg)	Risk of Further End-organ Damage
I	<150	Minimal
II	150–159	Mild
III	160–179	Moderate
IV	≥180	Severe

ACVIM, American College of Veterinary Internal Medicine.

NOTE: Therapeutic target is generally a systolic BP of 110 to 150 mm Hg.

In patients with end-organ damage consistent with hypertension that may progress rapidly (i.e., hypertensive retinopathy and hyphema or neurologic abnormalities associated with high BP or intracranial hemorrhage), it is appropriate to consider antihypertensive therapy on the basis of risk of developing subsequent end-organ damage (Table 42-2), with systolic BP of 160 to 180 mm Hg posing a moderate risk and systolic BP of 180 mm Hg or higher a severe risk.[9] Generally, the nature and course of end-organ damage, rather than the degree of BP elevation, will dictate the decision to rapidly reduce BP. For animals with systolic BP of 140 to 159 mm Hg that exhibit otherwise unexplained ocular or neurologic damage that is potentially attributable to hypertension, a short-term (3 to 7 days) trial of antihypertensive therapy may be cautiously employed.

42.6.2 Pharmacologic Agents

Once a decision is made to treat an animal with high BP, therapeutic intervention will generally be with a pharmacologic agent. Certain disease conditions identified during this evaluation may be best addressed with specific classes of agents, such as β-blockers for hypertension-associated hyperthyroidism, or α-blockers and β-blockers or surgical excision for pheochromocytomas, aldosterone receptor blockers or surgical excision of adrenal tumors in animals with hypertension associated with hyperaldosteronism, or some combination of calcium channel blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and aldosterone receptor blockers for hypertension associated with kidney disease in dogs.[9,14,34-37]

For emergency management, agents with a rapid onset of action are required. Cautious use of agents at reduced dosages is generally counterproductive and time consuming. Appropriate agents (Table 42-3)[9,38] include parenteral medications such as hydralazine, enalaprilat, labetalol, and esmolol, as well as those with rapid onset of effect when administered orally (e.g., amlodipine besylate). There is limited clinical information on the use of several of these agents for this purpose (e.g., esmolol). Hydralazine and amlodipine are employed most commonly. If medications are administered parenterally, continuous BP monitoring via arterial catheterization is strongly recommended. Many clinicians prefer oral calcium channel blockers, particularly in cats, because they generally lower BP in severely hypertensive animals within 4 to 6 hours irrespective of primary disease, and these agents carry a limited risk of causing hypotension or BP instability.

Table 42-3 Examples of Agents Used for Emergency Antihypertensive Therapy in Dogs and Cats*

Agent	Route	Dosage
Parenteral		
Hydralazine†	IV or IM	0.2 mg/kg, repeat q 2 hr as needed
Enalaprilat	IV	0.2 mg/kg, repeat q 1–2 hr as needed
Labetalol	IV	0.25 mg/kg over 2 minutes, repeat up to a total dosage of ≤3.75 mg/kg followed by a constant rate infusion of 25 μg/kg/min
Esmolol	IV	50–75 μg /kg/min constant rate infusion
Oral		
Amlodipine†	Oral	0.25 mg/kg q 24 hr; dosages up to 0.5 mg/kg q 24 h may be employed, albeit cautiously

IM, intramuscular; *IV,* intravenous.

* This list is not intended to be exhaustive; other antihypertensive agents may be appropriate.

† Most frequently employed agents.

42.6.3 Therapeutic Goals

The goal of antihypertensive therapy is to reduce the magnitude, severity, and likelihood of further end-organ damage, generally to reduce systolic BP to 110 to 150 mm Hg. Because end-organ damage is likely to be directly related to systolic BP and adversely affected by wide fluctuations in BP, it is preferable to achieve a stable reduction of BP to the lower half of this range. Some severely hypertensive animals (i.e., systolic BP >250 mm Hg) and those with secondary vascular changes may exhibit signs of hypotension (i.e., syncope, weakness, exercise intolerance, and prerenal azotemia) when BP is lowered rapidly. This is uncommon if the systolic BP is maintained above 110 mm Hg.

If an antihypertensive agent of choice is only partially effective, the usual approach is to consider increasing the dosage or adding an additional drug. Although not ideal, management of highly resistant hypertension in humans often requires more than three agents, and veterinary patients with severe hypertension often require more than one agent.

42.6.4 Follow-up

Measurement of BP and assessment for changes related to end-organ damage should be performed frequently, initially at least every 12 hours. Patients receiving parenteral antihypertensive agents should be assessed more frequently, generally at 1- to 3-hour intervals. Choice of agents, drug dosage, and dosage interval should be adjusted according to BP, with a goal of maintaining a stable systolic BP between 110 and 150 mm Hg without evidence of effects of low BP. It is important to carefully reevaluate any patient treated with emergency antihypertensive therapy before instituting further therapy. Follow-up evaluations should include measurement of BP, funduscopic examination, and other assessments specific to the individual's end-organ damage and concurrent diseases. Once end-organ damage and BP are stabilized, generally within 3 to 5 days, the transition to an oral antihypertensive regimen should be made gradually.

43 Chapter 43 Cardiac Tamponade and Pericardiocentesis

Wendy A. Ware, DVM, MS, DACVIM (Cardiology)

43.1 KEY POINTS

- Cardiac tamponade occurs when intrapericardial pressure rises to equal or greater than normal cardiac filling pressure.
- The rate of pericardial fluid accumulation influences how quickly cardiac tamponade develops. A large pericardial fluid volume implies a gradual process.
- Cardiac tamponade is relatively common in dogs, but rare in cats.
- Clinical signs usually reflect poor cardiac output and systemic venous congestion.
- Right atrial collapse is a characteristic echocardiographic finding with cardiac tamponade.
- Immediate pericardiocentesis is indicated for cardiac tamponade.

43.2 INTRODUCTION

Normally, a small volume (≈0.25 ml/kg) of serous fluid lies between the outer fibrous (parietal) pericardial layer and the serous visceral pericardium or epicardium.[1] Excess, abnormal fluid within this space (pericardial effusion) is a common disorder that has a variety of causes (see Chapter 44, Pericardial Diseases). Pericardial effusion impairs cardiac function when intrapericardial pressure rises and prevents normal cardiac filling. Most pericardial effusions in dogs are serosanguineous or sanguineous; these are usually of neoplastic or idiopathic origin.[2,3] Pericardial transudates, modified transudates, and exudates occasionally occur in both dogs and cats.

43.3 PATHOPHYSIOLOGY OF CARDIAC TAMPONADE

The hemodynamic consequences of pericardial effusion depend on the intrapericardial pressure-volume relationship. Because the fibrous pericardium is relatively noncompliant, increases in fluid volume can sharply raise intrapericardial pressure. Cardiac tamponade develops when intrapericardial pressure rises toward and exceeds normal cardiac diastolic pressures.[2-4] The external cardiac compression progressively limits right ventricular filling and, with increasing severity, also reduces left ventricular filling.[2,3,5] Systemic venous pressure increases and forward cardiac output falls. Eventually, diastolic pressures in all cardiac chambers and great veins equilibrate.[2,3]

The rate of pericardial fluid accumulation and the distensibility of the pericardial sac determine whether and how quickly cardiac tamponade develops. Rapid accumulation of a relatively small-volume effusion (e.g., 50 to 100 ml) can raise intrapericardial pressure markedly, because pericardial tissue stretches slowly. Conversely, a slow rate of fluid accumulation may allow for enough pericardial enlargement to maintain low intrapericardial pressure until the effusion is quite large. A large volume of pericardial fluid implies a gradual process. So long as intrapericardial pressure is low, cardiac filling and output remain relatively normal and clinical signs are absent. Fibrosis and thickening further limit the compliance of pericardial tissue, and this can increase the likelihood of pericardial tamponade. Pericardial fibrosis and inflammatory cell infiltrates are described with idiopathic as well as neoplastic causes of effusion.[6,7]

Neurohormonal compensatory mechanisms are activated as cardiac output falls.[8,9] These contribute to fluid retention and other clinical manifestations of tamponade. Signs of systemic venous congestion become especially prominent over time. Although pericardial effusion does not directly affect myocardial contractility, reduced coronary perfusion during tamponade can impair both systolic and diastolic function. Low cardiac output, arterial hypotension, and poor perfusion of other organs besides the heart can ultimately precipitate cardiogenic shock and death.

Cardiac tamponade also causes an exaggerated respiratory variation in arterial blood pressure known as *pulsus paradoxus*. Inspiration normally lowers intrapericardial and right atrial pressures slightly, which enhances right heart filling and pulmonary blood flow. Left heart filling diminishes as more blood is held in the lungs and the inspiratory increase in right ventricular filling pushes the interventricular septum leftward. Thus left heart output and systemic arterial pressure normally decrease slightly during inspiration. Patients with pulsus paradoxus exhibit a fall in arterial pressure during inspiration of 10 mm Hg or more.[10,11]

43.4 CLINICAL PRESENTATION

Cardiac tamponade is relatively common in dogs, but rare in cats. Clinical findings reflect poor cardiac output and usually systemic venous congestion as well. The typical history includes exercise intolerance, abdominal enlargement, tachypnea, weakness, collapse or syncope, and sometimes cough. Collapse is more common in dogs with cardiac neoplasia than in those with idiopathic disease.[12] Nonspecific signs such as lethargy, inappetence, or other gastrointestinal maladies can develop before obvious ascites does.

43.4.1 Physical Findings

Jugular venous distention or a positive hepatojugular reflux,* hepatomegaly, ascites, labored respiration, and weakened femoral pulses are common physical findings.[3,12-15] Pulsus paradoxus is detected occasionally by femoral pulse palpation. High sympathetic tone commonly produces sinus tachycardia, pale mucous membranes, and prolonged capillary refill time. The precordial impulse is palpably weak with a large pericardial fluid volume, and heart sounds are muffled by moderate to large pericardial effusions.[2,12,13] In addition, lung sounds can be muffled ventrally with pleural effusion. Pericardial effusion alone does not cause a murmur, but concurrent cardiac disease may do so. Reduced lean body mass (cachexia) is apparent in some chronic cases.

Although right-sided congestion predominates, signs of biventricular failure can occur. Rapid pericardial fluid accumulation can cause acute tamponade, shock, and death without signs of pleural effusion, ascites, or radiographic cardiomegaly. Pulmonary edema, jugular venous distention, and hypotension may be evident in such cases.

* The hepatojugular reflux is assessed by applying firm pressure to the cranial abdomen while the animal stands quietly with head in a normal position. This pressure transiently increases venous return, but normally there is little to no change in jugular vein appearance. Jugular distention that persists while abdominal pressure is applied constitutes a positive (abnormal) test result.

43.5 DIAGNOSIS

Cardiac tamponade is often suspected from the history and physical examination, but thoracic radiographs and especially echocardiography are important for diagnosis. The electrocardiogram (ECG) may suggest pericardial disease in some cases. Laboratory findings reflect underlying disease or tamponade-induced prerenal azotemia or hepatic congestion, but are otherwise nonspecific (see Chapter 44, Pericardial Diseases, for further information about pericardial effusion diagnosis and differentiation of causes).

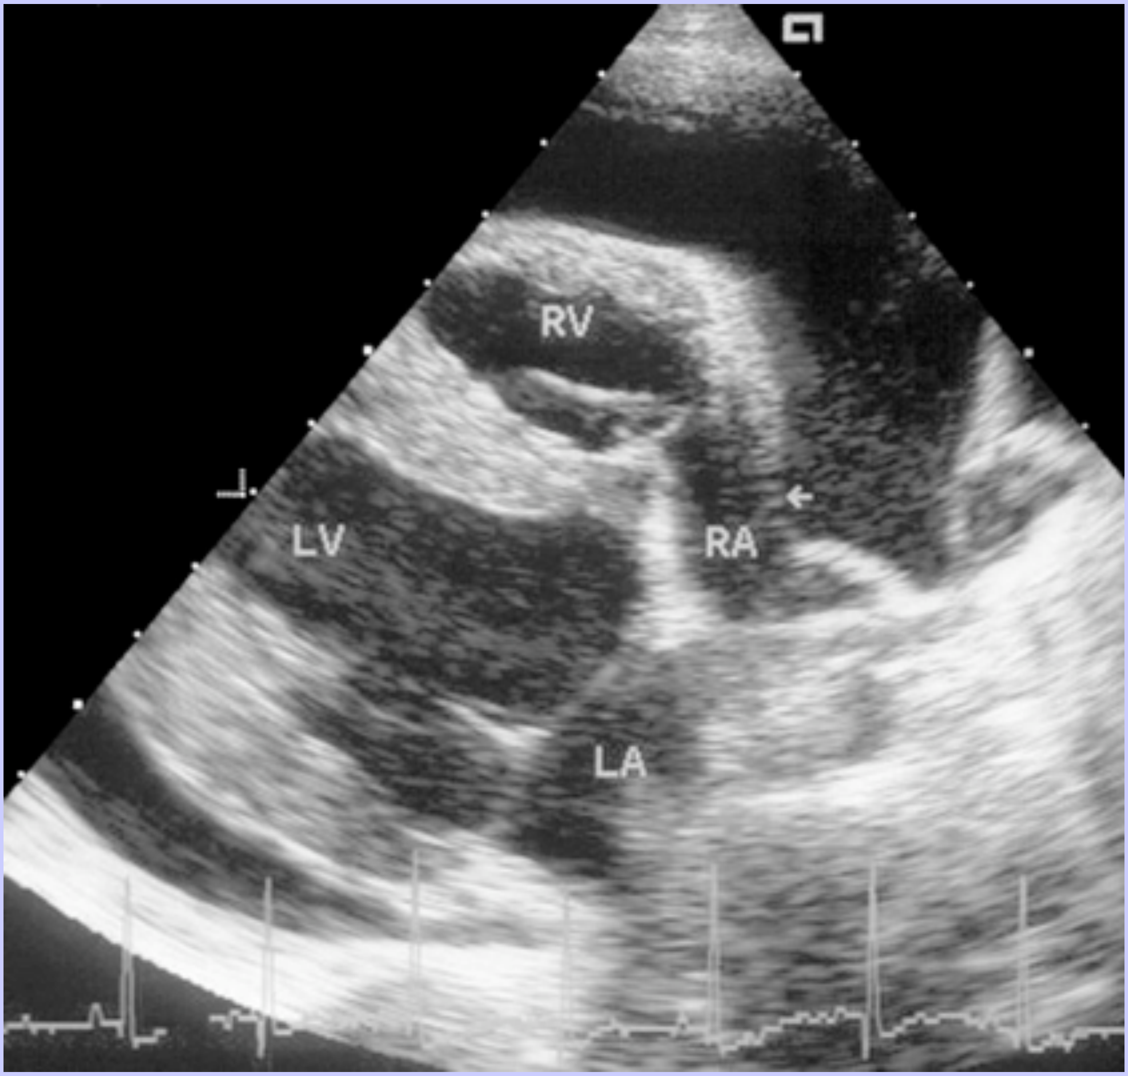
43.5.1 Thoracic Radiographs

The appearance of the cardiac silhouette depends on the volume of pericardial fluid as well as any underlying cardiomegaly.[2,3,16] Massive pericardial effusion causes the classic globoid-shaped cardiac shadow ("basketball heart") seen on both views. But other causes of a large, rounded heart shadow include dilated cardiomyopathy or marked tricuspid (with or without mitral) insufficiency. Smaller volumes of pericardial fluid allow some cardiac contours to be identified, especially those of the atria. Other radiographic findings associated with tamponade include pleural effusion, caudal vena cava distention, hepatomegaly, and ascites. Pulmonary infiltrates of edema or distended pulmonary veins are noted only occasionally. Tracheal deviation, a soft tissue mass effect, or metastatic lung lesions are seen in some cases of cardiac tamponade associated with heart base tumors.

43.5.2 Echocardiography

Because echocardiography is highly sensitive for detecting even small-volume pericardial effusion, it is the diagnostic test of choice.[2,3,17] The effusion appears as an echo-free space between the bright parietal pericardium and the epicardium. Abnormal cardiac wall motion and chamber shape, and intrapericardial or intracardiac mass lesions can also be visualized.[16-19] Cardiac tamponade is characterized by diastolic (and early systolic) compression or collapse of the right atrium and sometimes right ventricle (Figure 43-1).[18] The left ventricular lumen often appears small and the walls appear to be hypertrophied (pseudohypertrophy) because of the poor cardiac filling.

Figure 43-1 Right parasternal four-chamber echocardiographic image from a dog with cardiac tamponade. Pericardial fluid is seen surrounding the heart. Note the characteristic collapse of the right atrial wall *(arrow)* caused by elevated intrapericardial pressure. Electrocardiographic tracing along the bottom. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.



43.5.3

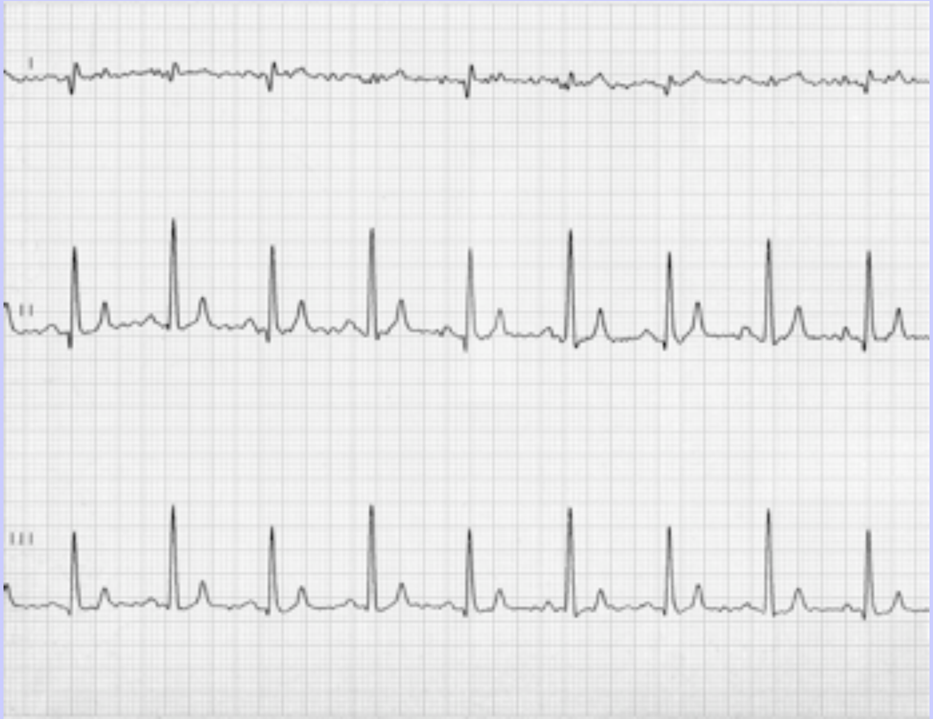
Electrocardiography

Although not specific for tamponade, ECG findings associated with large-volume pericardial effusion include reduced amplitude QRS complexes (less than 1 mV in dogs) and electrical alternans. The latter is a recurring, beat-to-beat alteration in the size or configuration of the QRS complex (and sometimes T wave) that results from the heart swinging back and forth within the pericardium (Figure 43-2).[20] Electrical alternans may be more evident at heart rates between 90 and 140 beats/min or in certain body positions (e.g., standing). ST segment elevation, suggesting an epicardial injury current, also is seen in some cases of pericardial effusion.[13,20] Sinus tachycardia is common with cardiac tamponade; atrial and ventricular tachyarrhythmias occur in some cases.

43.5.4 Central Venous Pressure

Central venous pressure (CVP) measurement may be useful in identifying tamponade, especially if it is difficult to assess jugular veins or it is unclear whether right heart filling pressure is elevated. CVP is normally in the range of 0 to 8 cm H_2O; CVP measurements of 10 to 12 cm H_2O are common with cardiac tamponade. Tamponade alters the CVP (and right atrial) waveform by markedly diminishing the *y* descent (during ventricular diastole). Although blood flow into the right atrium (and *x* descent on the CVP waveform) occurs during ventricular contraction, atrial filling is curtailed as the ventricles relax. Ventricular diastolic expansion causes an immediate rise in intrapericardial pressure when cardiac tamponade exists. The pericardial fluid instantly transmits this pressure to the atria, which severely impairs caval flow into the right atrium and prevents the normal early diastolic decrease in CVP (*y* descent). In contrast, a prominent *y* descent is associated with constrictive pericarditis.

Figure 43-2 Electrocardiogram showing sinus rhythm with electrical alternans, from a dog with large-volume pericardial effusion. Note the every-other-beat change in QRS complex size and configuration in each lead. See text for further information. Leads I, II, III: 50 mm/sec, 1 cm = 1 mV.



43.6 MANAGEMENT OF CARDIAC TAMPONADE

It is important to differentiate cardiac tamponade from other diseases that cause right-sided congestive signs because its management is unique. The compressed ventricles require high venous pressure to fill. By reducing cardiac filling pressure, diuretics and vasodilators further decrease cardiac output and exacerbate hypotension. Positive inotropic drugs do not improve cardiac output or ameliorate the signs of tamponade because the underlying pathophysiology is impaired cardiac filling, not poor contractility.

Immediate pericardiocentesis is indicated for cardiac tamponade. This sometimes also provides diagnostic information (see Chapter 44, Pericardial Diseases). Congestive signs should resolve after intrapericardial pressure is reduced by fluid removal. A modest dose of diuretic can be given after pericardiocentesis, but this is not essential. Subsequent management is guided by the underlying cause of the pericardial effusion and other clinical circumstances (see Chapter 44, Pericardial Diseases).

43.7 PERICARDIOCENTESIS TECHNIQUES

43.7.1 Preparation and Positioning

Pericardiocentesis is a relatively safe procedure when performed carefully. Depending on the clinical status and temperament of the animal, sedation may be helpful. ECG monitoring is recommended during the procedure; needle or catheter contact with the heart commonly induces ventricular arrhythmias. Although cardiac tamponade is uncommonly caused by coagulopathy, verifying that coagulation parameters are normal is helpful, if patient status allows time for this. Pericardiocentesis usually is performed from the right side of the chest. This minimizes the risk of trauma to the lung (via the cardiac notch) and major coronary vessels, most of which are located on the left. The patient usually is placed in left lateral recumbency to allow more stable restraint; sometimes sternal recumbency is used if the dog is cooperative. Alternatively, the author has had good success using an elevated echocardiography table with a large cut-out; the animal is placed in right lateral recumbency and the tap is performed from underneath (Color Plate 43-1). The advantage of this method is that gravity draws fluid down toward the collection site. But if adequate space is not available for wide sterile skin preparation or for needle or catheter manipulation, this approach is not advised. Echocardiographic guidance can be used, but is not necessary unless the effusion is of very small volume or appears compartmentalized. Sometimes pericardiocentesis can be performed successfully on the standing animal, but the risk of injury is increased if the patient moves suddenly.

Several methods can be used for pericardiocentesis. An over-the-needle catheter system (e.g., 16 to 18 gauge, 1.5 182 inch to 183 2 inches long) is recommended for most cases. Larger over-the-needle catheter systems (e.g., 12 to 14 gauge, 4 to 6 inches) allow for faster fluid removal in large dogs; a few extra small side holes can be cut (smoothly) near the tip of the catheter to facilitate flow, but care should be taken that the end of the catheter does not break off inside the patient. During initial catheter placement the extension tubing is attached to the needle stylet; after the catheter is advanced into the pericardial space and the needle removed, the extension tubing is attached directly to the catheter. In emergency situations or when an over-the-needle catheter is unavailable, an appropriately long hypodermic or spinal needle attached to extension tubing is adequate. A butterfly needle (18 to 21 gauge) is generally used in cats. For all methods a three-way stopcock is placed between the extension tubing and a collection syringe.

43.7.2 Pericardiocentesis Procedure

The skin is shaved and surgically prepared over the right precordium, from about the third to seventh intercostal spaces and from sternum to costochondral junction. Sterile gloves and aseptic technique should be used. The puncture site is identified by palpating for the cardiac impulse (usually between the fourth and sixth ribs just lateral to the sternum); the optimal site must be estimated if no precordial impulse is felt. Local anesthesia is recommended and is essential with use of a larger catheter. Two percent lidocaine is infiltrated (with sterile technique) at the skin puncture site underlying intercostal muscle and into the pleura. A small stab incision is made in the skin when using a larger catheter system.

The puncture site should be just cranial to a rib to avoid the intercostal vessels located caudal to each rib. Once the needle has penetrated the skin, an assistant should apply gentle negative pressure to the attached syringe (with three-way stopcock and extension tubing) as the operator slowly advances the needle toward the heart. In this way, any fluid will be detected as soon as it is encountered. Pleural fluid (usually straw colored) may enter the tubing first. It is helpful to aim the needle tip toward the patient's opposite shoulder. The pericardium causes increased resistance to needle advancement and may produce a subtle scratching sensation when contacted. The needle is advanced with gentle pressure through the pericardium; a loss of resistance may be noted with needle penetration, and pericardial fluid (usually dark red) will appear in the tubing. With a catheter system, the needle-catheter unit must be advanced far enough into the pericardial space that the catheter is not deflected by the pericardium as the needle stylet is removed. After the catheter is advanced into the pericardial space and the stylet removed, the extension tubing is attached to the catheter. Initial pericardial fluid samples are saved in sterile ethylenediaminetetraacetic acid (EDTA) and clot tubes for evaluation; then as much fluid as possible is drained.

A scratching or tapping sensation usually is felt if the needle or catheter contacts the heart; also, the device may move with the heartbeat, and ventricular premature complexes are often provoked. If this occurs the needle and catheter should be retracted slightly to avoid cardiac trauma. Care should be taken to minimize extraneous needle movement within the chest. If it is unclear whether pericardial fluid or intracardiac blood (from cardiac penetration) is being aspirated, a few drops can be placed on the table or into a clot tube and a sample spun in a hematocrit tube. Pericardial fluid does not clot (unless associated with very recent hemorrhage). The packed cell volume is usually lower than that of peripheral blood, and the supernatant appears yellow-tinged (xanthochromic). Furthermore, as pericardial fluid is drained, the patient's ECG complexes usually increase in amplitude, tachycardia diminishes, and the animal often breathes more deeply and appears more comfortable.

43.7.3 Complications of Pericardiocentesis

Ventricular premature beats occur commonly from direct myocardial injury or puncture. These are usually self-limited, resolving when the needle is withdrawn. Coronary artery laceration with myocardial infarction or further bleeding into the pericardial space can occur but is uncommon, especially when pericardiocentesis is done from the right side. Lung laceration causing pneumothorax or hemorrhage or both is also a potential complication during the procedure. In some cases, dissemination of infection or neoplastic cells into the pleural space may result.

44 Chapter 44 Pericardial Diseases

Nancy J Laste, DVM, DACVIM (Cardiology)

44.1 KEY POINTS

- The most common causes of pericardial effusion in dogs are hemangiosarcoma, idiopathic pericardial effusion, malignant mesothelioma (MM), and heart base tumors.
- Echocardiography is the main clinical tool for diagnosing pericardial effusion and cardiac masses.
- Dogs with a history of collapse have a shorter median survival time than dogs without collapse.
- Dogs with ascites have a longer median survival time than patients without ascites.
- MM can be difficult to differentiate from IPE, even with pericardial biopsy.
- Pericardial disease is more common in the dog than in the cat.
- The most common causes of pericardial effusion in the cat are lymphosarcoma, feline infectious peritonitis (FIP), and congestive heart failure.

44.2 INTRODUCTION

The clinical picture, pathophysiology, and therapeutic approach to acute pericardial effusion are covered in Chapter 43, Cardiac Tamponade and Pericardiocentesis. This chapter focuses on the differential diagnosis for canine and feline pericardial disease (Boxes 44-1 and 44-2) and details the more common causes of pericardial effusion in the dog.

44.3 CLINICAL SIGNS

The clinical signs associated with pericardial effusion will depend on the magnitude and rate of elevation of intrapericardial pressures. This will be determined chiefly by the volume of fluid within and the distensibility of the pericardial sac. Acute pericardial hemorrhage (hemangiosarcoma, left atrial tear) will typically result in signs of cardiac tamponade (see Chapter 43, Cardiac Tamponade and Pericardiocentesis) with lower volumes than those seen with causes associated with slower accumulation (idiopathic pericarditis, malignant mesothelioma [MM]). Accordingly, patients brought in for collapse have a worse long-term prognosis.[1] In addition, signs of right-sided congestive heart failure (jugular distention, ascites, pleural effusion) suggest a more chronic fluid accumulation, allowing time for cavitary fluid retention. Ascites has been correlated with a better long-term prognosis.[1] Disease processes associated with fibrosis of the pericardial sac will lead to clinical signs with lower volumes of effusion. In some cases (constrictive pericarditis) clinical signs are present even in the absence of pericardial effusion. Space-occupying lesions of the pericardial sac (pericardial cysts, peritoneopericardial diaphragmatic hernia) may result in right-sided congestive heart failure or cardiac tamponade, particularly with accompanying pericardial effusion.

44.4 SIGNALMENT

Golden Retriever dogs are significantly overrepresented for all major causes of pericardial effusion: hemangiosarcoma (HSA), idiopathic pericardial effusion (IPE), MM, and heart base tumor (HBT).[1–9] German Shepherd dogs are one of the breeds in which right atrial HSA and HBT are more common.[3,10–12] Boxers and other brachycephalic breeds traditionally are reported to be more predisposed to HBT, but in more recent reports Golden Retrievers and Labrador Retrievers were more commonly affected.[2,3,8,9] Saint Bernards and Labrador Retrievers are reported to be overrepresented for IPE, and Cocker Spaniel dogs and Labrador Retrievers may be overrepresented for MM (Laste, unpublished data).[2,8] Younger patients are at higher risk for congenital diseases (peritoneopericardial diaphragmatic hernia, pericardial cysts), and middle-aged to older patients are at higher risk for neoplastic causes.[3,13] Male dogs are more likely to develop IPE per most reports.[1,2,6,8,10] There is no reported 184 sex predilection with neoplastic causes of pericardial effusion, but intact animals, particularly intact females, have a 185 significantly lower incidence of cardiac tumors.[3]

*More common causes.

44.5 HISTORY

The history may help determine the likelihood of acute hemorrhage (hemorrhage from a tumor) versus a more chronic accumulation of pericardial effusion more typically associated with the insidious disease processes (IPE, MM). Travel history, history of trauma, or possible rodenticide exposure may be important in forming the differential diagnosis list for each patient. A history of preexisting valvular disease will raise the index of suspicion for the possibility of left atrial rupture with acute hemopericardium. In addition, previously diagnosed pericardial disease and the chronicity of the effusion may make some diagnoses more likely than others. Patients surviving longer than 7 months are unlikely to have HSA.[1] The longer the survival, the more likely it is that IPE is present.

44.6 DIAGNOSTIC FINDINGS

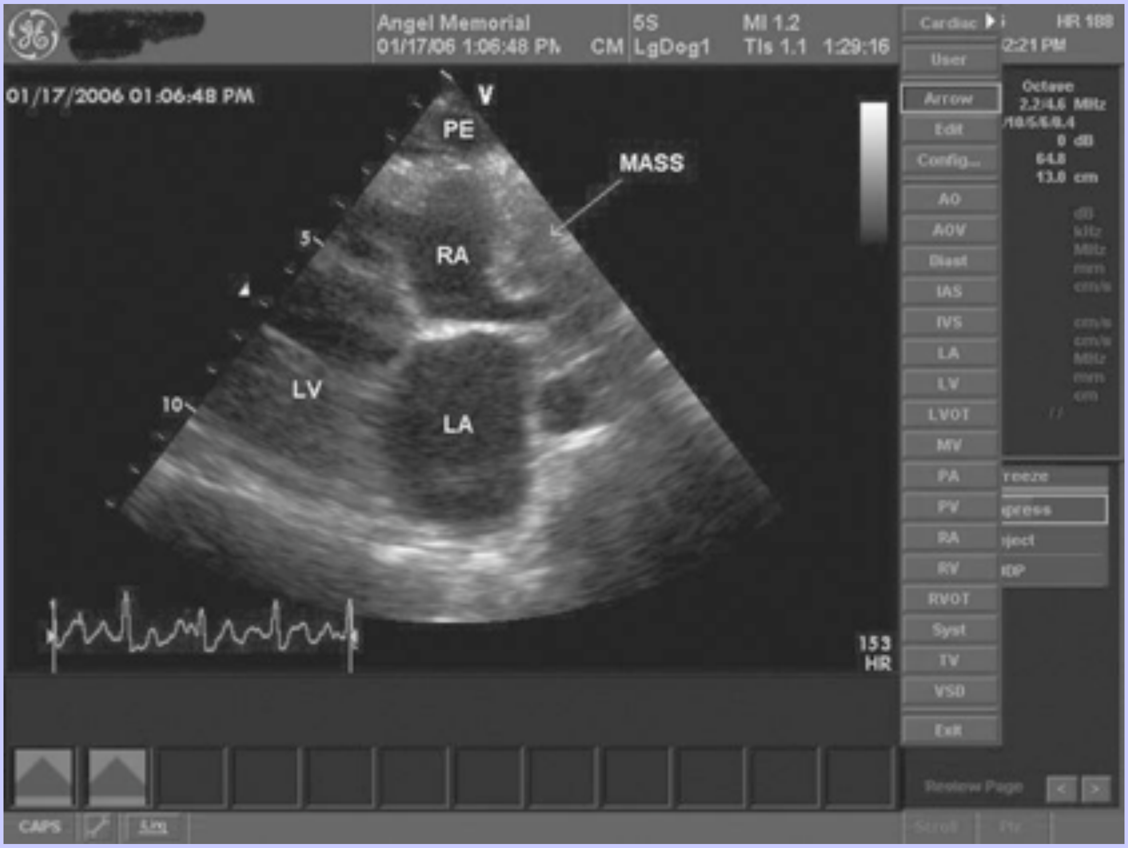
44.6.1 Laboratory Findings

Laboratory findings are not specific for most cases of pericardial effusion aside from marked azotemia in patients with uremic pericarditis. Increases in circulating nucleated red blood cells have been reported in patients with right atrial HSA, but this has not been substantiated by other sources.[10] Anemia may be noted in the patient with pericardial effusion, regardless of the underlying cause, but this has not been reported consistently.[2,10]

44.6.2 Radiographic Findings

Radiographic findings are variable. Heart size may be remarkably normal in patients with acute hemopericardium. The caudal vena cava usually is distended, suggesting elevated right atrial pressures. In cases of chronic-accumulation pericardial effusion, the heart may have the globoid “basketball” appearance classically described. Mass lesions may be suggested by bulges at the heart base. Pulmonary metastases may be noted in some cases with cardiac neoplasia. With more chronic disease, pleural effusion may be present and may obscure the cardiac silhouette and pulmonary parenchyma. Patients with peritoneopericardial diaphragmatic hernia (PPDH) show confluence of the cardiac silhouette and the diaphragm and, depending on the extent of organ involvement, the abdominal cavity may appear devoid of abdominal contents. If there are gastrointestinal segments within the pericardial sac, there may be a suggestive gas pattern, but omental fat and liver are more typically herniated through the defect. Sternal defects may be noted and, if present, are suggestive of a PPDH. Metallic foreign bodies are an uncommonly reported cause of pericardial effusion and can be noted on thoracic radiographs.[14]

Figure 44-1 Right parasternal long-axis 3-dimensional echocardiographic picture showing a right atrial mass (hemangiosarcoma, presumptive) and associated pericardial effusion in a dog. *LA,* Left atrium; *LV,* left ventricle; *PE,* pericardial effusion; *RA,* right atrium.



44.6.3 Electrocardiographic Findings

Low-amplitude QRS complexes are the most consistently reported electrocardiographic finding.[2,4,10] Although electrical alternans (beat-to-beat variations in the R wave amplitude) is described as a classic finding with pericardial effusion, this is reported only 6% to 37% of the time.[2,10] Electrical alternans is associated with higher volumes of pericardial effusion and is thought to be related to the heart swinging within the fluid-filled pericardial sac. ST segment changes, and ventricular or supraventricular arrhythmias may be present in patients with cardiac tamponade.[2,4,7,9]

44.6.4 Echocardiographic Findings

Two-dimensional echocardiography is the main diagnostic tool for pericardial disease.[15] It can be used to confirm the presence of pericardial effusion, roughly quantitate the amount, and identify whether signs of cardiac tamponade exist (Figure 44-1). Careful survey of the right atrium (particularly the right auricle), heart base, and main pulmonary artery is made because the vast majority of mass lesions associated with pericardial effusion are found in these areas (Figures 44-2 and 44-3). HBT generally can be identified adjacent to the aorta on the standard transthoracic views but HSA, particularly associated with the right auricular appendage, may be difficult to see. Therefore the absence of a mass lesion on echocardiography does not rule out the possibility of HSA or other neoplasia. Overall, echocardiography has been estimated to be up to 90% sensitive for the detection of cardiac masses.[16] The heart base and right auricle are surveyed more easily using transesophageal echocardiography, but this technique requires specialized equipment as well as general anesthesia and is thus limited in its practical application. False-positive findings (noting a mass when one is not present) have been reported. Normal cardiac structures can mimic a mass when imaged in oblique positions, particularly to the novice sonographer. One should use care not to overinterpret brightly echogenic periaortic fat. The myocardial texture should also be observed for any changes that could suggest primary or metastatic myocardial neoplasia (LSA, other). In patients that have suffered an endocardial split and left atrial tear, the preexisting valvular disease is noted (mitral valve thickening, varying degrees of left atrial and ventricular dilation), as well as the presence of pericardial effusion and a laminated clot within the pericardial sac, conforming to the heart.[16] Color-flow Doppler allows the identification of a jet aimed at the left atrial free wall, and occasionally an intraatrial clot may be seen adhering to the site of perforation.

Figure 44-2 Right parasternal short-axis 2-dimensional echocardiographic picture of the same patient in Figure 44-1. *PE,* Pericardial effusion; *RA,* right atrium.

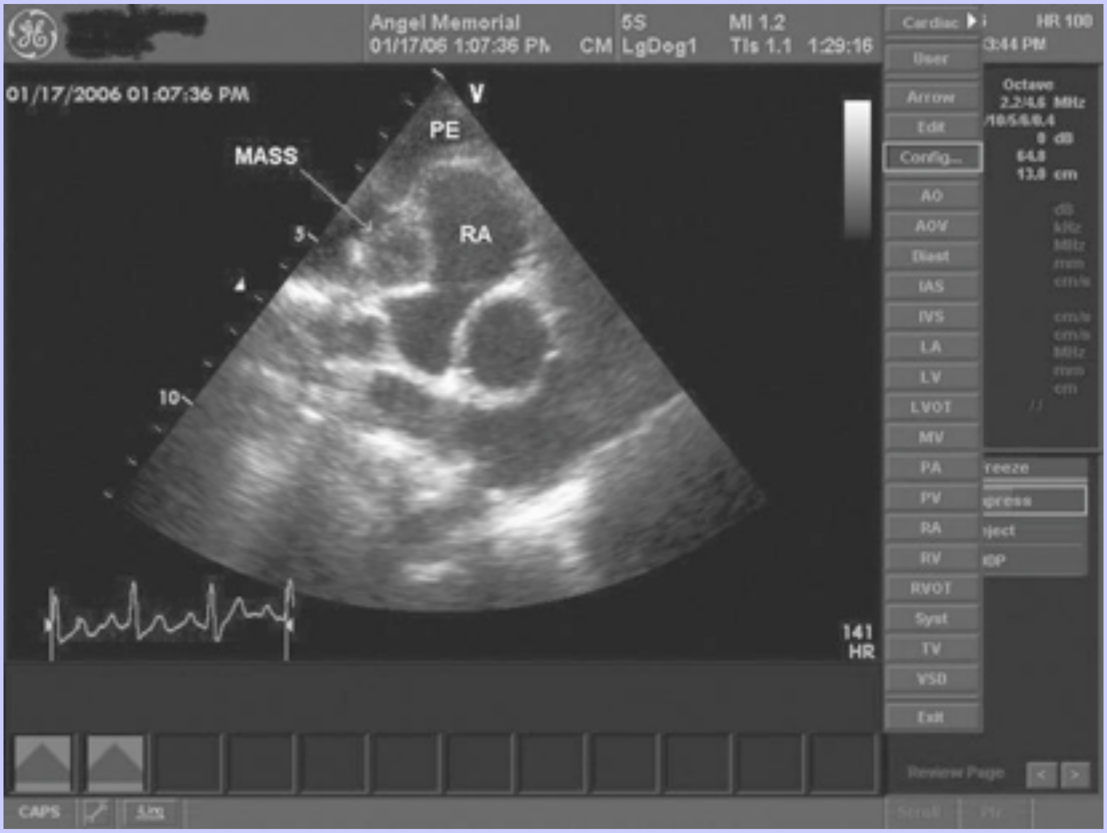


Figure 44-3 Right parasternal short-axis two-dimensional echocardiographic picture of a dog with a very large pericardial effusion. *LV,* Left ventricle; *PE,* pericardial effusion.

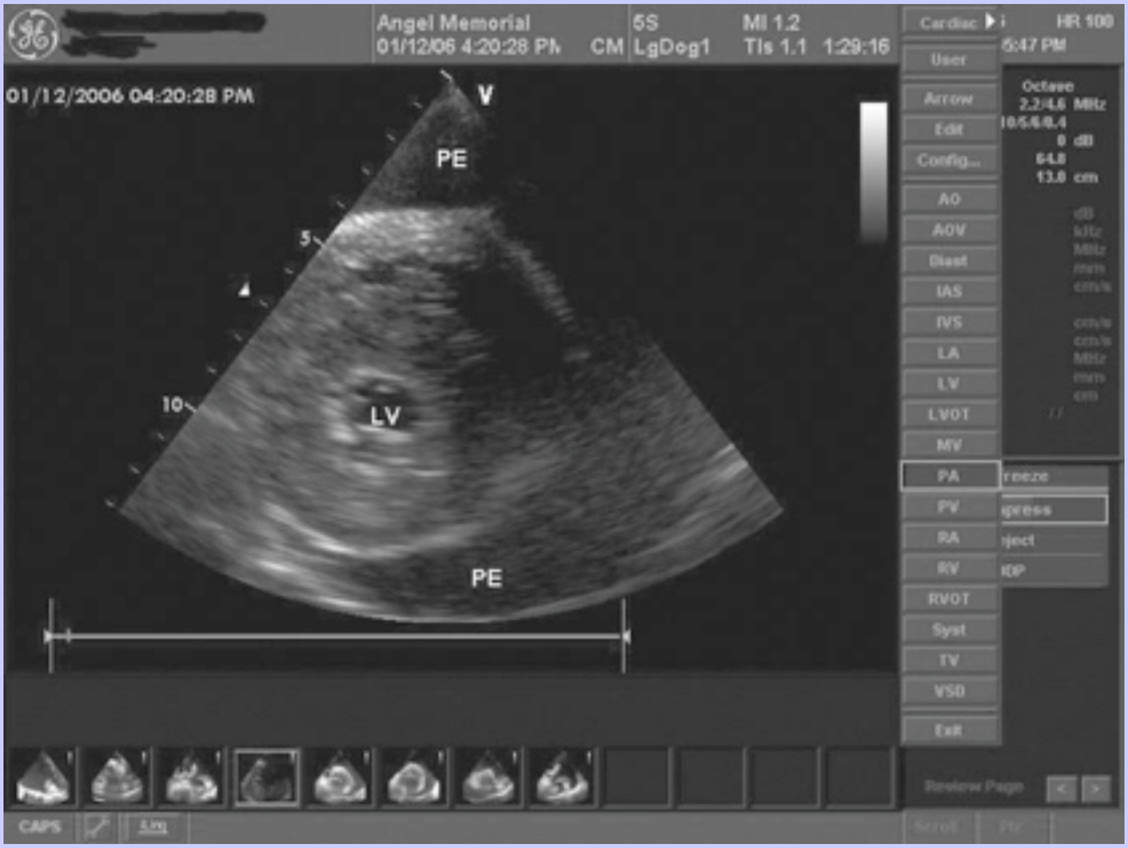

44.6.5 Pericardial Fluid Analysis

Pericardiocentesis generally is indicated for hemodynamic stabilization of the patient and the fluid is submitted for cytologic analysis. Pericardial effusion is grossly hemorrhagic in most cases. The fluid should always be submitted for cytologic analysis, because occasionally it will be diagnostic for causes requiring specific therapy (LSA, FIP, septic pericarditis).[16-19] In most cases, however, fluid analysis is not diagnostic.[20] MM may be suspected from pericardial fluid, but neoplastic cells may be difficult or impossible to differentiate from reactive mesothelial cells. Most pathologists will not make a diagnosis of MM without a tissue biopsy. There have been several investigations attempting to find qualities of pericardial fluid (pH, lactate, glucose) that will differentiate benign versus malignant origins. Although early investigation showed some promise, subsequent studies have found too much overlap between the two groups to make this an effective clinical tool.[21–23]

44.6.6 Advanced Imaging Modalities

Computed tomography and magnetic resonance imaging are excellent for identifying cardiac-associated masses in human patients, but these diagnostic tools are rarely used for veterinary patients because they are available only at larger referral centers, are relatively expensive, and require general anesthesia.

44.6.7 Surgical Exploration

44.6.7.1 Thoracoscopy

Thoracoscopy can be used to facilitate minimally invasive exploration of the thorax, to allow pericardial biopsy, and to create a pericardial window to prevent recurrent pericardial effusion.[24] This technique generally is used for patients that have recurrent pericardial effusion in the absence of a mass lesion. However, it may also be used as a palliative measure for patients with an HBT or right atrial tumor (HSA, presumptive) to avoid recurrent hospitalization for cardiac tamponade. Pleural and pulmonary surfaces can be inspected for metastatic disease and biopsies obtained. In cases with confirmed or suspected diffuse neoplasia (MM), the disease can be staged (microscopic versus gross disease) to help establish prognosis. Thoracostomy tubes can be placed concomitantly to facilitate intracavitary chemotherapy.

Dorsal recumbency is the easiest position for creating a pericardial window but limits exploration of the heart base. In cases where more complete exploration is desired, the patient may be positioned in lateral recumbency and multiple ports placed to allow better access to the heart base. Biopsy of associated mass lesions (right auricular mass, HBT) may be performed, but the risk of poorly controlled hemorrhage after biopsy of these very vascular tumors should be discussed with the owner. Full coagulation profiles should be run on all patients before thoracoscopy and any identified coagulopathies addressed with fresh frozen plasma transfusion before the procedure. Tumor biopsies are avoided in patients with coagulopathies and the surgical procedure limited to the palliative pericardial window.

44.6.7.2 Exploratory Thoracotomy

Exploratory thoracotomy allows the definitive detection of any cardiac-associated masses and provides pericardial tissue for histopathologic analysis. If possible, masses are resected; if resection is not possible, biopsy can be obtained. A subtotal pericardectomy is recommended at the time of the procedure to avoid recurrent cardiac tamponade. The main disadvantage of thoracotomy is patient morbidity. If the disease is advanced (pulmonary metastasis, large nonresectable mass compressing the heart), nonrecovery (euthanasia) should be considered. This possibility should be discussed with the owner before surgery.

186

187

44.7 THERAPEUTIC PLANS AND PROGNOSIS

The reported causes of pericardial disease in the dog are noted in Box 44-1. With many of the causes (hypoalbuminemia, uremia, right-sided congestive heart failure) the amount of pericardial effusion is smaller and does not typically result in significant cardiac compromise. The more common causes of pericardial effusion in the dog will be discussed in more detail later in this chapter.

Acute management of pericardial effusion is mainly pericardiocentesis (see Chapter 43, Cardiac Tamponade and Pericardiocentesis). Following pericardiocentesis, the patient should be monitored for recurrent pericardial bleeding, which is highly suggestive of an intrapericardial mass lesion. The long-term management plan for pericardial disease depends upon the underlying cause. After the diagnostic evaluation has been completed, patients can be classified tentatively as having no mass noted on echocardiography (echo-negative), a mass associated with the right atrium or right auricle (HSA presumptive), HBT, or more specific causes (PPDH, left atrial tear). Generally, echo-negative dogs are approached conservatively (discharged and monitored for recurrent pericardial effusion).

If the pericardial effusion does recur, the timing and pattern of recurrence may be suggestive as to the underlying cause. Patients returning in days to weeks with apparently abrupt recurrence are suspected to have an occult HSA, which may be detected on a repeat echocardiographic study. Right auricular HSA is best visualized when pericardial effusion is present and, when possible, the study should be performed before doing pericardiocentesis. In patients with less aggressive underlying disease processes, pericardial effusion may not recur (IPE) or may not recur for months to years (IPE, MM). Patients with an identified mass lesion have a variety of options as discussed later in this chapter.

44.7.1 Less Frequent Causes of Pericardial Disease

Animals with transudative effusion do not generally require treatment beyond medical management of the underlying disease process. Those with bacterial, fungal, or protozoal pericarditis require surgical management coupled with medical therapy directed at the underlying pathogen.[25–28] Patients with a PPDH who are symptomatic for that defect also require surgery. This defect is sometimes diagnosed as an incidental finding, in which case elective surgery should still be discussed.

Left atrial tears may be identified by echocardiography. These patients may be stable enough to treat conservatively with management of associated congestive heart failure (CHF) and the underlying heart disease, but they are at high risk for recurrent pericardial bleeding. Pericardiocentesis generally is avoided when possible because changes in the intrapericardial pressure may actually disrupt thrombosis and promote further hemorrhage. Surgical attempts to repair left atrial tears have been described. However, these procedures may be difficult to justify with advanced cardiac disease unless mitral valve repair or replacement will also be performed.

44.7.2 Heart Base Tumors

HBTs may be used as a catch-all term for masses that are seen in this location, but HBTs do not appear to be associated directly with the right atrium or other cardiac chambers. Alternatively, it may be used more specifically to indicate aortic body tumors (ABTs), chemodectomas that arise adjacent to the aortic root. Malignant transformation of ectopic thyroid and parathyroid tissue has also been reported in this location, so diagnosis requires biopsy and histopathology.[15]

Patients with HBT may be treated conservatively using periodic echocardiography to evaluate for recurrent effusion. A more aggressive approach includes thoracotomy to evaluate the mass for resectability, or biopsy for nonresectable lesions. A subtotal pericardectomy is performed to allow persistent effusion to drain into the pleural space, thereby avoiding future cardiac tamponade and pericardiocentesis. In more recent years a thoracoscopic pericardial window has emerged as a less-invasive palliative option. Although biopsy is feasible using this method, differentiation of the mass from nearby great vessels can be difficult and hemostasis may be more difficult.

The prognosis for HBT is variable. The classic description is one of a slow-growing tumor (ABT). HSA can appear to be a heart base mass but is expected to grow and metastasize much more quickly than an ABT. Some heart base masses can be associated with aggressive atrial or ventricular arrhythmias; others may cause signs of collapse related to poor cardiac output caused by impingement on the atria and great vessels. Signs of CHF may also be present. Ehrhart and colleagues reported survival times in 24 dogs with ABT as longer (median 730 days, range 1 to 1621 days) in patients that had a pericardectomy than in those that did not (median 42 days, range 1 to 180 days).[9] Of 46 dogs with a description of HBT that had histologic confirmation of the tumor type, only 24 were confirmed to have ABT. HSA was diagnosed in 16, 3 had ectopic thyroid carcinoma, and 3 had MM. Thus the echocardiographic diagnosis of heart base mass is not specific for ABT. Of the 24 dogs with ABT, 5 were Golden Retrievers, 5 were Labrador Retrievers, and 2 were German Shepherds. Only two dogs were brachycephalic (1 Boxer and 1 Boston Terrier).

44.7.3 Hemangiosarcoma

HSA is the most common primary cardiac tumor in the dog and typically is associated with the right atrial body, right atrioventricular junction, or the right auricular appendage.[3,11] HSA is an aggressive tumor with pulmonary metastasis presumed to be present at the time of diagnosis.[7] Approaches to therapy include euthanasia after the mass is identified, stabilization by pericardiocentesis followed by home care until symptoms of tamponade recur, palliative pericardial window via thoracoscopy, thoracotomy for pericardectomy, and possible tumor resection with or without chemotherapy. Right auricular masses that do not infiltrate the right atrial body may be removed along with the auricle using stapling equipment. Although early reports suggest a high incidence of complications and poor survival, more recent reports suggest that the prognosis may be better than previously reported.[7,29] Further study is required to better evaluate the effects of combined pericardectomy and chemotherapy with or without mass resection on the long-term prognosis for dogs with HSA.

44.7.4 Idiopathic Pericardial effusion

Idiopathic pericardial effusion (IPE) describes the syndrome of pericardial effusion, often recurrent, in the absence of known underlying cause. IPE is also known as idiopathic hemorrhagic pericardial effusion, benign idiopathic pericardial effusion, benign fibrosing pericarditis, and idiopathic pericardial hemorrhage. Biopsy 187 reveals inflammation and 188 varying degrees of fibrosis without evidence of neoplasia.[6,30] Although this syndrome appears to be a common cause of pericardial effusion in the dog, there is substantial overlap with cases of MM, which can also have a slow and insidious progression. In addition, small heart base masses or auricular appendage masses missed on echocardiography may lead erroneously to a working diagnosis of IPE.

44.7.4.1 Constrictive Pericarditis

Constrictive (restrictive) pericarditis is a subtype of idiopathic pericarditis. Fibrosis renders the pericardial sac nondistensible, so that cardiac tamponade occurs with small amounts of effusion (effusive-constrictive pericarditis) or even without pericardial effusion (pure constrictive pericarditis).[30] Restrictive physiology has been reported in association with tumor infiltrate, infectious pericarditis, and with pericardial foreign bodies.[26,27,31] Effusive-constrictive pericarditis most frequently develops in patients with a chronic history of pericardial effusion, with decreasing volumes of effusion present on serial examinations and centeses. Patients with constrictive pericarditis typically have signs of right-sided CHF (ascites, pleural effusion, jugular distention) without any underlying cardiac disease. Thoracotomy and pericardectomy should be recommended for patients with effusive-constrictive disease, although owners of older dogs may elect to start with a thorascopic pericardial window. In the latter case, owners are warned that the CHF may persist or recur if the remaining pericardium continues to fibrose around the heart.

Constrictive pericarditis is difficult to diagnose in the absence of pericardial effusion. Cardiac catheterization provides characteristic data but requires specialized equipment and is expensive. In patients for which there is a strong clinical suspicion of constrictive pericarditis, the patient may be referred for thoracotomy. Another option is exploratory thoracoscopy (where available) in which manipulation of the pericardial sac (thick and difficult to cut) confirms the suspicion. The procedure can be converted to an open chest thoracotomy for pericardectomy to allow complete release of the heart from the pericardial sac. Varying degrees of epicarditis generally accompany constrictive pericarditis. Although surgical “epicardial stripping” has been recommended for this condition, questions remain about the safety, efficacy, and necessity of this technique.[32]

44.7.5 Malignant Mesothelioma

MM does not appear to be as rare as was suggested previously in the literature and may be the underlying cause for some cases initially identified as IPE. Golden Retriever dogs are greatly overrepresented for this disease.[4,5] MM develops from the malignant transformation of the mesothelial cells lining the pericardial sac, pleural space, and occasionally the peritoneal space. MM may be suspected from pericardial or pleural fluid samples by a pathologist experienced with this disease, but definitive diagnosis requires histopathologic confirmation from tissue obtained via thoracoscopy or surgery.

MM is diagnosed frequently in patients that have a history of chronic and recurrent pericardial effusion, and that develop hemorrhagic pleural effusion following a pericardectomy. This suggests that MM may be insidious and difficult to diagnose, or alternatively that chronic inflammation may predispose dogs to the later development of MM.[5,13] In Stepien's small case series of 17 dogs with pericardial effusion, 2 of 8 dogs eventually diagnosed with MM were originally classified as having IPE via biopsy.[33] In this series of dogs, the chance of developing hemorrhagic pleural effusion was greatest during the first 3 months postoperatively.

The prognosis for dogs with MM is variable. Some animals may respond temporarily (months) to complete fluid drainage with a chest tube followed by prednisone at antiinflammatory dosages, with no recurrence of effusion for up to 6 months. Intracavitary cisplatin therapy has been described for the management of pleural and pericardial mesothelioma.[34] The author has found this therapy to be ineffective in dogs that have malignant pleural effusion and grossly evident pleural disease. Intracavitary and intravenous chemotherapy may be more successful in delaying metastasis in patients with a grossly normal thorax, no pleural effusion, and histopathologic confirmation of pericardial MM.[35]

44.8 PERICARDIAL DISEASE IN THE CAT

Pericardial disease is not nearly as common in the feline as the canine patient.[16] The reported causes of pericardial disease in the cat are listed in Box 44-2. Of these, FIP, LSA, and heart failure are the most common.[36] IPE has not been reported in cats. However, the author has treated a 4-year-old neutered male cat with a large volume of transudative pericardial effusion, no apparent underlying cause, and no fluid recurrence at 18 months postpericardiocentesis. PPDH occurs more commonly in the feline than in the canine patient. Many of these are incidental radiographic findings (even in the older patient), or the patient may become symptomatic when vascular compromise to an incorporated organ (usually omentum or a liver lobe) leads to fluid production and signs of cardiac tamponade. Surgical repair of the defect and removal of devitalized tissue are indicated.

45 Chapter 45 Bradyarrhythmias and Conduction Abnormalities

Dennis E. Burkett, VMD, PhD, DACVECC, DACVIM (Cardiology)

45.1 KEY POINTS

- Disease of cardiac tissue can result in regions of conduction delay or conduction block.
- Conduction delays or blocks can result in bradyarrhythmias or tachyarrhythmias.
- Conduction abnormalities that lead to bradyarrhythmias are due to conduction delays or conduction blocks within the specialized conduction system.
- Dogs and cats with persistent bradyarrhythmias causing clinical signs such as syncope generally require implantation of an artificial pacemaker.
- Right bundle branch block by itself does not usually cause clinical sequelae.
- Left bundle branch block usually indicates widespread disease and almost never occurs by itself as a benign abnormality.

45.2 INTRODUCTION

Conduction abnormalities may or may not produce an arrhythmia. The term *arrhythmia* literally means “no rhythm”. Because of this, some prefer the term *dysrhythmia*. However, arrhythmia is the more commonly used term and is used here to describe any abnormal heart rhythm. Mechanisms of arrhythmias primarily include disorders of cardiac electrical impulse conduction and electrical impulse formation. Conduction abnormalities commonly result in conduction delays and blocks but can also contribute to formation of ectopic tachyarrhythmias (premature depolarizations) by producing a substrate for reentry. Abnormalities of impulse formation produce both bradyarrhythmias and tachyarrhythmias.[1]

45.3 DISORDERS OF ELECTRICAL IMPULSE CONDUCTION

Almost all cardiac tissues depolarize during systole and help conduct the depolarization wave from site to site. Disease of cardiac tissue can result in regions of conduction delay or conduction block. Conduction delays or blocks can result in bradyarrhythmias or tachyarrhythmias.[1]

45.4 CONDUCTION ABNORMALITIES LEADING TO BRADYARRHYTHMIAS

Conduction abnormalities that lead to bradyarrhythmias are due to conduction delays or conduction blocks within the specialized conduction system. Conduction starts in the tissues surrounding the sinus node and terminates in the Purkinje network in the ventricles. Slowed conduction from the sinus node to the internodal tracts (first-degree sinoatrial block) does not cause any perceptible abnormality on an electrocardiogram (ECG) because it occurs before the P wave is inscribed. An intermittent conduction block in this region (second-degree sinoatrial block) results in the heart rhythm stopping, usually only for one beat, because of the lack of a P-QRS-T complex on the ECG. Complete blockage of conduction from the sinus node to the internodal tracts and atria theoretically results in atrial standstill and forces the atrioventricular (AV) node to take over the pacing function of the heart at a slower rate. In reality, other regions of automaticity (e.g., tissue around the coronary sinus) in the atria probably take over the function of the sinus node in this situation.[1]

Slowed conduction through the AV conduction system results in a prolongation in the PR interval (first-degree AV block). This conduction delay can occur in the proximal AV bundle, the AV node, the bundle of His, or the bundle branches (if both the left and right bundle branches are affected). It theoretically may also occur in the internodal tracts. An intermittent complete block of conduction results in the intermittent loss of a QRS-T complex (second-degree AV block). Third-degree AV block occurs when conduction is completely blocked through the AV node, bundle of His, or both bundle branches. Complete block of conduction through the internodal tracts is also reported to produce complete AV block (third-degree AV block) in dogs.[2]

45.5 DISORDERS OF IMPULSE FORMATION

Disorders of impulse formation encompass enhanced or depressed impulse formation by abnormal pacemaker cells and abnormal impulse formation by cells that are not normally automatic.[1]

45.6 DEPRESSED NORMAL AUTOMATICITY

A depression in normal automaticity results in a decrease in the discharge rate of an automatic site. This can be due to disease of the automatic tissue or depression of automatic tissue as a result of diverse influences, such as the parasympathetic nervous system, electrolyte disturbances (e.g., hyperkalemia), endocrine abnormalities (e.g., hypothyroidism), and hypothermia. To be manifested as a bradyarrhythmia, the sinus node must be affected, either 189 190 by itself or in combination with subsidiary pacemaker sites. For example, if the automatic cells within the AV node are suppressed by stimulation of the left vagus nerve such that their inherent rate decreases from 50 to 30 beats/min, but the sinus node continues to depolarize at a rate of 100 beats/min, the AV nodal cell depression will never be identified because the faster sinus nodal rate continues to control the heart rate. Normal automaticity can also be depressed by disease. Sick sinus syndrome is a disease in which the sinus node tissue is diseased and destroyed. When most of the sinus node tissue is destroyed, it loses its ability to produce depolarizations automatically.[1]

45.7 SPECIFIC BRADYARRHYTHMIAS

45.7.1 Sinus Bradycardia

Sinus bradycardia is a regular rhythm that originates in the sinus node but at a rate that is too slow for a given situation. A sinus rate less than 60 beats/min in an awake dog in an examination room is generally considered too slow. However, the sinus rate can be as slow as 20 beats/min in a normal dog that is sleeping. A heart rate less than 100 to 120 beats/min in a cat is generally too slow, although it may produce no clinical signs. Sinus bradycardia is an uncommon rhythm disturbance in clinical veterinary practice. It is identified most commonly during an anesthetic overdose. Other causes include increased vagal tone (athletic training, increased intracranial pressure, severe gastrointestinal (GI) or respiratory disease), sick sinus syndrome, hypothermia, severe hypothyroidism, and administration of parasympathomimetic or sympatholytic drugs, such as xylazine, digoxin, and β-blockers. Sick sinus syndrome is discussed later in this chapter. [1,3]

45.7.1.1 Treatment

Treatment of sinus bradycardia is unnecessary unless clinical signs are evident, and it depends on the underlying cause. If drug administration is precipitating the problem, it should be discontinued. If the problem is peracute, such as in a patient under anesthesia, atropine should be administered in an attempt to increase the heart rate. If this is unsuccessful, a β-adrenergic agonist, such as isoproterenol, can be administered; however, close monitoring for hypotension is recommended. Conscious patients that have no apparent underlying cause should be given atropine (0.04 mg/kg SC or IV) and an ECG repeated 30 minutes or 10 minutes later, respectively. In a dog with a normal sinus node, the heart rate should increase to 140 to 200 beats/min. If a normal response is identified, the diagnosis of increased vagal tone is made. If the dog is symptomatic, chronic anticholinergic therapy can be initiated. If there is no response or if the response is only partial (heart rate increases to 70 to 130 beats/min), sick sinus syndrome is most likely present.[1]

45.7.2 Sinoatrial Block

Sinoatrial block occurs when the tissue surrounding the sinus node fails to conduct the depolarization to the atria and ventricles. Some, but not all, depolarizations are conducted in a second-degree sinoatrial block. This is the most commonly diagnosed type of sinoatrial block. Second-degree sinoatrial block is diagnosed on an ECG when a pause occurs after a sinus beat and the interval between beats is an exact multiple (e.g., 2 or 3 times) of the normal P-P interval. This indicates that the sinus node is most likely depolarizing at its normal rate, but the depolarization is being blocked intermittently from conducting to the atria and internodal tracts. Consequently, no P waves and no QRS-T complexes are produced.[1]

45.7.3 Sinus Arrest

Sinus arrest is a cessation of sinus node activity for a short period. Although sinus arrest commonly is described as a pause in the sinus rhythm that lasts for more than two normal R-R intervals, this can also be seen with severe sinus arrhythmia. Consequently, there is a “gray zone” between severe sinus arrhythmia and sinus arrest in the dog.[1] Sinus arrest in dogs most commonly is due to either sinus node dysfunction or increased vagal tone. Sinus node dysfunction usually is due to end-stage sinus node disease and is commonly called *sick sinus syndrome*. Sinus node dysfunction in dogs can produce other arrhythmias, including sinus bradycardia and the so-called *tachycardia-bradycardia syndrome*. A supraventricular tachycardia can sometimes be seen with sick sinus syndrome, presumably because of reentry in or around the diseased sinus node. However, sinus arrest is the most common manifestation of end-stage sinus node disease in dogs.[4] Increased vagal tone can also produce periods of sinus arrest and can, on occasion, produce pauses long enough to cause syncope. Vagal tone can be increased secondary to chronic respiratory disease or secondary to systemic disease (e.g., GI disease).[1]

45.7.4 Escape Beats

Sinus arrest can last for a short period (<1 second in a dog) and be terminated by the sinus node depolarizing again. Sinus arrest can also last long enough that a subsidiary pacemaker, such as the AV node, takes over the heart rhythm. When the AV junction or the Purkinje fibers take over the heart rhythm, QRS complexes occur after a pause or occur at a rate between 20 and 60 beats/min. Depolarizations that occur after a pause are called *escape beats,* and the slow rhythms are called *escape rhythms*. Escape beats normally originate either from the

AV junctional region or from Purkinje fibers. Because the rates for these two sites differ, one can determine the origin of an escape beat by determining the rate at which it fires.

45.7.5 Sick Sinus Syndrome

Dogs with diffuse conduction system disease or with increased vagal tone to both the sinus node and the AV node may have more prolonged periods of sinus arrest because the subsidiary pacemakers are either suppressed or dysfunctional. If a period of sinus arrest lasts for more than approximately 6 seconds, weakness and syncope will occur.[4]

45.7.5.1 Treatment

Dogs with sick sinus syndrome generally require the implantation of an artificial pacemaker to prevent syncope. Occasionally a dog that is partially responsive to atropine administration can be treated chronically with an anticholinergic or a sympathomimetic agent. However, the disease usually progresses to the point that the arrhythmia becomes unresponsive to drug therapy and pacemaker implantation is required.

Dogs with vagally induced sinus arrest require therapy if clinical signs of episodic weakness or syncope occur. Anticholinergic or sympathomimetic therapy should be tried initially. Anticholinergic agents that can be administered on a long-term oral basis include atropine, isopropamide, prochlorperazine plus isopropamide (Darbazine), and propantheline. Atropine tablets are no longer manufactured. Isopropamide and propantheline are weak anticholinergic agents compared with atropine and generally are not as effective. Anticholinergic agents can produce side effects, including mydriasis and constipation.

Alternatively, a sympathomimetic agent can be administered. Terbutaline and albuterol syrup are the two choices. Sympathomimetic drugs act indirectly by counteracting the effects of increased vagal tone. They can produce side effects, including hyperactivity and tachycardia. Dosage adjustment may reduce the side effects while maintaining efficacy. Dogs that have intolerable side effects or that are unresponsive to medical therapy should have a pacemaker implanted. The pacemaker will prevent clinical signs that occur secondary to sinus arrest.[1]

45.8 ATRIAL STANDSTILL

45.8.1 Definition, Causes, and Electrocardiographic Findings

Atrial standstill is the rhythm diagnosis when no P waves are visible on the ECG and atrial fibrillation is not evident (Figure 45-1). Atrial standstill occurs when the atrial myocardium is unable to depolarize. This occurs for two broad general reasons: (1) either the atrial muscle is destroyed by disease or (2) the serum potassium concentration is increased to a level at which the resting membrane potential of atrial cells is so low (i.e., closer to zero) that they no longer depolarize.

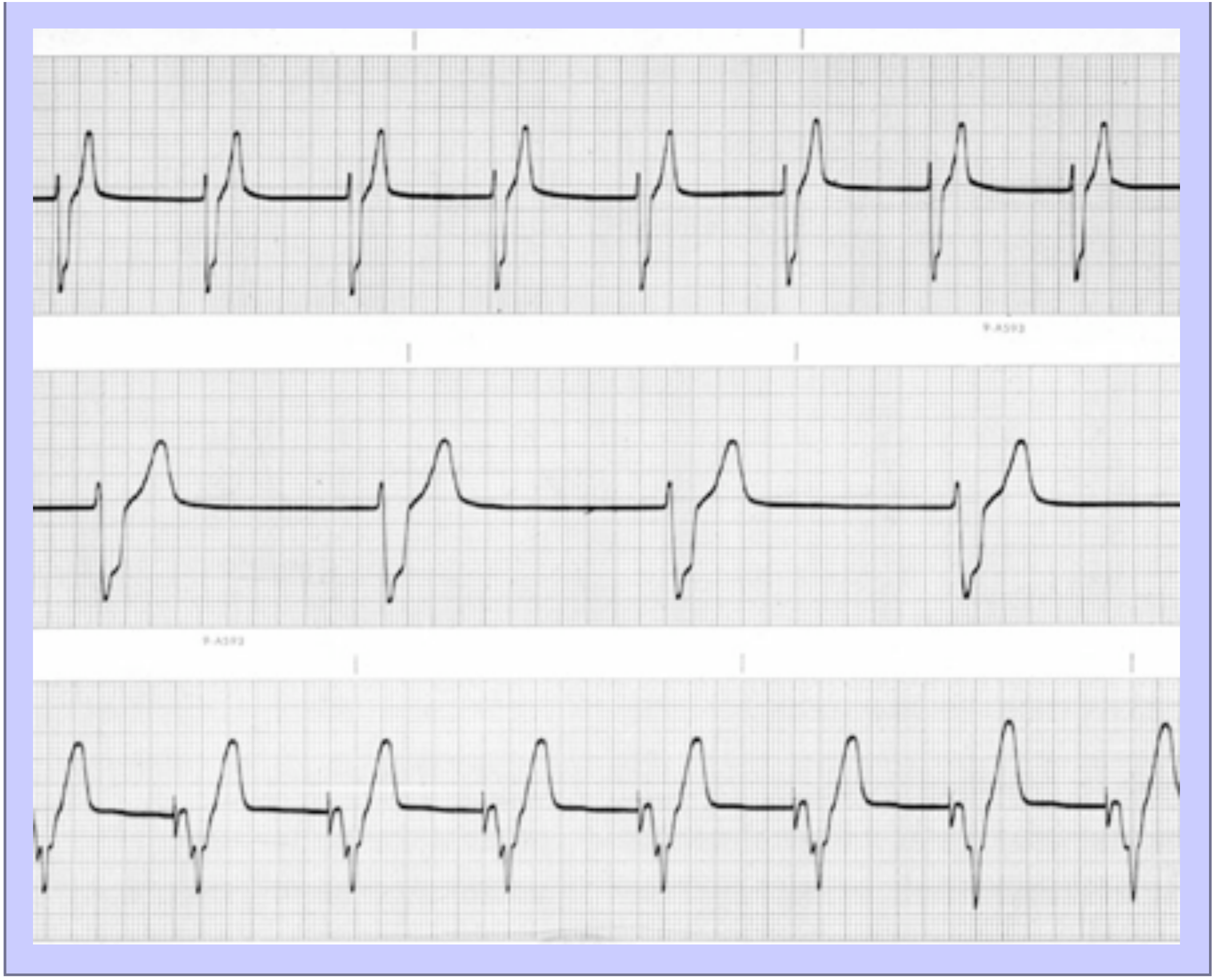
In the former, a particular type of cardiomyopathy or myocarditis destroys atrial myocardium and replaces it with fibrous tissue. In this disease, the internodal tracts and the sinus node apparently are also destroyed. Consequently, the AV junctional tissue takes over the pacing function of the heart. These dogs present with heart rates usually in the 40- to 60-beats/min range. A pacemaker can be implanted to control signs of episodic weakness or syncope. Pacemaker implantation may also improve signs of heart failure by increasing cardiac output through the increase in heart rate (see Figure 45-1). Long-term prognosis for these dogs is usually poor because of progressive AV valve regurgitation and ventricular myocardial dysfunction.[1]

In dogs or cats with moderate to severe hyperkalemia, the atrial myocardium loses its ability to depolarize (Figure 45-2). The sinus node and ventricular myocardium retain the ability to depolarize until even higher potassium concentrations are achieved. Moderate to severe hyperkalemia results in a sinoventricular rhythm in which the sinus node controls the electrical activity of the heart. Sinus node depolarization is carried through the internodal tracts to the AV node and the ventricles, and because the atrial myocardium does not depolarize, no P waves are generated on the ECG. Hyperkalemia also causes slowed depolarization of the sinus node and ventricular myocardium, resulting in a sinus bradycardia and prolonged QRS complexes.[1]

45.9 ATRIOVENTRICULAR BLOCKS

AV block refers to conduction disturbances that alter conduction of the cardiac electrical impulse from the sinus node to the ventricles. Altered intraatrial conduction, altered AV junctional conduction, altered bundle of His conduction, and altered conduction in both bundle branches simultaneously can alter AV conduction. AV blocks are classified as first-degree, second-degree, and third-degree AV blocks.[1]

Figure 45-1 Lead II electrocardiogram tracings from a dog that was presented for being lethargic for 1 month and that had had ascites for the previous 2 weeks. The heart rate was 50 to 60 beats/min on auscultation. There are no P waves visible in the top and middle tracings. The top tracing is recorded at 25 mm/sec, and the middle trace is recorded at 50 mm/sec paper speed. The ventricular rate is 55 beats/min and regular. These features are characteristic of atrial standstill. The QRS complexes are wide and bizarre in appearance. The configuration of the QRS complexes indicates that the escape focus in this dog is either in Purkinje fibers (ventricular escape beats) or in the atrioventricular junctional tissue and not conducted in the right bundle branch (nodal escape rhythm with a right bundle branch block). Because the rate is consistent with a nodal escape rhythm, the escape focus is most likely in the atrioventricular junctional tissue. The bottom tracing was recorded at 50 mm/sec after pacemaker implantation. The generator was set at a rate of 100 beats/min. A sharp deflection precedes each QRS complex. This is a so-called *pacemaker spike* that occurs when the generator produces its electrical signal. The pacemaker spikes are exactly 0.6 second apart, indicating that the set rate (100 beats/min) is being produced. The QRS complexes are wide and bizarre in appearance, because the wave of depolarization originates within myocardium and must conduct from muscle cell to muscle cell. (1 cm = 1 mV.) From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.



45.9.1 First-Degree Atrioventricular Block

45.9.1.1 Definition and Electrocardiographic Diagnosis

First-degree AV block occurs when the conduction time from the sinus node to the ventricles is prolonged beyond normal, causing a prolongation in the PR interval. It does not result in an arrhythmia. First-degree AV block is diagnosed when the PR interval is longer than 0.13 second in a dog and longer than 0.09 second in a cat. It can occur as an isolated abnormality or may be present in conjunction with second-degree AV block (Figure 45-3).

45.9.1.2 Causes

First-degree AV block can occur because of degenerative or inflammatory disease of the conduction system. It can also occur secondary to drug administration (e.g., digitalis glycosides, β-blockers, calcium channel blockers), hyperkalemia, and increased vagal tone.[1]

Figure 45-2 Sequential electrocardiogram tracings from a cat with anuric renal failure, severe hyperkalemia, and metabolic acidosis before *(top tracing)*, during (middle three tracings), and after *(bottom tracing)* hemodialysis. The top tracing (serum potassium concentration = 10.9 mEq/L) shows a slow heart rate or approximately 100 beats/min, a wide QRS complex, and no P waves. As the potassium concentration decreases, the QRS complex duration decreases, the heart rate increases, and the T waves become large and "tented." The QRS complexes and T waves normalize at a potassium concentration of 7.1 mEq/L, and P waves reappear when the potassium concentration reaches 6.6 mEq/L. (From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.) From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.

45.9.1.3 Prognosis

The prognosis for first-degree AV block is good to guarded. First-degree AV blocks that occur secondary to drug administration and electrolyte abnormalities disappear when these abnormalities are corrected. First-degree AV blocks secondary to increased vagal tone result in no clinical sequelae. Degenerative disease of the conduction system mild enough to produce only first-degree AV block often does not progress; however, it may, on occasion, progress to higher degrees of AV block. No treatment is necessary for first-degree AV block.[1]

45.9.2 Second-Degree Atrioventricular Block

45.9.2.1 Definition and Electrocardiographic Diagnosis

Second-degree AV block occurs when some sinus depolarizations conduct through the AV junction to reach the ventricles and others do not. On auscultation it is heard as “dropped beats.” Second-degree AV block produces an abnormal heart rhythm. It can range in severity from only an occasional P wave not followed by a QRS complex on the ECG to most P waves being blocked.

Figure 45-3 Lead II electrocardiogram tracing recorded from a dog that presented because of repeated episodes of syncope. The PR interval is markedly prolonged to 0.36 second (first-degree atrioventricular [AV] block). The rhythm is a second-degree AV block that varies between 3:1 and 2:1 AV block. The atrial rate is reasonably constant at approximately 80 beats/min. When there is a 2:1 block, the ventricular rate is approximately 40 beats/min. When the block is 3:1 it is approximately 27 beats/min. This is an example of first-degree AV block and high-grade second-degree AV block. Atropine administration increased the atrial rate but did not change the ventricular rate. A pacemaker was implanted. (Paper speed = 25 mm/sec; 1 cm = 1 mV.) (From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.) From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.

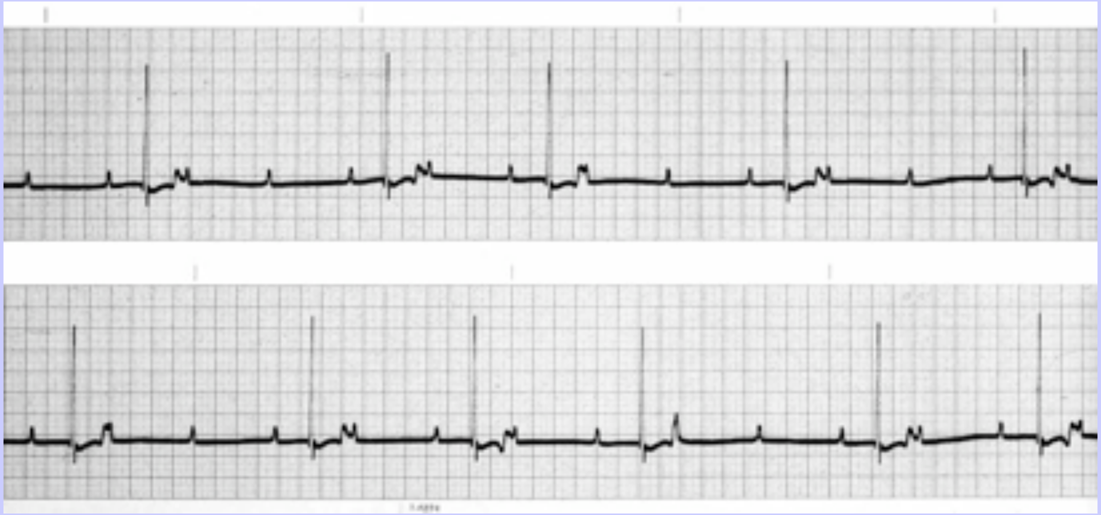

Figure 45-4 Lead II electrocardiogram tracing recorded from a dog with chronic respiratory disease and an arrhythmia. The ninth P wave is not followed by a QRS complex. Before this so-called *dropped beat,* the PR interval prolongs and then shortens immediately after the block. This is an example of a Mobitz type I (type I or Wenckebach) second-degree atrioventricular block. This type of atrioventricular block is usually vagally induced and can be abolished with atropine administration. (Paper speed = 50 mm/sec; 1 cm = 1 mV.) (From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.) From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.

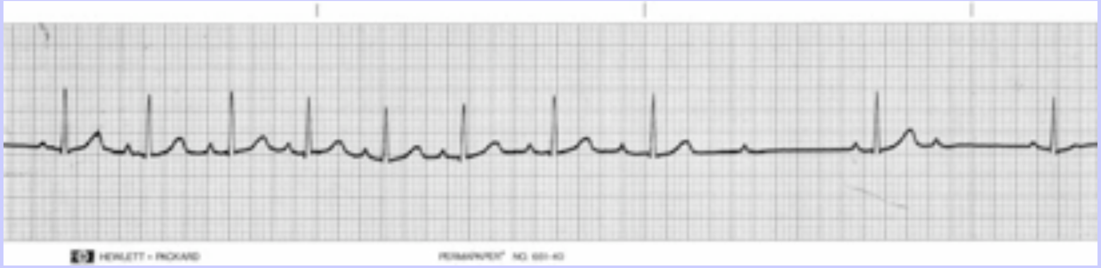


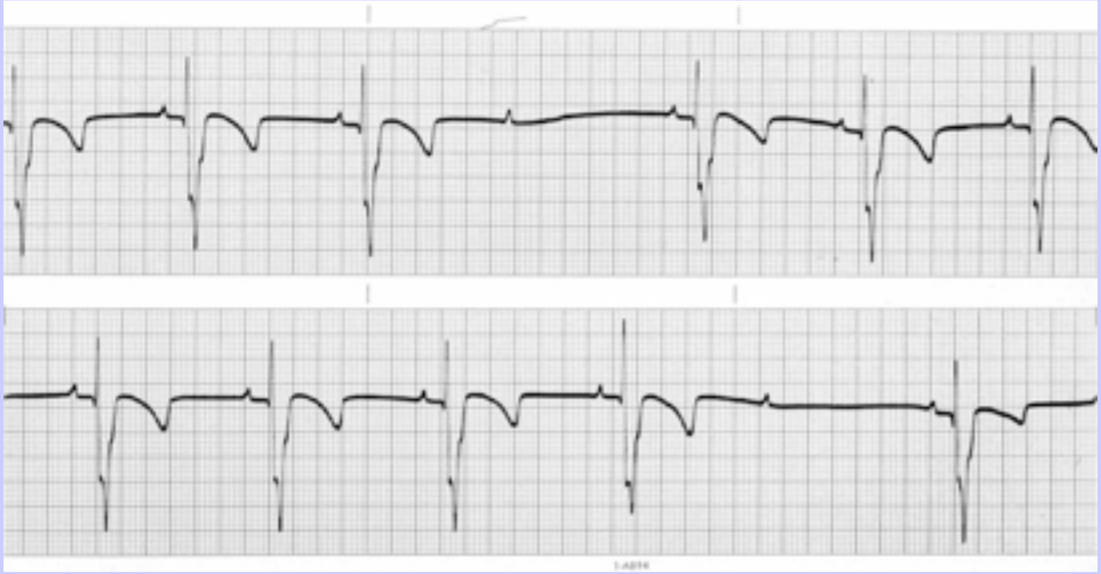
Second-degree AV block is divided into type I, type II, and high-grade blocks. In a type I (Mobitz type I), or Wenckebach, second-degree AV block, the PR interval progressively prolongs before the blocked beat (Figure 45-4). The PR interval before the block may be normal or too long (first-degree AV block). Type II (Mobitz type II) second-degree AV block is characterized by sudden failure of conduction without alteration in the PR interval (Figure 45-5). The PR interval may be normal or prolonged. Second-degree AV blocks commonly are labeled with the number of P waves followed by the number of QRS complexes generated. For example, if every other sinus depolarization is blocked from reaching the ventricles, this is called a 2:1 second-degree AV block. Similarly, if every fourth P wave is not followed by a QRS complex, it is called a 4:3 AV block (four P waves and three QRS complexes). Any block that is 2:1 or greater cannot be classified as type I or type II because there is no chance to determine whether progressive prolongation is occurring or not. Consequently, it is called a *high-grade block* (see Figure 45-3).[1]

45.9.2.2 Mechanisms

Second-degree AV block can be a normal finding (functional second-degree AV block). The normal AV node 192
prevents rapid impulses from being transmitted to the ventricles. This type of functional block is extremely 193
important in patients with atrial fibrillation or atrial flutter. If the AV junction were not present, atrial

fibrillation and flutter would conduct 1:1 to the ventricles, resulting in ventricular fibrillation and immediate death.

Figure 45-5 Lead II electrocardiogram tracing recorded from a dog that presented with an arrhythmia. This is a sinus rhythm with intermittent periods of second-degree atrioventricular (AV) block. The PR interval does not change before or after the block, so this is a Mobitz type II (type II) second-degree AV block. The QRS complex configuration is abnormal (deep and wide S waves), and the complexes are too wide. The mean electrical axis and the terminal axis were shifted to the right. Consequently, the diagnosis was a type II second-degree AV block with a right bundle branch block. This dog progressed to a third-degree AV block, developed syncope, and an artificial pacemaker was implanted. (Paper speed = 50 mm/sec; 1 cm = 1 mV.) (From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.) From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. In Kittleson MD, Kienle RD, editors: *Small animal cardiovascular medicine,* St Louis, 1998, Mosby.



As with first-degree AV block, conduction abnormalities in any region of the conduction system can create second-degree AV block. Few studies have been performed to delineate the exact sites of block in dogs or cats with second-degree AV block. Most type I second-degree AV blocks are caused by drug toxicity, physiologic changes, or disease within the AV node itself. One study in dogs, however, has documented type I second-degree AV block in dogs with His bundle pathology created by ischemia.[5]

45.9.2.3 Causes

Second-degree AV block can be observed in normal dogs, especially in puppies 8 to 11 weeks of age.[6] This normal finding occurs only at rest and is a Mobitz type I block. The presence of second-degree AV block in a dog in an examination room is almost always abnormal. It can occur secondary to increased vagal tone. The AV node is richly innervated with vagal fibers. Consequently, increased vagal tone usually produces a type I rather than a type II second-degree AV block. Chronic respiratory disease is a common cause of second-degree AV block secondary to increased vagal tone in dogs. Digitalis is an example of a drug that can produce second-degree AV block, primarily through its ability to increase vagal tone. Other drugs that can cause second-degree AV block via vagal stimulation include xylazine and intravenous atropine. The increase in vagal tone with intravenous atropine occurs before the decrease in vagal tone and is transient. Second-degree AV block can also be due to conduction system disease.

45.9.2.4 Treatment

Patients with type I or type II second-degree AV blocks generally do not exhibit any clinical signs. Consequently, usually no treatment is necessary for these patients except to remove an inciting cause if one exists. Dogs with high-grade second-degree AV block may not exhibit any clinical signs or may have signs identical to dogs with third-degree AV block (primarily syncope and weakness). Treatment for these patients is described in the next section[1] (see Figure 45-3).

Figure 45-6 Lead II electrocardiogram tracings recorded from a dog that was presented with syncope. The P waves and the QRS complexes are dissociated (atrioventricular dissociation), as evidenced by the varying PR intervals. The sinus rate (approximately 180 beats/min) is faster than the ventricular rate (35 beats/min). These characteristics are diagnostic of third-degree atrioventricular block. The ventricular rate suggests that the escape rhythm originates in the Purkinje fibers. The QRS duration, however, is normal, which means that the escape focus must be in the atrioventricular junction. (*Top,* Paper speed = 50 mm/sec; 1 cm = 1 mV. *Bottom,* Paper speed = 25 mm/sec; 1 cm = 1 mV.) (From Kittleson MD: Diagnosis and treatment of arrhythmias [dysrhythmias]. 45.9.3 Third-Degree Atrioventricular Block

45.9.3.1 Definition and Electrocardiographic Diagnosis

Third-degree AV block (complete heart block) occurs when there is no conduction between the sinus node and the ventricles (Figure 45-6). In third-degree AV block, the sinus node depolarizes at its own inherent rate, depolarizing the atria and producing P waves, whereas the ventricles are depolarized by a subsidiary pacemaker (either the AV node or Purkinje fibers) that depolarizes at a slower rate, depolarizing the ventricles and producing QRS complexes. On the ECG, there is no relationship between the P waves and QRS complexes (AV dissociation), resulting in varying PR intervals from beat to beat (see Figure 45-6). The atrial rate and the ventricular rate are often constant such that the P-P intervals and the R-R intervals are constant.[1]

45.9.3.2 Causes

The cause of third-degree AV block in almost all cases is unknown. Most affected canine and feline patients are middle-age to geriatric patients. This may suggest a degenerative disease of the conduction system. Rarely, a dog younger than 1 year of age will have third-degree AV block that may be congenital. Third-degree AV block has been reported in one dog with myocarditis that was seropositive for Lyme disease.[7]

AV block also has been described in humans with Lyme carditis. The AV block in this disease is usually transient. Occasionally, third-degree AV block in dogs will resolve spontaneously or will resolve after glucocorticoid administration, suggesting an inflammatory lesion in the conduction system.[1] It is interesting to speculate that this situation could be secondary to Lyme carditis, but there is no evidence to support this.

AV nodal disease has been described in dogs that have died suddenly. Lesions described include mineralization of the crest of the interventricular septum, with degeneration and fibrosis of the AV conduction fibers and cartilage and bone formation in the central fibrous body.[8] Doberman Pinschers appear to be overrepresented in the group of dogs described with these findings.[9]

45.9.3.3 Clinical Signs

Dogs with third-degree AV block generally either have no clinical signs or are presented because they are having episodes of syncope. Most cats have no clinical signs of their disorder. In general, clinical presentation depends on the underlying heart rate. Dogs generally fall into two categories: those with a ventricular rate between 40 and 60 beats/min and those with a heart rate between 20 and 40 beats/min. His bundle escape rhythms typically have a rate of 35 to 65 beats/min, so the AV node is likely the site of the block in dogs with this heart rate (see Figure 45-6).

Apparently, the subsidiary pacemakers in cats depolarize at a rate faster than those of dogs and humans. Cats with third-degree AV block generally have a ventricular rate of 80 to 130 beats/min. Because cats' ventricular rates are generally quite fast and because cats are usually sedentary, those with third-degree AV block usually do not exhibit any clinical signs.[1]

45.9.3.4 Clinical Findings

On physical examination, most dogs with third-degree AV block appear normal between syncopal events. However, in some dogs the heart rate is slow enough to produce signs of weakness. In dogs that appear weak, measuring whole blood lactate concentration may be helpful. In many of these dogs it is increased, signifying inadequate oxygen delivery to systemic tissues because of a low cardiac output.

On auscultation, the heart rate is slow and the first heart sound may be loud. By listening carefully in a quiet room, one can often identify soft fourth heart sounds in the background. These sounds are generated each time the atria contract. Cannon *a* waves may be generated in the jugular veins when atrial contraction occurs when the mitral valve is closed.[1]

45.9.3.5 Treatment

Treatment of third-degree AV block is implantation of an external pacing generator and lead (artificial pacemaker). Some dogs with very slow heart rates (usually less than 30 beats/min) are very weak, and some are unable to stand at presentation. In these dogs, measuring blood lactate concentration is recommended. If it is increased, place a temporary pacemaker, implant a permanent pacemaker on an emergency basis, or administer isoproterenol as a constant rate intravenous infusion to increase the heart rate until a permanent pacemaker can be implanted. Isoproterenol infusion is generally safe, but tachyarrhythmias and hypotension secondary to systemic arteriolar dilation can be produced.[1]

45.10 BUNDLE BRANCH BLOCKS

The left and right bundle branches originate in the bundle of His. Their function is to spread the cardiac electrical impulse rapidly to the Purkinje fibers in both ventricles and to coordinate the depolarization of the ventricles. The bundle branches, like the rest of the conduction system, cannot be seen on gross examination.[1]

Ventricular depolarization is abnormal in bundle branch blocks. Normally the cardiac electrical impulse proceeds from the AV node through the bundle of His, and then rapidly down both left and right bundle branches to the Purkinje fibers. The bundle branches spread the cardiac electrical impulse to both ventricles rapidly. If a bundle branch cannot conduct to a particular ventricle, conduction to that ventricle still occurs. However, the impulse must travel from muscle cell to muscle cell. This is a much slower process. Consequently, if a bundle branch is unable to conduct the cardiac electrical impulse, conduction to the unaffected ventricle is normal and conduction to the ventricle served by the abnormal bundle branch is delayed. Complete block of both the right and left bundle branches produces complete (third-degree) AV block.

Bundle branch blocks are usually persistent. However, they can also be intermittent (i.e., the QRS morphology is normal at times and abnormal at other times).[10] Intermittent bundle branch blocks are most commonly rate related; they occur at certain heart rates but not at others. Bundle branch blocks can occur when the heart rate increases or decreases to a certain level, but most commonly they emerge at faster heart rates. In this situation, at least some cells in a bundle branch must have a prolonged refractory period.[11]

45.10.1 Right Bundle Branch Block

Right bundle branch block (RBBB) can be complete or incomplete; it occurs because of conduction system disease or secondary to right ventricular enlargement. Rarely, a dog can have a congenital RBBB. The cause of most conduction system disease in dogs and cats is unknown. At the time of diagnosis, all that can be seen histologically are degenerative changes. Because conduction time is so prolonged, the QRS complex is wider than normal (longer than 0.06 second in the dog and longer than 0.04 second in the cat). RBBB causes decreased R wave amplitude and large, wide S waves in leads I, II, III, and aVF.

RBBB by itself does not cause clinical sequelae. Dogs can have a congenital RBBB, be normal clinically, and live a normal life span.[10] The only hemodynamic abnormality produced by a RBBB is delayed activation of the right ventricle and a prolonged right ventricular ejection time (the time it takes to eject blood in systole). This results in delayed closure of the tricuspid and pulmonic valves and can result in split heart sounds, most commonly a split second heart sound.[10]

45.10.2 Left Bundle Branch Block

The left bundle branch is a fan-shaped network of interwoven fibers. Complete disruption of the left bundle branch results in delayed depolarization of the left ventricle. Because the left ventricle can no longer be depolarized from the left bundle branch, depolarization must proceed down the right bundle branch and across the interventricular septum to the left ventricle. In this situation the initial depolarization of the ventricles is relatively normal and may produce a small Q wave. After this, the left ventricular depolarization wave predominates like it normally does. Consequently, the orientations of the QRS complexes on the ECG are normal (there is no change in the mean electrical axis).

Because of the delayed left ventricular activation, one major change noted in the QRS complex is an increase in its duration (it is wider than normal). The other major change that commonly occurs is an increase in the R wave height in the lead most parallel with the left ventricular depolarization wave (usually lead II). Besides abnormal ventricular depolarization, ventricular repolarization is also abnormal in left bundle branch block (LBBB). The T wave in LBBB is always large and opposite in polarity to the QRS complex.[1]

LBBB occurs secondary to degenerative conduction system disease, left ventricular myocardial disease, or diseases that produce severe left ventricular hypertrophy. Because the left bundle branches early and widely throughout the left ventricle, LBBB usually indicates widespread disease. LBBB almost never occurs by itself as a benign abnormality.[1]

46 Chapter 46 Supraventricular Tachyarrhythmias

Kathy Wright, DVM, DACVIM (Cardiology and Small Animal Internal Medicine)

46.1 KEY POINTS

- Supraventricular tachyarrhythmias (SVTs) are rapid rhythms originating from or dependent on tissues above the ventricles.
- Once thought relatively benign, SVTs are an important cause of morbidity, and even mortality, in small animals.
- Recognition of underlying structural heart disease and the contribution of SVTs to myocardial dysfunction are critical for accurate patient treatment.
- Acute termination of SVTs should be accomplished by medical means, based on the likely mechanism of the tachyarrhythmia. Drugs that slow atrioventricular (AV) nodal conduction often are combined with those that suppress an abnormal atrial or nodal focus or interrupt a reentrant circuit within an accessory pathway or the atria.
- Long-term management can include antiarrhythmic therapy or procedures to eliminate an abnormal electrical circuit (such as an accessory pathway). Individual responses to antiarrhythmic drugs, both therapeutic and adverse effects, must be monitored carefully, with individual adjustments made accordingly.

46.2 INTRODUCTION

SVTs are defined as rapid cardiac rhythms that (1) originate in the atria or AV junction (above the bundle of His) or (2) involve the atria or AV junction as a critical component of a tachyarrhythmia circuit.[1] The most clinically useful classification system broadly groups SVTs into atrial tachyarrhythmias or AV nodal–dependent tachyarrhythmias.[2] Such classification helps us to guide therapy of these abnormal heart rhythms and is discussed in detail later in this chapter.

The importance of managing SVTs has become clearer in recent years. Not only can these abnormal rhythms result from structural heart disease, but they can be the cause of structural heart disease, as well. Pacing studies and clinical cases have demonstrated that sustained or frequently occurring SVTs can result in a poorly functioning, dilated heart.[3–6] This is known as *tachycardiomyopathy* or *tachycardia-induced cardiomyopathy* and cannot be distinguished initially from idiopathic dilated cardiomyopathy. Tachycardiomyopathy, however, can be partially or completely reversible with adequate rhythm control. It is the most frequently unrecognized curable cause of heart failure in human (and likely veterinary) patients.[4] SVTs can also result in sudden death, although less frequently than does sustained ventricular tachycardia. Sudden death has occurred in a number of dogs with sustained tachyarrhythmias secondary to accessory pathways. The presumed mechanism is myocardial ischemia that gives rise to ventricular tachycardia and fibrillation, although the sudden onset of electromechanical dissociation has been seen in two dogs.

46.3 HISTORICAL DATA

Careful questioning of owners should be pursued to try to determine clinical signs that may be related to an SVT or structural heart disease. Those commonly reported include decreased exercise tolerance, weakness, collapse, gastrointestinal (GI) signs (particularly vomiting and inappetence), noticeably rapid heart rate (most evident when the animal is in lateral recumbency), and pulsing of the ears or bobbing of the head with each heart beat. Several animals were diagnosed initially as having primary GI disease, only to find later that their GI signs were related to an SVT. Signs reported by owners whose animals have developed congestive heart failure include dyspnea, tachypnea, and abdominal distention. Some owners believe that their dogs are asymptomatic, only to realize how affected they have been once the tachyarrhythmias is controlled.

46.4 PHYSICAL EXAMINATION FINDINGS

It is important to remember that at the time an animal with SVT is presented to the veterinarian, the physical examination findings may be normal if the SVT was paroxysmal. On the other hand, a tachyarrhythmia may be detected at the time of arrival or while the animal is hospitalized. Decreased systemic arterial pulse quality, mucous membrane pallor, a peritoneal fluid wave, tachypnea or dyspnea with auscultable pulmonary abnormalities, murmurs of mitral or tricuspid regurgitation secondary to tachycardiomyopathy, and murmurs associated with a primary underlying heart disease are all potential physical examination findings.

46.5 EXAMINING THE ELECTROCARDIOGRAM

46.5.1 Distinguishing Supraventricular from Ventricular Tachyarrhythmias

It is most important to distinguish ventricular tachyarrhythmias from SVTs because the treatment and differential diagnoses for each will differ. A narrow QRS complex tachyarrhythmia will almost always be an SVT. The vast majority of wide complex tachyarrhythmias are ventricular tachyarrhythmias. Up to 80% of wide complex tachyarrhythmias in human case series are ventricular in origin.[7] If the patient has prior ECGs when in sinus rhythm or exhibits conversion, even briefly, to sinus rhythm during the tachyarrhythmia, the QRS complexes can be compared with those during tachyarrhythmia. Preexisting bundle branch block can thus be identified. Distinguishing ventricular arrhythmias from SVTs with bundle branch aberration that develops during SVT or antegrade conduction of a tachycardia over an accessory pathway (very rare in companion animals) is the most difficult task for the clinician. No criteria are absolute; however, the following rules are helpful[7,8]:

1. Identification of P′ waves (representing atrial depolarization that originates outside the sinoatrial node) with a consistent relationship to the QRS is indicative of an SVT with aberration. In dogs undergoing electrophysiologic studies, retrograde AV nodal conduction is rare and has a long effective refractory period when it does occur. As many leads as possible should be run to identify P′ waves. Lewis leads, using the right and left arm electrodes of the standard ECG placed on various positions over the precordium while monitoring the lead I channel, are very helpful in identifying P′ waves.

2. QRS fusion complexes are a hallmark of ventricular tachyarrhythmia.

3. If the tachycardia terminates in response to a vagal maneuver, this indicates that the tachycardia is supraventricular in origin. If the tachycardia does not terminate with a vagal maneuver, it may be of either supraventricular or ventricular origin.

4 If the tachycardia terminates with the administration of intravenous lidocaine, this diagnostic and therapeutic procedure indicates that the wide complex tachyarrhythmia is much more likely ventricular in origin.

46.5.2 Diagnosing Atrial Versus Atrioventricular Node–Dependent Tachyarrhythmias

Once an SVT has been identified, it is helpful to determine if it is atrial or AV node dependent. If the SVT is irregularly irregular and no organized atrial activity is identifiable, then atrial fibrillation is the diagnosis. Differentiation of regular SVTs involves several steps. Initiation and termination of the SVT are important diagnostic features. If an SVT continues despite AV block, it is atrial in origin. If a premature ventricular contraction terminates the SVT, it is far more likely that it is an AV node–dependent tachyarrhythmia. If a vagal maneuver terminates the SVT, it is also far more likely an AV node–dependent tachyarrhythmia.

Identification of P′ waves is an important diagnostic step, but it can be difficult in a rapid SVT. Precordial and Lewis leads help with their identification. The relationship of the P′ wave to the preceding QRS complex relative to the total R-R interval identifies an SVT as either a short RP′ (RP′ interval ≤50% of the RR interval) or a long RP′ (RP′ interval >50% of the RR interval) SVT.[1] Important identifying characteristics and mechanisms of the more common SVTs are reviewed in Table 46-1 and Figure 46-1. The most commonly occurring SVTs in small animals appear to be atrial fibrillation, intraatrial reentrant tachycardia, orthodromic AV reciprocating tachycardia (a macroreentrant circuit in which an impulse is carried from the atria to the AV node–His-Purkinje system to the ventricles to a retrograde-conducting accessory pathway to the atria), and automatic atrial tachycardia. Because the retrograde conduction properties of the canine AV node are poor, AV nodal reentrant tachycardia has not been identified in dogs undergoing electrophysiologic study for clinical tachyarrhythmias.

46.6 TREATMENT OF SUPRAVENTRICULAR TACHYARRHYTHMIAS

It is essential to identify predisposing factors that are contributing to the initiation or perpetuation of SVT in a given patient. Acid-base abnormalities, electrolyte disturbances, significant anemia, and hypoxemia should be corrected. AV node–dependent tachyarrhythmias are treatment in some cases by single-agent therapy aimed at interrupting conduction through the AV node. Other AV node–dependent SVTs require that an additional drug be added to suppress another site in the circuit. Atrial tachyarrhythmias are best addressed by dual therapy: one drug to slow AV nodal conduction and a second drug to inhibit the atrial automatic focus or interrupt conduction in an atrial reentrant circuit. Sites of antiarrhythmic drug action in SVT are shown in Figure 46-2.

Table 46-1 Characteristics of Common Supraventricular Tachyarrhythmias

SVT Mechanism	P′ Waves Visible?	P′ Wave Morphology	RP′ vs. RR Interval	Initiation and Termination	Response to AV Block
ATRIAL					
Automatic atrial	Yes	Variable, differs from sinus P	Varies with SVT rate, often long	Gradual rate acceleration and deceleration	SVT continues
Intraatrial reentry	Yes	Variable, differs from sinus P	Varies with SVT rate, often long	Abrupt onset and offset at SVT rate	SVT continues
Atrial flutter	*f* Waves	Identical saw-toothed F waves	Not applicable	Abrupt onset and offset at SVT rate	SVT continues
Atrial fibrillation	No, *f* waves may be seen	No visible P waves; *f* waves may be seen	Not applicable	Abrupt onset and offset at SVT rate, often incessant	SVT continues
AV NODE–DEPENDENT					
OAVRT	Often visible within ST-T segment	Retrograde: (–) in II, III, avF	Typically short	Abrupt onset and offset	SVT terminates
Automatic junctional	Generally yes; AV dissociation common	Variable	Variable	Gradual rate acceleration and deceleration	SVT continues with AV dissociation
AV nodal reentry	Generally no	Retrograde: (–) in II, III, avF	Short	Abrupt onset and offset	SVT terminates

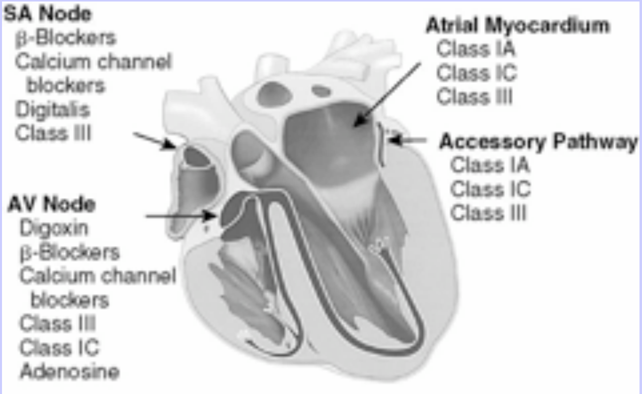
46.6.1 Emergent Therapy

Animals in incessant, rapid SVT require interruption of the tachyarrhythmia. Vagal maneuvers may be tried first and may terminate the SVT if it is AV node dependent. Subjectively, the most effective vagal maneuver in small animals is carotid sinus massage. Sustained, gentle compression is applied for 5 to 10 seconds over the carotid sinus, which is located immediately caudal to the dorsal aspect of the larynx. The ECG needs to be monitored continuously throughout the procedure. More often, however, the SVT does not terminate with such maneuvers and drug therapy must be initiated.

Parenteral negative dromotropic agents can be used to interrupt a tachyarrhythmic circuit that uses the AV node and is causing hemodynamic compromise. In atrial tachyarrhythmias, such agents will not terminate the arrhythmia but will slow conduction to the ventricles. Intravenous calcium channel blockers, β-blockers, or adenosine have been used for this purpose. Blood pressure and ECG should be monitored before and throughout the procedure.

A comparison of the electrophysiologic and hemodynamic responses of intravenous diltiazem, esmolol, and adenosine in normal dogs demonstrated the superior efficacy of intravenous diltiazem in slowing AV nodal conduction while maintaining a favorable hemodynamic profile.[9] Esmolol was a significantly less effective negative dromotrope than diltiazem and caused a severe drop in left ventricular contractility measurements at dosages which did prolong AV nodal conduction. Adenosine, even at dosages of 2 mg/kg, was ineffective in slowing canine AV nodal conduction. A similar study has not been performed in cats. Diltiazem is administered at dosages of 0.125 to 0.35 mg/kg slow IV over 2 to 3 minutes.[1,9] A constant rate infusion (CRI) (0.125 to 0.35 mg/kg/hr) can be used if frequent recurrence of the arrhythmia occurs before the onset of efficacious oral antiarrhythmic therapy. Esmolol is an ultrashort-acting β_1-selective blocker that typically is administered at 0.5 mg/kg IV over 1 minute.[1] Its brief half-life compared with that of propranolol makes esmolol the preferred parenteral β-blocker. It should nonetheless be used very cautiously in animals with impaired ventricular systolic function, because it will markedly depress ventricular contractility.

Figure 46-2 Sites of action for various antiarrhythmic drugs, highlighting their utility for specific supraventricular tachyarrhythmias. *AV,* Atrioventricular; *SA,* sinoatrial. From Bonagura JD: *Kirk's current veterinary therapy XIII,* ed 13, Philadelphia, 2000, Saunders.



Other agents can prolong the effective refractory period or slow conduction within the myocardium, including an accessory pathway or atrial myocardium. These agents can terminate both atrial and AV node–dependent tachyarrhythmias. Of these, procainamide is the agent most commonly used in veterinary medicine. A sodium and potassium channel blocker, procainamide decreases abnormal automaticity, slows conduction, and prolongs the effective refractory period in atrial (and ventricular), accessory pathway, and retrograde fast AV nodal tissue. In atrial tachyarrhythmias, other agents are used first to slow AV nodal conduction before administration of procainamide. Parenteral procainamide is administered in dosages of 6 to 8 mg/kg IV over 5 to 10 minutes or 6 to 20 mg/kg IM in dogs. A CRI of 20 to 40 μg/kg/min can be used once a therapeutic response is obtained with bolus administration. Parenteral procainamide in cats is used cautiously at dosages of 1 to 2 mg/kg IV or 3 to 8 mg/kg IM and a CRI of 10 to 20 μg/kg/min.

Direct current (DC) cardioversion or overdrive pacing can be used to terminate certain hemodynamically unstable, sustained SVTs.[10] DC cardioversion in a proper critical care environment with appropriate hemodynamic and electrocardiographic monitoring offers certain distinct advantages over emergency drug therapy. The need to distinguish between supraventricular and ventricular tachyarrhythmias to design appropriate drug therapy is less important when DC cardioversion is employed. Sinus rhythm may be restored immediately with successful DC cardioversion, avoiding the slower titration and potential side effects seen with parenteral drug administration. The need for general anesthesia (albeit brief) is a risk factor for DC cardioversion but should not preclude its use in patients who would benefit from it.

DC cardioversion and overdrive pacing are effective in terminating SVTs caused by reentry rather than abnormal automaticity. Overdrive pacing can be performed without general anesthesia if the patient is depressed or moribund. The jugular furrow can be locally anesthetized with lidocaine, a catheter introducer placed in the external jugular vein, and a multipolar catheter guided fluoroscopically into the right atrium (for intraatrial reentry) or ventricle (more effective for terminating orthodromic AV reciprocating tachycardia). The distal and second poles of this catheter are then attached to a programmable pacemaker. An electrophysiologic recorder (ideal but not necessary) or multilead surface ECG is used to continuously record cardiac electrical activity. Once the myocardium is captured, the pacing rate is increased to 10 to 20 beats/min faster than the tachyarrhythmia rate. One-to-one capture is ensured for a brief period, and then pacing is stopped once intracardiac electrograms confirm termination of the SVT. If only the surface ECG is recorded, pacing is stopped after a brief period to determine if the tachyarrhythmia terminated. If not, a longer period or slightly faster pacing rate is used. Failure to terminate or rapid resumption of the tachyarrhythmia can indicate either an SVT caused by an automatic mechanism or successful termination but then rapid reinitiation of a reentrant SVT.

46.6.2 Long-Term Therapy

46.6.2.1 Medical Treatment

Long-term antiarrhythmic drug therapy must be tailored to each patient based on the type of SVT, the presence or absence of congestive heart failure or structural heart disease, comorbid conditions (particularly hepatic or renal dysfunction, acid-base disturbances, or endocrine diseases that alter the metabolism of specific antiarrhythmic drugs), and concurrent drug administration. Atrial tachyarrhythmias typically are managed by dual antiarrhythmic therapy, one drug to slow AV nodal conduction and a second to terminate the atrial tachyarrhythmia itself. This general rule is violated when persistent atrial fibrillation is present, when rate control becomes the goal. AV node–dependent tachyarrhythmias sometimes will respond to single agent therapy aimed at slowing AV nodal conduction. In reality, however, these tachyarrhythmias often are managed by combination therapy as well. For instance, with orthodromic AV reciprocating tachycardia, one agent is used to slow AV nodal conduction and a second agent is used to block conduction or prolong the effective refractory period within an accessory pathway.

Drugs that slow AV nodal conduction include the classes that were discussed under emergency therapy. The three major classes include: digitalis glycosides, calcium channel blockers, and β-blockers. Animals with systolic dysfunction classically are placed on digoxin as a first-line negative dromotrope (0.005 to 0.01 mg/kg PO q12h in a normokalemic dog with normal renal function; 0.0312 mg PO q24-48h in a normokalemic cat with normal renal function).

The ventricular rate is almost never slowed adequately with digoxin as a single agent, however, and other drugs must be added. The calcium channel blocker diltiazem is effective in prolonging the effective and functional refractory periods of the AV node. This effect is most notable at faster stimulation rates (use dependence) and in depolarized fibers (voltage dependence).[10] Diltiazem has gained preference over verapamil because of its more favorable hemodynamic profile (i.e., minimal negative inotropic effect) at effective antiarrhythmic dosages. Diltiazem is administered 3 times a day, which can be difficult particularly for cat owners. Sustained release preparations, however, appear to have more variable absorption in companion animals, with resultant poorer arrhythmia control. Such preparations also have had a high incidence of side effects in cats, including vomiting, inappetence, and hepatopathies.[9]

Atenolol is a relatively β_1-selective blocker that competitively inhibits the effects of catecholamines on cardiac β-receptors. Thus, underlying sympathetic tone plays an important role in determining the effectiveness of atenolol in prolonging AV nodal conduction and refractoriness or suppressing abnormal atrial foci.[9,10] Because of its negative inotropic effects, the dosages required to affect AV nodal conduction significantly are often not well tolerated by animals with left ventricular (LV) systolic dysfunction. The beneficial effects of β-adrenergic blockade in the face of impaired LV systolic function have been well demonstrated in human patients; therapy must begin at very low dosages and up-titration performed very slowly.[11] Patients with rapid SVTs do not have the luxury of this prolonged time for control of their ventricular rate. Remember that the rapid ventricular rate is worsening or may be the sole cause for their myocardial dysfunction. Atenolol is particularly useful in cats with hypertrophic cardiomyopathy and SVTs. Because of its renal clearance, the dosage of atenolol must be decreased in the face of concurrent renal disease.

Class I antiarrhythmic drugs block fast sodium channels and thus suppress abnormal automaticity and slow myocardial conduction velocity. The most commonly used class I drug in small animals with SVT is procainamide, a class Ia drug that also prolongs repolarization through its potassium channel blocking capabilities. Oral procainamide typically is used as an extended release preparation, administered 10 to 30 mg/kg PO q8h in dogs and 3 to 8 mg/kg PO q8h in cats. Poor absorption of sustained release procainamide preparations can limit their effectiveness in certain animals. The need for 2-hour to 6-hour dosing of formulations that are not extended release makes compliance nearly impossible. GI side effects can be prominent, and proarrhythmia is a definite concern with long-term procainamide therapy.

Class III antiarrhythmic agents are used to prolong the effective refractory period of atrial myocardium and accessory pathways. Sotalol and amiodarone, the two agents used in small animals, have additional antiarrhythmic actions, including slowing of AV nodal conduction. Sotalol typically is administered at 1 to 2 mg/kg PO q8h for SVTs, but amiodarone dosing varies and typically includes a loading period.[9] The author uses 15 mg/kg q24h for 7 days, then 10 mg/kg q24h for 7 days, then 5 mg/kg q24h for maintenance. Serum amiodarone levels can be measured but may not correlate with tissue concentrations. The high incidence of reported side effects in dogs receiving long-term amiodarone therapy has limited its widespread use.[9,12] Amiodarone has not been used in cats.

46.6.2.2 Catheter Ablation

Certain SVTs can be cured, rather than simply controlled, with transvenous radiofrequency catheter ablation.[6,13] The tachyarrhythmia circuit is first mapped with numerous multielectrode catheters. Once, for example, an accessory pathway is identified, detailed mapping is used to locate precisely the pathway along the AV groove. A specialized catheter with a 4-mm to 5-mm distal electrode is positioned at this critical site, and radiofrequency energy is delivered to the tip electrode causing thermal dessication of a small volume of tissue, to permanently interrupt the tachycardia circuit. This technique has been used by this author and others in a number of canine cases.

47 Chapter 47 Ventricular Tachyarrhythmias

Romain Pariaut, DVM, DACVIM (Cardiology), DECVIM-CA (Cardiology)

47.1 KEY POINTS

- Wide QRS complex tachycardia with atrioventricular dissociation, fusion beats, and capture beats are electrocardiographic features diagnostic of ventricular tachycardia (VT).
- Clinical signs secondary to VT are determined by its rate and duration.
- The most common noncardiac causes of VT are hypoxemia, electrolyte imbalances (hypokalemia), acid-base disorders, and drugs.
- The most common cardiac diseases associated with clinical VT are Boxer cardiomyopathy and dilated cardiomyopathy in Doberman Pinschers.
- Antiarrhythmic medications do not prevent sudden death.
- Antiarrhythmic therapy is initiated if clinical signs associated with VT are present.
- When the origin (supraventricular or ventricular) of a wide QRS tachycardia cannot be determined, it must be managed as if it were VT.
- Lidocaine is the first-choice parenteral antiarrhythmic drug for treatment of VT in dogs.

47.2 INTRODUCTION

Physiologically, specialized ventricular cells, known as *Purkinje fibers,* may work as a pacemaker when the sinus and atrioventricular nodes fail to function appropriately, resulting in a ventricular escape rhythm or idioventricular rhythm at a rate of about 30 to 40 beats/min in dogs and 60 to 130 beats/min in cats.[1,2] Three arrhythmogenic mechanisms known as *enhanced automaticity, triggered activity, and reentry* (Box 47-1) may affect Purkinje cells or any excitable ventricular myocyte and result in ventricular tachycardia (VT).[3] They result in a ventricular rhythm faster than the physiologic idioventricular rhythm. Most human cardiologists define VT as three or more consecutive ventricular beats occurring at a rate faster than 100 beats/min, the conventional upper limit for normal sinus rhythm. In our patients, normal sinus rhythm can probably reach 150 to 180 beats/min in dogs and 220 beats/min in cats. These rates define the lower limit for VT. If a ventricular rhythm is faster than the physiologic idioventricular rhythm and slower than VT, it is called *accelerated idioventricular rhythm (AIVR)*. The rate of an AIVR is within the range of the underlying sinus rhythm. Therefore both rhythms are seen competing on a surface electrocardiogram (ECG) because the faster pacemaker inhibits the slower one, a property known as *overdrive suppression*. [2] Besides rate, an important feature of VT is duration, because both determine the clinical consequences of the arrhythmia. VT is described as nonsustained if it lasts less than 30 seconds and sustained if it lasts longer.

47.2.1

Box 47-1 Electrophysiologic Mechanismsof Ventricular Tachycardia

Reentry: Requires an impulse to leave a point of departure and return to its starting point with a sufficient delay that the cardiac tissue has recovered its excitability. It usually circles around an area of nonconductive tissue (fibrosis, vessel). Shortening of the refractory period and slow conduction favor this self-perpetuating mechanism.

Enhanced automaticity: A myocardial cell that never possessed the property of automaticity while healthy gets the ability to depolarize spontaneously when depressed. Its membrane potential is less negative, and the action potential becomes similar to that of the sinus node.

Triggered activity: Results from small membrane depolarizations that appear after and are dependent on the upstroke of the action potential. They trigger an action potential when they reach the threshold potential. When they occur during the process of repolarization they are called *early afterdepolarizations (EADs),* and when they occur after full repolarization they are called *delayed afterdepolarizations (DADs)*. Hypokalemia and drug-induced prolongation of the QT segment increase the risk of EADs. DADs occur secondary to intracellular calcium overload associated with sustained tachycardia and digoxin toxicity.

47.3

ELECTROCARDIOGRAPHIC DIAGNOSIS

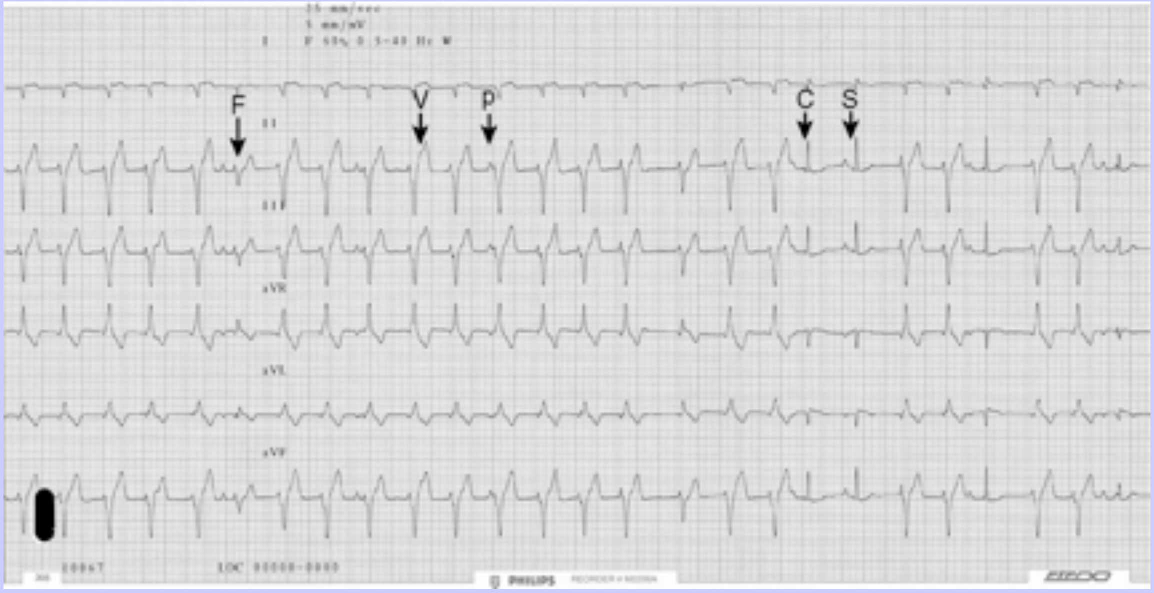
In the intensive care unit, VT is first suspected on physical examination or detected on a continuous ECG monitor. Confirmation of VT relies on a good-quality 6-lead to 12-lead surface ECG recording with the patient placed in right lateral recumbency.

Ventricular tachycardia is identified as a broad QRS tachycardia with complexes wider than 0.06 second in dogs and 0.04 second in cats. Each QRS complex is followed by a large T wave, directed opposite to the QRS deflection.

The challenge of ECG interpretation is to differentiate VT from supraventricular tachycardias (SVTs) with broad QRS complexes because of aberrant conduction of the electrical impulse within the ventricles. Aberrant ventricular conduction results from a structural bundle branch block, a functional or rate-related bundle branch block, or finally an accessory atrioventricular pathway causing preexcitation.[4]

The three most reliable diagnostic criteria of VT are atrioventricular dissociation, fusion beats, and capture beats (Figure 47-1). Atrioventricular dissociation is demonstrated when P waves are occasionally seen on the ECG tracing but are not related to ventricular complexes. These P waves reflect atrial activity independently from the ventricle. 200 201 On occasion apparent atrioventricular association may be seen, or ventricular beats can conduct in a retrograde fashion to the atrium in a 1:1 ratio. Therefore signs of atrioventricular association do not rule out VT. Fusion beats and capture beats are seen with paroxysmal VT and AIVR. Fusion beats result from the summation of a ventricular impulse and a simultaneous supraventricular impulse resulting in a QRS complex of intermediate morphology and preceded by a P wave (unless there is concurrent atrial fibrillation). A capture beat is a supraventricular impulse conducting through the normal conduction pathways to the ventricle during an episode of VT or AIVR. This complex occurs earlier than expected and is narrow if the conduction system is intact.[4]

Figure 47-1 Electrocardiographic recording from a dog; paper speed is 25 mm/sec. There is ventricular tachycardia *(V)* at a rate of 150 beats/min. P waves *(p)* not related to the wide QRS complexes *(V)* indicate atrioventricular (AV) dissociation. There are fusion beats *(F)* with an intermediate morphology and capture beats *(C)*. Note that the PR interval of the capture beat is prolonged compared with a normal sinus beat *(S)*. It results from retrograde depolarization of the AV node by the preceding ventricular impulse and secondary slowing of the propagation of the sinus impulse in a partially refractory node, a phenomenon known as *concealed AV conduction*.



Regularity of the rhythm is a less accurate criterion because VT can be slightly irregular. When the RR interval varies by 100 msec or more, it is suggestive of atrial fibrillation with aberrant ventricular conduction. Other criteria have been suggested by human cardiologists to make the correct diagnosis; for example, QRS complexes are usually wider with VT than with SVT.[4] Although rarely effective, vagal maneuvers can be done to slow the atrioventricular conduction, revealing P waves associated to the QRS complexes in case of SVT. It is also important to consider the overall clinical picture. For example, Boxers and Doberman Pinschers usually have VT. Finally, it is accepted that managing SVT as VT is usually less dangerous than the opposite, because drugs used to stop SVT or to slow the ventricular response rate to rapid atrial impulses (i.e., calcium channel blockers and β-blockers) do not interrupt VT and worsen hypotension with their vasodilatory or negative inotropic effects.

If doubt persists, treat as if it were VT.

47.4 APPROACH TO THE PATIENT WITH VENTRICULAR TACHYCARDIA

Once VT is confirmed on a surface ECG, the possible causes for the initiation and maintenance of the arrhythmia must be identified. The knowledge will help planning an effective treatment protocol and predicting the short-term and long-term prognoses. It is useful to differentiate cardiac from noncardiac causes of VT.

47.4.1 Noncardiac Causes Of Ventricular Tachycardia

Ventricular cells are sensitive to hypoxemia, electrolyte and acid-base imbalances, sympathetic stimulation, and various drugs. These changes typically affect the passive and energy-dependent ion exchanges across the cellular membrane of the myocyte during the initiation and propagation of the action potential.

Hypokalemia is the most commonly reported electrolyte disturbance responsible for or contributing to VT. It increases phase 4 depolarization, increasing spontaneous automaticity, and prolongs the action potential duration, which promotes arrhythmias from triggered activity.[5] Because digoxin competes with potassium on its receptors, hypokalemia increases the risk of digoxin toxicity. Similar arrhythmias result from hypomagnesemia, because magnesium is necessary for proper functioning of the sodium-potassium ATP pump, which maintains normal intracellular potassium concentration. Hypocalcemia and hypercalcemia are also responsible for ventricular arrhythmias.

Increased adrenergic tone potentiates arrhythmias through various mechanisms. In the intensive care unit, drugs with sympathetic or sympatholytic activity are used commonly and should be stopped when possible to assess their role in the perpetuation of VT.

It is also important to evaluate the potential proarrhythmic effects of all the medications given to a patient with VT. There are many publications on drug-induced prolongation of the QT segment. Prolongation of the QT segment reflects prolongation of the cardiac cell membrane repolarization and indicates a risk of ventricular arrhythmia from triggered activity. Antiarrhythmic drugs, such as procainamide and sotalol, but also domperidone, cisapride, chlorpromazine, and erythromycin, are known to prolong the QT segment. Bradycardia and hypokalemia contribute to this effect on repolarization and increase the risk of VT.[6]

Oxygen therapy, identification and correction of all electrolyte disturbances, and discontinuation of proarrhythmic medications are the initial and necessary first steps in the treatment of all patients with VT.

47.4.2 Cardiac Causes of Ventricular Tachycardia

In most patients with VT an echocardiogram is indicated as soon as possible to identify an underlying cardiac disease as the cause for the arrhythmia. In humans the association of sustained VT and heart failure is a marker of increased risk of sudden death from arrhythmia, and this is probably true in our patients as well.[7] Identification of cardiac disease may help to elaborate an effective treatment strategy, to know what to expect from the intervention, and to give the most accurate prognosis to the owner. Today there is valuable information on some breed-specific VTs.

VT is on occasion observed in patients with cardiac tumors (with or without associated tamponade), myocarditis, endocarditis, and acute coronary events associated with hypothyroidism.

VT is an important part of the clinical picture of dilated cardiomyopathy in some breeds. The prevalence of ventricular arrhythmias was 21% in a pool of breeds with dilated cardiomyopathy, 16% in Newfoundlands and 92% in Doberman Pinschers. The natural history of the disease has been studied extensively in Doberman Pinschers. There is an occult stage of the disease with no clinical signs but with echocardiographic indicators of left ventricular dysfunction and a risk of sudden death of approximately 30%. It can last 2 to 4 years. In the overt stage of the disease, congestive heart failure is present and the risk of sudden death is about 30% to 50%. In Doberman Pinschers, most ventricular ectopies have a right bundle branch block morphology in lead II of the surface ECG, indicating their origin in the left ventricle.[8]

Cardiomyopathy of Boxers is known as *arrhythmogenic right ventricular cardiomyopathy (ARVC)*. It is an adult-onset disease with a concealed form characterized by occasional ventricular ectopies only, followed by an overt form with VT associated with exercise intolerance and collapse. On occasion myocardial failure is observed. In ARVC, ventricular ectopies typically have a left bundle branch block morphology, indicating their right-sided origin.[9]

An inherited ventricular arrhythmia has been identified in some German Shepherds. In the most severe form of the disease these dogs have a propensity for sudden death until 18 months of age. The form of VT responsible for sudden death is polymorphic, rapid (more than 300 beats/min), nonsustained, and usually preceded by a pause.[10]

Dogs with severe subaortic stenosis and pulmonic stenosis are prone to syncope and sudden death. VT progressing to ventricular fibrillation may contribute to some of these episodes.

In cats, VT may be seen in association with idiopathic hypertrophic cardiomyopathy and with concentric hypertrophy secondary to hypertension and hyperthyroidism.

47.5 ANTIARRHYTHMIC TREATMENT

47.5.1 Decision to Treat

Antiarrhythmic agents are indicated to treat symptomatic VT and prevent its recurrence. Despite many large-scale randomized studies in humans and a few publications in veterinary medicine, there is no indication that antiarrhythmic agents can prevent sudden death, and on some occasions they may precipitate it.[7]

Hemodynamic compromise usually is associated with rapid (more than 200 beats/min) and sustained VT in a patient with concurrent cardiac disease. Slower nonsustained VT and AIVR are usually auscultatory or ECG findings in patients with motor vehicle–related trauma, gastric dilatation-volvulus, or metabolic imbalances and resolve spontaneously, with no antiarrhythmic medications within 4 days.[11]

Some ECG characteristics of VT are viewed as indicators of an increased risk for sudden death and may influence the decision of the clinician toward treatment. Hemodynamic collapse is more likely to result from polymorphic VT, which is characterized by a continuously changing QRS complex pattern, than monomorphic VT. Antiarrhythmic agents are generally considered for sustained VT with rates greater than 180 to 200 beats/min. The presence of polymorphic VT may encourage treatment at the lower rate range. “R-on-T phenomenon” describes the superimposition of an ectopic beat on the T wave of the preceding beat. Some observations suggest that it may represent an increased risk for VT and sudden death from ventricular fibrillation. Nevertheless strong evidence is lacking and this finding by itself cannot justify treatment.

Regardless of its cause, rate, duration, or morphology, the decision to treat VT with antiarrhythmic medications must be dictated primarily by the clinical signs related to it.

47.5.2 Antiarrhythmic Drugs

A few antiarrhythmic agents will manage most VTs. Because studies in veterinary medicine are lacking and antiarrhythmic medications are complex drugs with many side effects including proarrhythmic effects, it is important to gain experience with only a few commonly used drugs.

47.5.2.1 Lidocaine

Lidocaine is the first-choice intravenous agent to control VT. It works better on rapid VTs and in normokalemic animals. In dogs boluses of 1 to 2 mg/kg can be repeated every 10 to 15 minutes. A maximum dose of 8 mg/kg/hr is recommended to avoid neurotoxic effects. The arrhythmia can be controlled over time with a continuous infusion of lidocaine at a rate between 25 and 80 μg/kg/min. In cats, the safety margin is smaller and lower dosages of lidocaine can be used, but β-blockers usually are preferred. Mexiletine has properties similar to those of lidocaine and is available as an oral medication. Mexiletine, 4 to 8 mg/kg q8h, combined with atenolol, 0.5 mg/kg q12-24h, has been shown to control VT in Boxers with ARVC.[9,12]

47.5.2.2 Procainamide

Procainamide is used intravenously for VTs that do not respond to lidocaine. A bolus of 10 to 15 mg/kg over 1 to 2 minutes can be followed by a constant rate infusion at 25 to 50 μg/kg/min. Rapid intravenous injection can cause hypotension. Long-term management of VT can be attempted with oral procainamide at 10 to 20 mg/kg q6h, or q8h if the sustained-release form is used.[12]

47.5.2.3 β-Blockers

Sympathetic activation has been implicated in the pathogenesis of ventricular arrhythmia. β-Blockers provide adrenergic system blockade and may help control arrhythmias. 202 203 Esmolol is a short-acting β-blocker that can help control sympathetically driven VTs such as those associated with pheochromocytoma or thyrotoxic disease in cats, but its negative inotropic effects may be too pronounced in some patients and cause cardiovascular collapse.

47.5.2.4 Sotalol

Sotalol is an oral medication usually effective in controlling VT. It was the second most effective treatment protocol after a combination of mexiletine and atenolol in Boxers with ARVC. In Boxers, sotalol usually is given at 2 mg/kg q12h.[9,12]

47.6 POSTINTERVENTION MONITORING

Because the response to antiarrhythmic agents cannot be predicted, continuous ECG monitoring is essential after the medication is started and for a minimum of 24 hours. It will give valuable information on the control of the arrhythmia and the possible proarrhythmic effects of the drugs. Twenty-four hour Holter recording is more adapted to long-term management of the arrhythmia.

48 Chapter 48 Myocarditis

Meg Sleeper, VMD, DACVIM (Cardiology)

48.1 KEY POINTS

- Myocarditis is an inflammatory process involving the heart. Inflammation may involve the myocytes, interstitium, or vascular tree.
- Myocarditis has been associated with a wide variety of diseases. Infectious agents (viral, bacterial, protozoal) may cause myocardial damage by myocardial invasion, production of myocardial toxins, or activation of immune-mediated disease.
- Myocarditis can also be associated with physical agents (doxorubicin), underlying metabolic disorders (uremia), toxins (heavy metals), or physical agents (heat stroke).

48.2 INTRODUCTION

Myocarditis is a rare cause of heart failure in dogs and extremely rare in cats. Clinical pictures vary, including asymptomatic patients who may have electrocardiographic abnormalities and patients with or without heart enlargement, systolic dysfunction, or even full-blown congestive heart failure. The patient's history (i.e., environment and exposure) is often critical in determining likely risk and suggesting appropriate diagnostic tests. Clinical reports of canine myocarditis are most common in immunocompromised or immunonaïve patients.

48.3 INFECTIOUS MYOCARDITIS

48.3.1 Viral Myocarditis

Numerous viruses have been associated with myocarditis in humans. In dogs, viral myocarditis appears most commonly in immunonaïve patients, and the virus most commonly associated with the disease is parvovirus. However, at this time the entity appears to be very rare. In the late 1970s and early 1980s, when the parvovirus pandemic first was recognized, puppies did not receive maternal antibodies and very young puppies developed a fulminant infection with acute death due to pulmonary edema when exposed to the virus. Older puppies (2 to 4 months) often died subacutely from congestive heart failure, but others developed a milder myocarditis and later developed dilated cardiomyopathy (DCM), usually as young adults. Basophilic intranuclear inclusion bodies are found in the myocardium of acutely affected younger puppies, but may be absent in older puppies.[1] 204 Older dogs typically have gross myocardial scarring. Rare cases of parvovirus-induced myocarditis have been reported since the early to mid-1980s.

Rarely, other viruses have been associated with myocarditis in dogs. In 2001, Maxson and others evaluated myocardial tissue from 18 dogs with an antemortem diagnosis of DCM and 9 dogs with a histopathologic diagnosis of myocarditis based on a polymerase chain reaction analysis to screen for canine parvovirus, adenovirus types 1 and 2, and herpesvirus. Canine adenovirus type 1 was amplified from myocardium of only one dog with DCM and none of the dogs with myocarditis, suggesting these pathogens are not commonly associated with DCM or active myocarditis in the dog.[2] Distemper virus–associated cardiomyopathy with a mild inflammatory infiltrate has been produced by experimental infection of immunonaive puppies.[3] Natural infection with West Nile virus was associated with myocarditis in a wolf and a dog in 2002, the third season of the West Nile virus epidemic in the United States.[4] Viral genomic deoxyribonucleic acid has also been identified in feline myocardial tissue from patients with hypertrophic cardiomyopathy, DCM, and restrictive cardiomyopathy, suggesting that viral myocarditis may be a factor in these feline-acquired diseases.[1]

48.3.2 Protozoal Myocarditis

48.3.2.1 Chagas Disease

Chagas disease is caused by *Trypanosoma cruzi,* a protozoal parasite. Chagas disease is the leading cause of DCM in humans of Latin America, but it is rare in North America. In North American dogs, Chagas disease occurs most commonly in Texas and Louisiana. There have been no reported feline cases in North America. The organism is transmitted by an insect vector (Reduviidae), and reservoir hosts include rodents, raccoons, opossums, dogs, cats, and humans. The trypomastigote is the infective stage, but on entering host cells the organism enters the reproductive stage and becomes an amastigote. Amastigotes multiply until the host cell ruptures.[1,8]

Dogs with clinical Chagas disease have an acute or a chronic syndrome. In the acute stage, circulating trypomastigotes may be seen in a thick blood smear, and most dogs are brought for treatment because of sudden development of signs of right-sided heart failure (ascites, tachycardia, lethargy). Dogs with chronic Chagas disease may enter a quiescent stage free of clinical signs for months or even years. Nervous system damage often causes ataxia and weakness in these patients.[1,8]

48.3.3 Bacterial and Other Causes of Myocarditis

Bacterial myocarditis is possible whenever bacteremia or sepsis is present, with the most common agents being staphylococcal and streptococcal species.[1] Myocarditis associated with *Citrobacter koseri,* an opportunistic pathogen of immunosuppressed human patients, has been described in two 12-week-old sibling Boxer puppies.[5] Tyzzer disease (infection with *Bacillus piriformis*) was associated with severe necrotizing myocarditis in a wolf-dog hybrid puppy.[6]

Myocarditis has also been recognized secondary to rickettsial organisms such as *Rickettsia rickettsii, Ehrlichia canis,* and various *Bartonella* species.[1] Myocarditis has been noted in 2 of 12 dogs diagnosed with endocarditis, 11 of which were seroreactive to *Bartonella vinsonii* subspecies.[7] Lyme disease (secondary to infection by the spirochete *Borrelia burgdorferi*) has been implicated as a cause of myocarditis in dogs, but documented cases are rare. Clinical signs are often vague and nonspecific, and serologic testing is not a reliable method to determine active infection.[1] In humans, Lyme myocarditis may be due to direct toxic effects or immune-mediated mechanisms, and the disease is usually self-limiting.[11] Fungal infections of the myocardium are extremely rare but have occurred in immunocompromised patients.[1]

A group of cats was described with transient fever and depression that appeared to be infectious in nature. Postmortem examination revealed microscopic lesions consistent with myonecrosis and an inflammatory cell infiltrate. A viral etiology was suspected, but no organism was identified.[8] In a retrospective study reviewing

1472 feline necropsies over a 7-year period, 37 cases were diagnosed with endomyocarditis. The cats with endomyocarditis had a mean age at death of 3.4 years, and 62% of them had a history of a stressful event 5 to 10 days before being brought for treatment. Interstitial pneumonia was present in 77% of the cats at postmortem examination. Special stains for bacteria and fungi were negative.[9]

Parasitic agents can also lead to myocarditis. *Toxoplasma gondii* bradyzoites can encyst in the myocardium, resulting in chronic infection. Eventually the cysts rupture, leading to myocardial necrosis and hypersensitivity reactions.[1] *Neospora caninum* can infect multiple tissues, including the heart, peripheral muscles, and central nervous system. Clinical signs associated with noncardiac tissues typically predominate; however, collapse and sudden death has been reported in affected dogs.[1] Infestation with *Trichinella spiralis* is a common cause of mild myocarditis in humans.[11] The parasite has been associated with at least one case of canine myocarditis complicated by arrhythmias (Figure 48-1).[12]

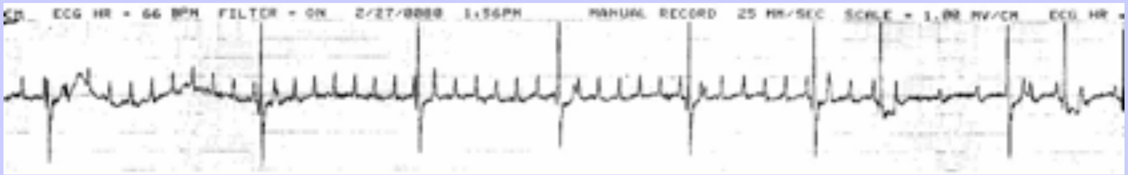
48.4 NONINFECTIOUS MYOCARDITIS

48.4.1 Doxorubicin Toxicity

Doxorubicin cardiotoxicity may be manifested as arrhythmias, myocardial failure, or both. Cardiotoxicity is dosage-dependent and irreversible and is more common at cumulative doses exceeding 250 mg/m^2; however, in one study in which only two doses of 30 mg/m^2 were administered, 3% of dogs developed cardiomyopathy.[1,8] The time to onset of CHF in affected dogs is highly variable. Although pathologic changes have been seen in the feline myocardium following administration, no antemortem echocardiographic or electrocardiographic changes associated with doxorubicin toxicity have been reported.

Other causes of noninfectious myocarditis, although rarely recognized in veterinary medicine, include allergic reactions, systemic diseases such as vasculitis, or physical agents such as radiation or heat stroke.[11] Numerous chemicals and drugs may lead to cardiac damage and dysfunction. A severe reversible DCM has been observed in humans with pheochromocytoma,[11] and similar findings have been observed in experimental animals receiving prolonged infusions of norepinephrine.[11] Myocardial coagulative necrosis was found in a dog that died suddenly after an episode of severe aggression, restraint, and sedation for grooming.[13] Myocardial lesions were presumed to be caused by catecholamine toxicity.

Figure 48-1 Electrocardiogram from a mixed-breed dog with trichinosis involving the heart. The dog was brought in for collapse due to complex arrhythmias. Note the ventricular escape beats. An underlying supraventricular tachycardia is likely as well.



ECG HR = 66 BPM FILTER = ON 2/27/0000 1:56PM MANUAL RECORD 25 MM/SEC SCALE = 1.00 MV/CM ECG HR

48.5 DIAGNOSIS

Definitive diagnosis, unless the history clearly suggests myocarditis (e.g., doxorubicin toxicity) is elusive (Box 48-1). Supportive clinical laboratory tests include leukocytosis or eosinophilia, particularly in parasitic or allergic myocarditis. Elevated cardiac troponin I levels provide evidence of myocardial cell damage in patients suspected of having myocarditis. If a high suspicion for Chagas disease is present, serologic examination for *T. cruzi* is diagnostic. Demonstration of a rising titer is also helpful to establish the diagnosis of myocarditis associated with *T. gondii* or *N. caninum*. Viral and rickettsial testing should be performed if indicated. Blood cultures should be performed if a bacterial cause is suspected. Thoracic radiographs may show normal heart size or heart enlargement with or without evidence of CHF. The electrocardiographic findings may also be varied, and ventricular arrhythmias or conduction disturbances are common. Echocardiography most often demonstrates systolic dysfunction, either global or regional, and cardiac chambers may be normal or increased in size.

Endomyocardial biopsy (the gold standard for diagnosis of myocarditis in humans[10]) may allow definitive antemortem diagnosis (Color Plate 48-1). However, a focal myocarditis can still be missed because the sample size is small. At postmortem examination, immunohistochemistry or electron microscopy can confirm the diagnosis of *N. caninum* infection.[9] Gross pathology findings may be insignificant, or they may reveal cardiac dilation or ventricular hypertrophy, focal petechiae, and myocardial abscesses.[1] Specific findings depend on the underlying etiology. Focal or diffuse myocarditis is definitively diagnosed by histopathology when myocyte necrosis, degeneration, or both are associated with an inflammatory infiltrate.[1]

48.6 TREATMENT

Most recommendations for managing myocarditis in dogs and cats are extrapolated from human medicine or research with models of viral myocarditis. Supportive care is the first line of therapy for patients with myocarditis. In those patients with signs of CHF, typical therapy should include preload reduction with diuretics and afterload reduction with angiotensin-converting enzyme inhibitors (see Chapter 21, Pulmonary Edema). Digoxin increased expression of proinflammatory cytokines and increased mortality in experimental myocarditis, so it is recommended to be used with caution and at low dosages.[10] Intravenous inotropic therapy in the form of dobutamine can be useful if significant systolic dysfunction is present.

Eliminating unnecessary medications may help reduce the possibility of allergic myocarditis. Results of recent studies suggest that immunosuppression is not routinely helpful in myocarditis patients, but it may have an important role in patients with myocardial dysfunction caused by systemic autoimmune disease.[10] Nonsteroidal antiinflammatory agents are contraindicated during the acute phase of myocarditis in humans (during the first 2 weeks), because they increase myocardial damage. However, they appear to be safe later in the course of disease.[11] In a murine model of viral myocarditis, angiotensin-converting enzyme inhibition (with captopril) was beneficial. Similarly, interferon therapy is beneficial in the experimental model of myocarditis and may be useful clinically.[11]

48.6.1 Box 48-1 Characteristics Suggestive of Myocarditis

- History suggests it is possible (e.g., oncology patient receiving doxorubicin, dog lives in Texas)
- Unusual signalment for heart disease (e.g., Irish Setter, German Shepherd)

- Supportive electrocardiographic findings that include conduction abnormalities or arrhythmias
- Supportive echocardiographic findings that include myocardial dysfunction (which may be regional) with or without heart enlargement
- Supportive clinical laboratory findings that include leukocytosis, eosinophilia, elevated cardiac troponin I levels

When diagnosis of acute Chagas disease is possible, several agents appear to inhibit *T. cruzi;* however, by the time a diagnosis is made it is often too late for this approach. Patients with chronic Chagas disease are treated symptomatically for CHF. Similarly, successful treatment has been reported using several agents in dogs affected with *N. caninum* myocarditis, but severely ill dogs often die.[1] Clindamycin is the drug of choice for treating clinical toxoplasmosis in dogs and cats; however, significant damage to the heart is irreversible.[14]

Dogs with evidence of bacteremia should be treated with antibiotics pending culture and sensitivity results. Empiric treatment should be effective against staphylococcal and streptococcal species (see Chapter 108, Gram-Positive Infections). Animals with suspected rickettsial disease should be treated with doxycycline (5 mg/kg PO or IV q12h) pending titer results.

49 Chapter 49 Arterial Catheterization

Elisa M. Mazzaferro, MS, DVM, PhD, DACVECC

49.1 KEY POINTS

- Arterial catheters can be placed in the dorsopedal, radial, femoral, coccygeal, and auricular arteries.
- Arterial catheters can be used for direct blood pressure monitoring and procurement of arterial blood samples for blood gas and other analyses.
- Arterial catheters are generally well tolerated, but they can become dislodged easily with excessive patient movement.
- Arterial catheters should be avoided in patients with severe coagulation abnormalities whenever possible because of the risk of arterial hemorrhage.
- Arterial catheters are not well tolerated in cats and should be kept in place no longer than 6 to 8 hours.
- All arterial catheters should be labeled “Arterial Catheter—Not for IV Infusion” to prevent inadvertent injection of fluids or drugs into the arterial line.

49.2 INTRODUCTION AND INDICATIONS FOR ARTERIAL CATHETERIZATION

An indwelling arterial catheter is a necessary and useful procedure for many critically ill veterinary patients. Arterial catheters can be used to collect arterial blood samples when measuring an animal's arterial oxygenation and ventilation and for invasive direct arterial blood pressure monitoring. To avoid complications associated with hemorrhage or arterial thrombosis, the animal's coagulation status should be checked before considering placement of a catheter in any artery. Ideally, a platelet count or estimate, activated partial thromboplastin time, and prothrombin time should be evaluated before catheter placement. If severe thrombocytopenia (<50,000 platelets/µl) or prolonged activated partial thromboplastin time and prothrombin time are present, the patient may be at risk for hemorrhage from the site of arterial catheterization.

Arterial catheters are placed most frequently in the dorsopedal artery.[1] This location is technically the simplest, and it enables easy hemostasis. Alternative locations for arterial catheter placement include the auricular artery on the dorsal surface of the ear pinna,[2] and the femoral, coccygeal, radial, and brachial arteries.[3] With practice, arterial catheterization and maintenance is not technically difficult and can provide information that helps guide lifesaving therapeutic interventions in the most critically ill veterinary patients.[3]

49.3 PATIENT PREPARATION

A patient's coagulation status should be considered carefully before arterial catheter placement. If a coagulopathy is not found or suspected, the site should be chosen based upon the patient's anatomy and consideration of underlying diseases, such as vomiting, diarrhea, pyoderma, or aural hematomas. For example, a radial arterial catheter may be inappropriate in a vomiting patient because of the risk of contamination. Similarly, femoral, coccygeal, or dorsopedal placement may be inappropriate in a patient with severe diarrhea. Patients with aural hematomas frequently shake their heads, and thus can easily dislodge an auricular arterial catheter, even when placed in a healthy ear. Because of the increased risks of auricular, coccygeal, and radial catheter dislodgement in ambulatory patients, dorsopedal catheters are preferred whenever possible.[1]

49.4 PERCUTANEOUS ARTERIAL CATHETER PLACEMENT

Once the proposed site of arterial catheterization has been chosen, the operator should become familiar with the animal's anatomy, palpating over the artery as it courses along the leg, tail, or ear while simultaneously feeling carefully for the arterial pulse. The designated site of catheterization should be clipped, then scrubbed aseptically with antimicrobial soap. The operator should perform careful hand washing and wear gloves to maintain aseptic technique during the procedure.

49.4.1 Percutaneous Dorsopedal Artery Catheterization

For dorsopedal artery placement, the patient should be positioned in lateral recumbency, and the leg with the proposed catheter site located down, adjacent to the table. The fur should be shaved on the anteromedial portion of the limb from the level of the tarsus distally along the length of the metatarsal bones. The artery usually is palpable just distal to the hock, between the second and third metatarsal bones.[1] Once the artery has been palpated and the site clipped and aseptically prepared, a 20- to 24-gauge over-the-needle catheter can be placed percutaneously or via percutaneous facilitation technique.

Percutaneous facilitation refers to the practice of making a small nick in the skin using the bevel of a 20-gauge needle. Use care to not penetrate the artery during this process because arterial spasm is common, and prevent cannulation until a palpable pulse returns. Whether the over-the-needle catheter is placed directly through the skin or through a nick incision formed by percutaneous facilitation, the needle and catheter should be inserted through the skin at a 15-degree to 30-degree angle over the palpable pulse.[1] The needle and catheter should be directed dorsally and laterally to the metatarsals over the site of a palpable pulse in small maneuvers, watching for a flash of blood in the catheter hub. Once a flash of blood is observed, the catheter should be pushed off of the stylet into the artery. Pulsatile arterial blood should be observed as soon as the stylet is withdrawn from the arterial catheter, if it is placed correctly.[1] Vasospasm may preclude further advancement in very small animals or cats, in which case a drop of papaverine hydrochloride can be flushed into the catheter to cause local vasodilation. If the catheter snags or does not feed easily, it can be pulled gently over the stylet and another attempt at catheterization performed (being careful not to pierce the catheter with the stylet).

In some cases when the original attempt catheterizes a vein, the catheter can be left in its original place and a second attempt performed proximally, if an arterial pulse is still palpable (Color Plate 49-1). Leaving the original catheter in place prevents hematoma formation that may preclude catheterization. Should all attempts at arterial catheterization fail, a pressure bandage should be placed for a minimum of 15 minutes to prevent hemorrhage and hematoma formation.[1]

Once the dorsopedal arterial catheter is in place, it should be flushed and secured as indicated in Box 49-1.

49.4.2 Femoral Artery Catheterization

Except for anatomic landmarks, percutaneous placement of a femoral arterial catheter is similar to that for the dorsopedal artery. The risk of hemorrhage is increased compared with other sites, however. The patient is placed in lateral recumbency, and the medial thigh clipped and aseptically scrubbed from the inguinal region distally to the stifle. The femoral arterial pulse is palpable on the medial thigh ventral to the inguinal region and proximal to the stifle. The over-the-needle catheter should be placed at a 20- to 30-degree angle through the skin and inserted in a proximal direction, watching carefully for a flash of blood in the catheter hub. Once a flash of blood is observed, the catheter should be advanced off of the stylette into the femoral artery. As the stylet is removed from the catheter, pulsatile arterial blood will be visible if the catheter has entered the artery. Once the catheter is placed, it should be flushed and secured as indicated in Box 49-1. Catheters in the femoral artery should also be secured with butterfly tape around the catheter hub, which is then secured to the patient's skin with sutures on either side of the hub.

49.4.2.1

Box 49-1 Procedure to Flush and Secure the Arterial Catheter

- A Luer-Lok T-port or male adapter flushed with preservative-free heparinized saline should be attached to the catheter hub to prevent further blood loss.
- The catheter should be flushed with preservative-free heparinized saline, then secured in place parallel to the artery using ½-inch and 1-inch white adhesive tape.
- The catheter hub and adjacent skin and fur should be carefully wiped dry of any blood and other liquids or debris before attempting to place tape around the catheter hub.
- The tape should be secured tightly around the catheter hub, to prevent dislodgement of the catheter. Additional lengths of 1-inch tape should be secured under the catheter hub and around the associated body part. Some clinicians use a combination of surgical glue, suture, and tape to secure the catheter, although this is not always necessary.
- The site of catheter insertion should be covered with antimicrobial ointment and bandage material, then labeled “Arterial Catheter—Not for IV Infusion” to prevent inadvertent injection of fluids or drugs into the arterial line.

49.4.3

Auricular Artery Catheterization

Catheterization of the auricular artery can be performed in dogs with large ears, such as hounds and hound mixes. The auricular artery lies on the dorsal surface of the ear pinna.[2] This type of catheter usually is placed while the patient is under heavy sedation or general anesthesia. The auricular arterial pulse can be palpated on the dorsal surface of the ear and the vessel traced toward the ear tip. The area over the artery should be clipped, then scrubbed aseptically. With the patient positioned in sternal or lateral recumbency, the ear is pulled gently such that the pinna is held perpendicular to the skull. The tip of the ear should be bent ventrally toward the operator such that the operator's fingers support the ear pinna from below. The artery is now bent at a perpendicular angle such that it can be traced from the point of a palpable pulse to the ear tip, and the over-the-needle catheter can be placed through the skin directly into the artery, with careful observation for a flash of blood in the hub of the catheter (Color Plate 49-2). Once a flash of blood is observed in the catheter hub, the catheter can be fed gently off of the stylet into the artery. Vasospasm may preclude further advancement in very small animals or cats, in which case a drop of papaverine hydrochloride can be flushed into the catheter to cause local vasodilation. Once the catheter is advanced into the artery, it should be flushed and secured as indicated in Box 49-1. In addition, the skin adjacent to the catheter hub should be dried carefully, and several drops of surgical glue placed adjacent to the catheter hub to help secure it to the skin. The ear can be supported from below with rolled up gauze 4 × 4-inch squares or rolls of gauze. Because the weight of the bandage is cumbersome, an awake and alert patient may attempt to shake its head, potentially causing catheter dislodgement. For this reason, the auricular arterial catheter is often limited to obtunded, comatose, or anesthetized patients.

49.4.4 Radial Artery Catheterization

The radial artery is technically more difficult to catheterize than those in other anatomic locations, but catheterization can be performed in large dogs. The patient should be placed in lateral recumbency, and the palmar aspect of the forelimb clipped just proximal to the large carpal pad, just distal to the accessory carpal pad, where the arterial pulse is palpable. The clipped area should be scrubbed aseptically. The operator should hold the patient's paw in one hand, palpating the arterial pulse with a thumb or forefinger. With the other hand, an over-the-needle catheter should be inserted through the skin at a 15-degree to 20-degree angle toward the palpable arterial pulse. The operator should watch carefully for a flash of blood in the catheter. As soon as a flash of blood is visible, the catheter should be pushed off the stylet into the artery. Once in place, the catheter should be flushed and secured as indicated in Box 49-1.

49.4.5 Coccygeal Artery Catheterization

The coccygeal arterial pulse is easily palpable on the ventromedial aspect of the tail just distal to the tail base. The fur over the palpable pulse should be clipped, then scrubbed aseptically. The patient can be positioned in dorsal or lateral recumbency, depending on operator preference. The arterial pulse should be palpated between coccygeal vertebrae and the over-the-needle catheter inserted through the skin at a 15-degree angle, pushing cranially toward the tail base until a flash of blood is seen in the hub (Color Plate 49-3). Once a flash of arterial blood is visualized, the catheter should be fed off the stylet, then flushed and secured as indicated in Box 49-1. Coccygeal catheters should be bandaged thoroughly to maintain cleanliness. Because coccygeal catheters become contaminated easily with the patient's feces during defecation and can become dislodged with patient movement, use of this site is limited largely to intraoperative procedures.

49.5 SURGICAL CUTDOWN FOR ARTERIAL CATHETER PLACEMENT

If percutaneous placement is unsuccessful, surgical cutdown can be performed to allow direct visualization and catheterization of the artery. Patient anatomy largely limits surgical cutdown procedures for arterial catheter placement to the dorsopedal and femoral arteries. Sterile technique should be used at all times. The area over the artery should be clipped and scrubbed aseptically, then draped with sterile field towels secured with towel clamps. A small bleb of 2% lidocaine should be injected into the skin and subcutaneous tissues, taking care to avoid intravenous or arterial administration of the local anesthetic.

The skin over the arterial pulse should be incised, taking care to avoid lacerating the artery and vein underneath the skin. The artery should be visible directly under the skin, surrounded by perivascular fascia. The dorsopedal artery usually is visible on top of the metatarsal bones.[3] Several drops of lidocaine should be placed directly over the artery to prevent arterial spasm as the perivascular fascia is bluntly dissected away from the vessel with a curved mosquito hemostat. Once the fascia has been removed from around the artery, a length of suture can be placed around the artery to help lightly elevate it parallel with the skin incision. It is very important to remove every bit of the perivascular fascia before attempting catheter placement.[1]

Once the artery has been elevated gently from the incision, the over-the-needle catheter can be inserted directly into the vessel, taking care to not penetrate through the other side. Excessive traction on the artery can cause arterial spasm, making catheterization difficult. A flash of blood will be observed in the hub of the catheter once the catheter has been introduced into the lumen of the artery. The catheter can then be fed off the stylet, flushed, and capped with a Luer-Lok T-port or male adapter. The suture that was used to elevate the artery can be used to secure the catheter to the vessel. The skin over the catheter should be closed with nonabsorbable suture, and the catheter taped in place, bandaged, and labeled as with any other arterial catheter (see Box 49-1).

49.6 MAINTENANCE OF THE ARTERIAL CATHETER

Depending on patient mobility, arterial catheters can be connected to a continuous flushing system with preservative-free heparinized saline, or flushed intermittently every 1 to 4 hours.[3] In extremely small patients, care must be taken to avoid excessive heparinization. As with other vascular catheters, arterial catheters should be examined on a daily basis for signs of erythema or infection. The area distal to the catheter should be palpated for any evidence of a coolness or pain, which indicate a compromise of blood flow. The bandage should be changed daily or more frequently as needed for soiling. Small volumes of preservative-free flush solution should be used to maintain catheter patency. However, other infusions (drugs or fluids or blood products) should never be administered into an arterial line.

Arterial catheters frequently cause vascular spasm and arterial occlusion in feline patients. Because cats have poor collateral circulation they are prone to developing ischemia subsequent to arterial catheter placement. It is therefore recommended that arterial catheters be kept in place for only 6 to 8 hours in feline patients.

49.7 THREE-SYRINGE SAMPLING TECHNIQUE

The three-syringe technique should be employed whenever a blood sample is obtained from an arterial catheter. To perform this technique, first flush the catheter with 0.5 ml of heparinized saline. Using the same syringe, withdraw 3 ml of blood from the catheter, and save it in a sterile manner, to be infused back into the patient through a peripheral venous catheter. Next, withdraw the desired volume of arterial blood into a heparinized or nonheparinized syringe. Finally, flush the arterial catheter with 2 to 3 ml of preservative-free heparinized saline, and clamp off or reconnect the T-port to the continuous flushing system. The arterial blood sample should be analyzed immediately or placed on ice for blood gas analysis.

50 Chapter 50 Pulmonary Artery Catheterization

Benjamin M. Brainard, VMD, DACVA, DACVECC

Deborah C. Mandell, VMD, DACVECC

50.1 KEY POINTS

- Pulmonary artery catheters (PACs) are placed through the right side of the heart and the right ventricular outflow tract, into a pulmonary artery (PA).
- PACs may be used to measure cardiac output by thermodilution, to calculate systemic vascular resistance, and to sample mixed venous blood.
- Information from a PAC may be used to tailor fluid or pressor choices in the anesthesia or intensive care setting.
- A PAC may be placed by following pressure tracings or by using fluoroscopy.
- PA catheterization is not a benign procedure and may be associated with significant morbidity, requiring a thorough evaluation of the risk-to-benefit ratio.
- Many alternative techniques for measuring cardiac output that do not require a PAC are available for use in veterinary patients.

50.2 INTRODUCTION

Pulmonary artery (PA) catheterization is a technique that places a catheter through the right heart and right ventricular outflow tract into the PA. It is used to measure cardiac output by thermodilution, to calculate systemic vascular resistance, and to sample mixed venous blood. Often, placement is assisted by a latex balloon at the tip of the catheter that allows its course to follow the flow of blood (flow-directed catheter placement).

50.3 TYPES OF CATHETERS AND USES

There are many types of pulmonary artery catheters (PACs) designed for angiographic studies or for measuring the blood pressure in the pulmonary arteries. These catheters may be single-lumen or double-lumen catheters.[1] Some catheters designed to be introduced into the PA have sensors 4 cm distal to the tip of the catheter that allow temperature measurement (e.g., the Swan-Ganz type catheter). Other catheters may measure blood oxygenation (e.g., the oximetry thermodilution catheter) (Tables 50-1, 50-2, and 50-3). Diameters of thermodilution catheters range from 5 to 7.5 Fr. Angiographic catheters are available from 4 to 8 Fr. Most Swan-Ganz catheters are made of polyvinyl chloride (PVC) and are available in lengths of 75 or 110 cm, which are adequate for most small animal species, but which may not be of sufficient length for horses or other large animals. Other thermodilution catheters are made of polyurethane, which has the characteristic of softening at body temperature.

Table 50-1 Pulmonary Arterial Catheter Types, Sizes, and Manufacturers: Angiographic Catheters

Trade Name	Company	Diameter	Length
Berman angiographic catheter	Arrow Intl, Reading, PA	4 Fr	50 cm
		5 Fr	50, 60, 80 cm
		6 Fr	60, 90 cm
		7 Fr	90, 110 cm
		8 Fr	70, 110 cm
Double-lumen, pulmonary artery monitoring catheters	Edwards LifeSciences, Irvine, CA	5, 6, 7 Fr	110 cm
Pulmonary angiography catheters	Edwards LifeSciences, Irvine, CA	7 Fr	110 cm

Because of the wide diameter, complicated placement, and need to adjust the depth of catheter insertion, it is necessary to place PACs via a catheter introducer sheath. The introducer sheath should be at least one size larger than the catheter itself. For example, a 7 Fr catheter will fit through an 8 or 8.5 Fr introducer sheath, while a 6 or 6.5 Fr introducer sheath is adequate for the 5 Fr catheter. For sterility, a plastic sleeve attached to the sheath covers the catheter and keeps the catheter sterile while the PAC is moved into and out of the vessel.

Most commercial catheters designed for thermodilution measurement of cardiac output have multiple ports and lumens (Color Plate 50-1). The proximal port, or central venous pressure (CVP) port, is used to measure right atrial or central venous pressure. This port is also used for fluid boluses during cardiac output determination in humans, dogs, and cats. Because the proximal port is located 30 cm from the tip of the catheter where the thermistor is located, it is necessary to have a separate catheter advanced into the right atrium (RA) in large animals for the purpose of injecting fluid for thermodilution measurements (the proximal port will be located in the right ventricle [RV] in the horse).[2] Separate RA catheters have also been used in cats and small dogs, where the proximal port would be located outside of the RA.[3] When using separate injection catheters, it is important that the catheter volume be the same as the injection port on the Swan-Ganz catheter, because the K2 constant of the Stewart-Hamilton equation used by cardiac output computers is specific for the catheter type.[4] The distal port of the catheter is the central lumen and is used to measure both PA pressure and pulmonary capillary wedge pressure (PCWP) or PA occlusion pressure. Mixed venous blood is also sampled from this port. The balloon port allows for inflation of the balloon tip of the catheter with a small amount of air (usually ≤1.5 ml) for flow-directed catheter placement, and measurement of PCWP. The catheter will also have an electronic thermistor connection for temperature measurement.

RVEDV, Right ventricular end diastolic volume; *SvO2*, venous oxygen saturation.

50.3.1 Cardiac Output

A PA catheter is necessary for evaluation of cardiac output using some thermodilution techniques (see Chapter 212, Cardiac Output Monitoring). Briefly, 1.5 ml/kg of saline (or 5% dextrose in water) of a known temperature is injected into the proximal port of the multilumen catheter.[4] In most animals, this proximal port (30 cm proximal to the tip of the catheter) will sit either in the RA or in the jugular vein, where it is appropriate to inject the indicator bolus. As mentioned previously, placement of a second injection catheter in the RA may be necessary to perform thermodilution in smaller or larger animals.[2,3] The thermistor probe on the distal end of the catheter will measure the change in blood temperature over time and will calculate cardiac output based on the area under the temperature curve. Newer Swan-Ganz catheters have thermistor probes near the junction of the proximal port and the catheter to more accurately measure the temperature of the injectate (it may warm significantly during injection). For larger animals such as horses, it is necessary to use chilled injectate, because subtle changes in blood temperature may not be sensed by the thermistor probe because of the relatively large cardiac output and blood volume in these animals. The indicator bolus must also be administered quickly, because a slow injection will minimize the change in temperature that is recognized by the thermistor and cause inaccurate readings (if injected too slowly, falsely low cardiac output measurement will be displayed). The use of a power injector pump is recommended for these measurements in large animals, and the bolus should be injected as quickly as possible in small animals.

50.3.2

Pulmonary Capillary Wedge Pressure

Measurement of PCWP via a PAC enables an estimation of left ventricular preload, because it can correlate with the left ventricular end-diastolic pressure. This correlation may not be reliable in patients with pulmonary hypertension, mitral regurgitation, or decreased ventricular compliance.[5,6] Airway and intrathoracic pressure can also affect this relationship. The methods for determination of the PCWP are discussed below. The PCWP may also be used to derive the pulmonary transcapillary pressure in dogs and cats.[4]

50.3.3

Right Ventricular End-Diastolic Volume

Right ventricular end-diastolic volume and index are used increasingly in human medicine to estimate volume status, especially in patients who are receiving positive-pressure ventilation with positive end-expiratory pressure, or other scenarios in which the PCWP does not accurately indicate left ventricular end-diastolic pressure. These values may be measured via catheters with special rapid-response thermistors that will sense small beat-to-beat changes in temperature induced by an upstream heat filament. These catheters need to be synchronized with the electrocardiogram, and patients need to have a regular R-R interval.[7] This same rapid-response thermistor and filament combination is used in catheters that will continuously measure cardiac output without the need for bolus injection (CCO PA catheter, CCOmbo Continuous Cardiac Output catheter, Baxter Healthcare Corporation, Edwards Critical Care Division, Irvine, CA).[7]

50.3.4

Selective Pulmonary Angiography

Selective pulmonary angiography via a PA catheter is sometimes indicated to elucidate complex congenital defects of the cardiopulmonary system in veterinary species.[1] Presurgical right heart catheterization for angiographic purposes is performed commonly in humans before cardiac surgery.[1] In animals, congenital defects such as stenosis of the pulmonic valve may be delineated via angiography and managed with balloon valvuloplasty by inflating a balloon catheter across the stenotic area.[8]

50.3.5 Additional Measurements

Balloon-tipped PACs that measure cardiac output and PCWP can also calculate systemic vascular resistance and pulmonary vascular resistance (see Chapter 212, Cardiac Output Monitoring).

50.4 INDICATIONS

The indications for placement of a PAC for the purposes of cardiac output measurement or mixed venous blood sampling have received much scrutiny in human medicine because of questions about the risk-to-benefit ratio. A 1997 consensus found a specific usefulness of the PAC in the management of hemodynamic instability during and after cardiac surgery and after myocardial infarction.[9] There was an uncertain benefit in the use of the PAC in defining shock states other than cardiogenic shock. Additionally, there was some evidence that the PA catheter was useful for treatment of trauma patients, as well as in certain pediatric populations.[9] A more recent study also questions the benefit of the PAC for management of heart failure, showing no benefit (but no detriment) in the group that had diuretic and afterload reduction therapy based on PAC measurements.[10] A recent metaanalysis of randomized controlled studies concluded that, although there was no increased morbidity in the PAC groups, a benefit was not realized from its use.[11,12] One reason that a clear benefit has not been shown for the PAC may be a result of inaccurate interpretation of the data obtained from the catheter.[13] Alternatively, the studies cited above evaluated a heterogeneous group of treatments, of which some may have been more effective than others.[14]

In veterinary medicine, catheters placed in the PA have been used for thermodilution measurement of cardiac output in many research studies.[15,16] The PAC seems useful for evaluation and treatment of cardiogenic shock. Information such as cardiac output and systemic vascular resistance can be used to guide inotropic and vasodilator therapy. Knowledge of systemic hemodynamics and cardiac output may also be helpful for guiding fluid resuscitation and pressor therapy in the small animal patient with hypovolemic and distributive shock. However, studies of the use of PACs in clinical veterinary patients are lacking.

Human data have focused on the optimization of oxygen delivery in shock and multiple organ dysfunction syndrome.[17] Although initial studies of this goal-directed therapy have been promising, the overall clinical benefit of this strategy compared with prior techniques has not been ascertained. Swan-Ganz catheters with oximetry probes are available to allow real-time measurement of venous oxygen saturation to allow optimization of oxygen delivery.

50.5 PLACEMENT

Judicious sedation using a benzodiazepine or an opioid may be indicated in some animals during placement of the introducer sheath and PAC. In the unanesthetized animal, a local block using lidocaine should be performed, because it is often necessary to make a skin incision to facilitate dilation of the vessel and smooth placement. Introducer sheath placement may be performed via a cutdown procedure to the external jugular vein, although percutaneous placement via a Seldinger technique is also appropriate and somewhat less complicated.[4] Before placing the catheter, a wide area of skin should be clipped and prepared aseptically. During placement, sterile drapes should be used to isolate the area, and sterile gowns, gloves, and a cap and mask should be worn.

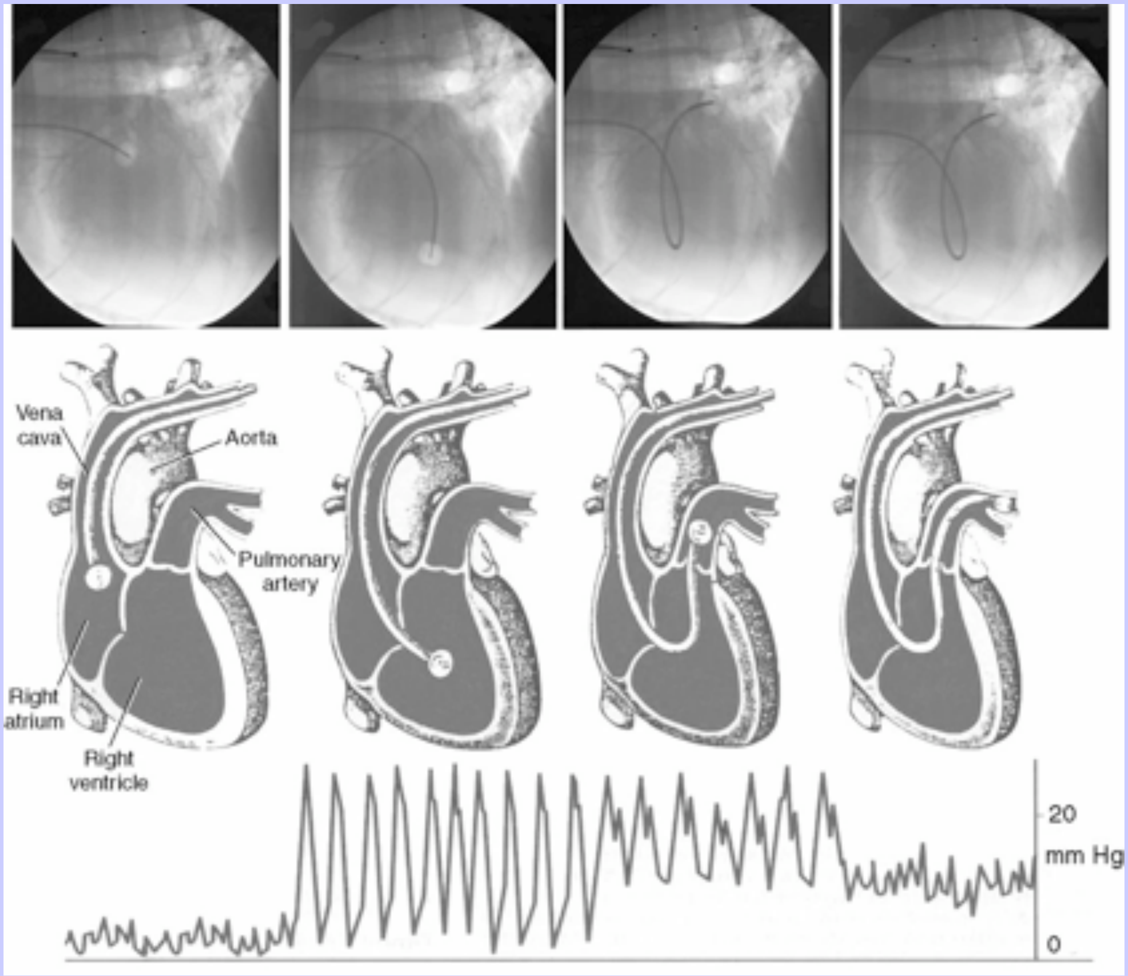
Regardless of technique, it is important to have an idea of the length of the catheter and distance from cardiac structures before placement. A lateral thoracic radiograph may be helpful for this purpose. Most Swan-Ganz thermodilution catheters are marked with thin black lines every 10 cm and thicker black lines every 50 cm (e.g., 70 cm is represented by one thick line and two thin lines, Figure 50-1). Placement is accomplished most easily through an introducer sheath placed in the external jugular vein.[5] The introducer catheter has a valve, which allows for ease of catheter placement and subsequent adjustments of catheter position, while preventing injection of air or loss of blood from the vessel. The addition of a sterile plastic sleeve allows for preservation of the sterility of the PAC during placement and adjustment. Once the introducer sheath is in place, the neck of the animal should be wrapped to protect the introducer sheath insertion site, as would be done with any jugular catheter.

Before feeding the PA catheter through the introducer sheath, the integrity of the balloon should be assessed. All ports of the catheter should be flushed with heparinized saline before introduction, and the catheter itself may be moistened with saline to allow smooth advancement through the introducer sheath.

50.5.1 Flow-Directed Placement

Classically, PACs are placed by attaching the distal port of the catheter to a calibrated pressure transducer and connected to a monitor. If continuous monitoring is to be performed, a system with a heparinized saline flush is indicated. By monitoring the pressure tracing as the catheter is advanced into the jugular vein (via the preplaced 211
introducer sheath), the position of the catheter tip may be deduced by recognition of the different waveforms 212
generated in each area of the heart and vessels (see Figure 50-1). After inserting the catheter into the RA (approximately 20 cm in a medium to large dog), the balloon may be inflated with air (the appropriate volume is usually listed on the port and is usually 1.5 cc) and then advanced further. It may not be necessary to inflate the balloon until the catheter tip is in the RV. The balloon should always be deflated before withdrawal of the catheter to prevent valvular damage or knotting of the catheter, and also after PCWP measurement to avoid unnecessary obstruction of blood flow.

Figure 50-1 The characteristic pressure waveforms recognized as the PAC is fed through (from left to right) the right atrium, the right ventricle, the pulmonary artery, and the wedge pressure tracing. Accompanied with a schematic and the fluorographic appearance at each step. In the fluorographic images, the dog is in right lateral recumbency with the dog facing left (NOTE: The third and fourth images are both in the pulmonary capillary). From Lalli SM: The complete Swan-Ganz, *RN* 41:64, 1978; and Headley JM: *Invasive hemodynamic monitoring: physiological principles and clinical applications,* Irvine, CA, 2002, Edwards Scientific.



In humans, the RA is entered at approximately 25 cm, the RV at approximately 30 cm, and the PA at approximately 40 cm; the PCWP can be identified at approximately 45 cm.[18] Thus, if 30 cm of catheter has been introduced but no atrial tracing is still seen, the catheter tip may have traveled into the azygous vein and should be withdrawn for another attempt. This may be avoided by keeping the tip directed ventrally, combined with slight rotation at the junction of the vena cava and the RA.[1] Once in the RA, the catheter may also become lodged in the coronary sinus or enter the caudal vena cava if it is directed too far caudally or dorsally.[1] If 10 cm has been introduced after attaining an RA tracing and the tracing has not changed, or reverts to a CVP tracing, inappropriate placement is suspected. Likewise, once in the RV, if the RV waveform persists 20 cm after initial appearance, the catheter may be coiling in the RV, and should be withdrawn slowly to the RA, after deflating the balloon, to avoid knotting of the catheter or damage to the tricuspid valve. Ventricular ectopic beats may be observed if the catheter contacts the walls of the RV. After the catheter has been floated into the PA, it should be pulled back 1 to 2 cm to straighten any redundant loops in the RV.

The pressure waveforms have characteristic tracings that allow the user to identify the position of the catheter tip. The RA tracing is similar to the CVP tracing from the jugular vein. Normal systolic RA pressure ranges from 4 to 6 mm Hg, with normal diastolic pressure from 0 to 4 mm Hg in anesthetized cats and dogs, giving a normal mean RA pressure of 2 to 5 mm Hg. Once the catheter is in the RV, a similar diastolic pressure is measured, but with a mean systolic pressure of 15 to 30 mm Hg. The PA tracing is notable because the diastolic pressure no longer decreases to zero because of the pulmonic valve, giving a mean diastolic pressure of 5 to 15 mm Hg (see Figure 50-1). Normal mean pulmonary artery pressure in dogs is 8 to 20 mm Hg.[1,15]

The characteristic waveform of the PCWP (similar to the RA tracing, but now representing the LA) is obtained by advancing the catheter slowly into the PA, with balloon inflated, until a point is reached when the diameter of the vessel is completely occluded by the balloon (see Figure 50-1). The waveform will change and the mean pressure will be lower than the mean PA pressure on entering the pulmonary capillary (mean PCWP is 5 to 12 mm Hg).[18] The catheter should not remain in a wedged position for longer than 10 to 15 seconds, or two respiratory cycles.[19] Once the PCWP is obtained, the balloon should be deflated, once again displaying the PA pressure waveform. For subsequent readings, because there is a tendency for the catheter to migrate distally as it warms to body temperature and softens, the balloon should be inflated slowly, with constant monitoring of the pressure tracing. PA rupture has been reported secondary to overzealous balloon inflation.[20] In humans, if a PCWP tracing is obtained before instillation of the full volume of air into the balloon (with less than 1.25 ml), it is recommended to deflate the balloon and to back the catheter out until PCWP is seen with full inflation of 1.5 ml of air.[18]

In the PA, the balloon should always be inflated slowly over 3 to 5 seconds, not only to avoid overinflation, but also because a rapid balloon inflation may be associated with spurious results.[18] If the pressure tracing shows a constantly increasing pressure, the tip of the catheter may be covered by the balloon, or may be pressed closely on the vessel wall or in a distal PA branch. This phenomenon, called over-wedging, may be remedied by deflating the balloon and situating the catheter tip more proximally before reinflating the balloon.

50.5.2 Fluoroscopy

Fluoroscopy provides a way to visually monitor catheter placement. PA catheters are radiopaque and so may be followed in their path from the jugular vein through the heart via radiography (see Figure 50-1). Fluoroscopy will help to quickly identify misplacement (e.g., into the azygous vein) and may enhance the speed of the procedure. The cons of fluoroscopy include the need for specialized equipment and generation of radiation during the procedure. All participants should wear protective lead aprons. Depending on the condition of the patient, it may not always be prudent to travel to a radiology suite to perform this procedure. Portable fluoroscopy units (C-arm) may simplify this procedure and move it closer to the bedside.

50.6 COMPLICATIONS

Complications of catheter placement reported in the human literature include wire or catheter embolus, cardiac tamponade, carotid artery puncture, hemothorax, and pneumothorax.[20] Many of these are related to the initial approach for vascular access (usually the internal jugular or subclavian veins), which is less of a problem in veterinary species with prominent external jugular veins suitable for placement of the introducer sheath. Insertion of the PA catheter into the mediastinum or the pleural space has also been reported in humans.[6] More serious complications associated with the PA catheter, although rare (estimated 0.0031%), include PA rupture from overzealous or erroneous balloon inflation or by direct catheter puncture. Risk factors for PA rupture in humans include advanced age, pulmonary hypertension, and improper inflation or positioning techniques.[6] Patients whose blood has been anticoagulated are also at risk. Little veterinary information is available about PA catheter complications; however, one postmortem study of horses after PA catheterization showed evidence of minor endocardial lesions.[21]

During catheter advancement through the heart, cardiac arrhythmias (premature atrial and ventricular contractions) may be seen. In humans, ventricular tachycardia and ventricular fibrillation have been reported, especially in patients with preexisting heart disease. Lidocaine was ineffective at suppressing these arrhythmias in one study, so the most effective way to decrease the incidence of ventricular ectopic beats is expedient passage of the catheter through the RV.[18] Right bundle branch block has also been reported during catheter advancement, which is of concern in patients with preexisting left bundle branch block, because complete heart block may result.[6] For this reason, it is recommended that the ability to perform transvenous or transthoracic pacing is available before performing this procedure in patients with left bundle branch block.[6] Some PA catheters are also equipped with a separate channel for the placement of pacing leads, and some have electrodes integrated into the catheter. Antiarrhythmic drugs should be available.

Once placed, maintenance of a PAC may be complicated by the formation of thrombi at the insertion site or at the tip of the catheter, or by embolic events from balloon rupture, inadvertent air administration, or thrombi, or distal catheter migration causing pulmonary infarction.[6,18] Infection is also a risk in patients with long-term indwelling PA catheters.[18] Anticoagulation is not routinely practiced after placement of a PA catheter, unless indicated for treatment of the underlying disease process. Anticoagulation in humans may be associated with increased severity of bleeding in the event of a PA rupture.[6] Heparin-coated PA catheters are available.[22]

50.7 ALTERNATIVES

Because of concerns related to the morbidity associated with PA catheters in critically ill patients, other techniques have been developed to measure cardiac output and systemic oxygenation. Direct measurements of ejection fraction and cardiac output may be obtained in anesthetized patients with transesophageal echocardiography, a technique that has been investigated in dogs,[23] but one which requires some skill in both obtaining and interpreting the images. Another technique for measuring cardiac output is similar to earlier indicator-dilution techniques that used indocyanine green dye as a marker of blood flow. With use of lithium chloride as a “dye,” concentrations measured by an ion-specific electrode may be analyzed and translated into cardiac output via a modified Stewart-Hamilton equation.[24,25] For cardiac output determinations using lithium dilution, the only necessary catheters are an arterial line for sampling and a central venous catheter for injection of the lithium chloride. Peripheral catheters may also be used for injection of the lithium chloride in dogs.[26] This technique has been investigated in dogs, cats, horses, and foals. Lithium ions do not reach toxic levels during routine use of this system.[27,28]

Some systems will derive continuous cardiac output measures via analysis of the arterial pressure waveform. The PulseCO system requires initial calibration with a cardiac output obtained via lithium dilution, and only periodic recalibration thereafter.[29] The PulseCO system has been evaluated in dogs and horses.[29,30] Newer systems (e.g., Flo-Trac, Edwards, Irvine, CA) do not require calibration to cardiac output.[31] A variation on the Fick principle, using partial carbon dioxide rebreathing, has also been developed to measure cardiac output. Termed *NiCO* (Respironics, Inc., Murrysville, PA), this technique uses a loop of tubing attached to the patient's endotracheal tube to measure the levels of expired carbon dioxide during a brief period of rebreathing.[32-34] An obvious detriment with use of this technique is the requirement of an intubated patient. This system has also been evaluated in dogs.[35]

Although a true mixed venous blood sample can not be obtained without a PAC, alternatives to measuring mixed venous oxygen saturation have been evaluated in human studies. The modification of goal-directed therapy using central venous oximetry has been proposed (see Chapter 10, Shock), and central venous catheters with fiberoptic oximetry probes are available for this purpose (PreSep Central Venous Oximetry Catheter, Baxter Healthcare Corporation, Edwards Critical Care Division, Irvine, CA).[17]

51 Chapter 51 Temporary Transvenous Pacing

Teresa DeFrancesco, DVM, DACVIM (Cardiology), DACVECC

51.1 KEY POINTS

- Temporary transvenous pacing refers to a minimally invasive modality in which a pacing lead is inserted, either via the jugular or femoral vein, into the right ventricle. A current is generated from a temporary pulse generator that is external to the body.
- Indications for temporary transvenous cardiac pacing are emergency stabilization of a patient with symptomatic, medically refractory bradycardia, usually as a bridge to permanent pacing or when the bradycardia is transient or reversible, as with drug overdoses.
- Temporary transvenous cardiac pacing is preferred over the transcutaneous when pacing is required for longer than a few hours.
- The most common complication with temporary transvenous pacing is lead dislodgement and loss of capture. Other complications include thrombosis, bleeding, infection, ventricular arrhythmias, and cardiac perforation.

51.2 INTRODUCTION

Temporary transvenous cardiac pacing is a minimally invasive technique used primarily to correct profound medically refractory bradycardia in hemodynamically unstable patients.[1-3] Temporary cardiac pacing is also useful prophylactically to support heart rate and blood pressure in patients with sick sinus syndrome or high-grade atrioventricular block who are undergoing general anesthesia for permanent pacemaker implantation. The need for any type of temporary cardiac pacing for permanent pacemaker implantation is debatable in patients who are hemodynamically stable. However, in patients with erratic ventricular escape rhythms or with extremely low ventricular escape rates (<30 beats per minute [bpm]), temporary pacing does improve cardiac output and blood pressure during anesthesia until the permanent pacing system is in place.

Additionally, prophylactic use of temporary pacing during permanent pacemaker implantation ensures rapid rescue if problems such as asystole arise. Arguments against temporary transvenous pacing include increased surgical time, need for sedation for placement, and the lack of clear improved outcome. In a large retrospective review of artificial pacemaker practices and outcomes from seven veterinary institutions, the use of temporary transvenous pacing in patients undergoing permanent pacing varied from 4% to 100%, depending on the institution and personnel performing the procedure.[4] No complications from temporary cardiac pacing were reported in this case cohort. Complications, in general, from cardiac pacing were related primarily to the operator's experience level and frequency in placing artificial pacemakers.

Temporary transvenous cardiac pacing is the preferred modality in humans.[1,2] Advantages of the transvenous system, as compared with transcutaneous pacing, include more consistent capture, improved patient comfort, and relative ease of insertion by experienced personnel. In the veterinary arena, temporary transvenous pacing usually is available only at university or private specialty hospitals.

51.3 INDICATIONS FOR TEMPORARY TRANSVENOUS PACING

Indications for temporary transvenous pacing follow:

1. Support of heart rate and blood pressure is provided by temporary transvenous pacing while the patient is under general anesthesia during permanent pacemaker implantation.
2. A patient with medically refractory bradycardia that is in eventual need of a permanent pacemaker and requires hemodynamic support needs temporary pacing. Some of these patients are being stabilized until permanent pacemaker implantation is possible (e.g., personnel issues). Other patients may have systemic infection or endocarditis; thus permanent pacemaker implantation is being postponed until the patient is free of infection.
3. A patient with medically refractory and potentially reversible bradycardia, usually caused by a drug overdose, needs the hemodynamic support provided by a temporary transvenous pacemaker. Drugs that commonly cause medically refractory bradycardias include digoxin, diltiazem, verapamil, and β-blockers.

51.4 DESCRIPTION OF THE TEMPORARY TRANSVENOUS PACEMAKER

The equipment needed for temporary transvenous pacing includes a sheath introducer set, a temporary pacing lead wire, and a temporary pacemaker. Additionally, electrocardiography and, ideally, fluoroscopy are used to guide lead wire placement and identify ventricular capture.

The sheath introducer set includes a vascular access needle or catheter, placement wire, vessel dilator, and sheath introducer with a one-way hemostatic valve to allow passage of the lead wire. The diameter of the sheath introducer should be big enough to accommodate the pacing wire. The most common catheter size used by the author in dogs is 5 Fr.

The temporary pacing lead is usually a bipolar lead, although quadripolar electrophysiologic catheters are also available. The pacing lead can simply be a semirigid lead wire or can be associated with a balloon-tipped catheter to ease passage across the tricuspid valve. In humans, a new temporary pacing lead wire with active fixation has been described for long-term temporary pacing (days to weeks), such as in a patient with endocarditis.[5] These new active-fixation temporary wires dramatically decrease the rate of dislodgement in long-term temporary pacing.

The temporary pulse generator is a small hand-held battery-operated device in which heart rate, energy output, and sensitivity can be adjusted to the individual patient. This demand pacemaker allows sensing of the patient's intrinsic heart rhythm and subsequent suppression of the pacing impulse.

51.5 IMPLANTATION OF THE TRANSVENOUS TEMPORARY PACEMAKER

The dog is placed in lateral recumbency for central venous access. The need for sedation depends on the patient's demeanor and hemodynamic status. Either the jugular or femoral vein is cannulated aseptically with the sheath introducer, using the Seldinger technique. The author uses a small subcutaneous infusion of lidocaine for local anesthesia at the catheter insertion site. If using the jugular vein for temporary pacing, the left jugular is used to save the right jugular for the permanent system. Once the introducer is in place, it is flushed with heparinized saline and sutured in place.

The pacing lead wire is then inserted via the sheath introducer's hemostatic port, preferably through a plastic contamination guard. The wire is advanced into the right ventricular apex, ideally with fluoroscopic and electrocardiographic guidance, until ventricular capture is noted (Figure 51-1), associated with a smooth coursing of the lead wire into the apex of the right ventricle seen fluoroscopically. The pacing lead is connected to the external temporary pacemaker. The temporary pacemaker is usually set for a heart rate of about 80 to 100 beats/min. The energy output usually is set at 3 mA initially. At this voltage, the ventricle should be captured with each pacing impulse. One can determine the voltage threshold by gradually turning down the voltage until capture is lost. The pacemaker voltage is set at least twice the threshold voltage. The author typically sets the sensitivity at 3 V for temporary pacing, but this may need to be adjusted to ensure that no oversensing or, more importantly, undersensing of intrinsic beats occurs. Once the pacing wire and external temporary pacemaker settings are made and the lead wire position is deemed adequate, the insertion site is dressed with antimicrobial ointment and the neck is wrapped with a triple-layer bandage to ensure that the wire and external generator are secured and protected.

51.6 TROUBLESHOOTING

One potential problem with insertion is that the lead wire does not advance across the tricuspid valve into the right ventricular apex, and continues to loop in the right atrium or goes out the caudal vena cava. Balloon-tipped pacing catheters ease the passage across the tricuspid valve into the right ventricle. Additionally, before insertion of the wire, molding 3 to 4 cm of the tip of the wire to a gentle 20- to 30-degree angle may help slip it into the right ventricle.

The other common problem is inability to capture the ventricle. Pacing spikes are seen, but no QRS complex or capture is seen. This typically results from poor contact of the wire with the ventricular muscle. The position of the wire is checked using fluoroscopy. The ideal placement for the tip of the pacing wire is the apex of the right ventricle. If no pacing spikes are seen at all, then failure of the battery, pulse generator, or a loose connection is usually at fault. Ideally, a new battery is used for each case.

51.7 COMPLICATIONS

Lead dislodgement is the most common complication with temporary transvenous pacing, based on the human literature and the author's experience.[1,2,5,6] Lead dislodgement usually is well tolerated for brief periods but is potentially life threatening in a patient that is entirely pacemaker dependent. Interestingly, there are no reports of complications associated with temporary transvenous pacing in the veterinary literature. Several reports of complications associated with permanent transvenous pacing in dogs[4,7,8] describe similar complications that have been reported in the human literature for temporary transvenous pacing. These include hemorrhage, infection, ventricular arrhythmias, cardiac chamber perforation, and thrombosis. It is important to emphasize that although the serious complication rate is probably low for temporary transvenous pacing in dogs, there is the potential for significant and serious sequelae.

Figure 51-1 An electrocardiogram from a dog with a transvenous temporary pacemaker. Note the large pacing spikes *(arrows)* followed by QRS-T, confirming ventricular capture.

52 Chapter 52 Transcutaneous Pacing

Teresa DeFrancesco, DVM, DACVIM (Cardiology), DACVECC

52.1 KEY POINTS

- Transcutaneous pacing (TCP) is a noninvasive modality of cardiac pacing in which patch electrodes are placed on the skin of the right and left hemithorax at the cardiac precordium. A current passed between these electrodes causes both electrical and mechanical capture of the heart.
- Indications for TCP are similar to those for temporary transvenous cardiac pacing—that is, emergency management of medically refractory and hemodynamically significant bradyarrhythmias, and support of heart rate and blood pressure of patients with sick sinus syndrome or high-grade atrioventricular block undergoing general anesthesia, typically for permanent pacemaker implantation.
- TCP is preferred over transvenous pacing in life-threatening situations because of the shorter time to implementation.
- The most common complications of TCP in dogs are discomfort and musculoskeletal stimulation associated with the pacing stimulus, which requires heavy sedation or general anesthesia. These limit its use for short-term temporary cardiac pacing.

52.2 INTRODUCTION

Transcutaneous pacing (TCP) is a noninvasive mode of temporary pacing used in patients with life-threatening, medically refractory bradyarrhythmias. TCP is also used to support cardiac output in patients with medically refractory bradyarrhythmias that are undergoing general anesthesia, typically but not exclusively for permanent pacemaker implantation. TCP is an attractive alternative to transvenous cardiac pacing for short-term pacing. Although transvenous cardiac pacing is well tolerated by most patients, it is an invasive procedure requiring considerable operator skill, and its use has been associated with serious complications in humans such as arrhythmias, infection, lead dislodgement, cardiac perforation, hemorrhage, and thromboembolism.[1,2]

TCP is preferred in emergency situations because of the shorter time to cardiac pacing.[3] TCP does not require vascular access. Vascular access, even with an experienced operator, can cause unacceptable delays in initiation of cardiac pacing. TCP was introduced in human patients during the 1950s and has been used routinely in acute care settings for approximately 20 years.[4,5] It was first described for use in client-owned dogs with medically refractory bradyarrhythmias in 2003.[6] Because of the cost of the equipment needed to implement TCP, the procedure usually is available only at selected university and private specialty veterinary hospitals.

52.3 INDICATIONS FOR TRANSCUTANEOUS PACING

Indications for TCP include emergency treatment of medically refractory and life-threatening bradyarrhythmias. Typical case scenarios include dogs with hemodynamically unstable complete AV block. In the author's experience, the dogs in this category are those with erratic ventricular escape rhythms in which many seconds can elapse with no ventricular contraction. TCP is also useful for an in-hospital cardiac arrest due to complete AV block or other medically refractory bradycardias in which a meaningful recovery can be expected.

A second indication for TCP is support of heart rate and blood pressure in dogs undergoing general anesthesia for permanent pacemaker implantation. Candidates are generally dogs with high-grade AV block or symptomatic sick sinus syndrome. TCP can also be used for permanent pacemaker replacement or readjustment of a dislodged lead wire. These dogs generally are hemodynamically stable at rest but have the potential for low cardiac output and even cardiac arrest while under general anesthesia. The TCP system typically is placed just before induction of general anesthesia and is in a ready state to implement for asystole, or simply for support of cardiac output if hypotension or extreme bradycardia occurs during the anesthetic period.

A third indication for TCP is support of heart rate and blood pressure in dogs with clinically silent sinus node dysfunction that have experienced an episode of profound and medically refractory bradycardia while undergoing general anesthesia. Typically these dogs were undergoing anesthesia for surgery unrelated to the heart, such as cataract extraction or cystotomy for urolithiasis removal, which was aborted because of the medically refractory and life-threatening bradycardia. If the owner or the dog's clinical status dictates that the surgery be reattempted, these dogs usually require temporary cardiac pacing to tolerate the anesthesia. The author generally does not recommend permanent pacemakers in dogs with asymptomatic sinus node dysfunction. The author believes TCP is a better option than transvenous cardiac pacing in these surgical cases because of its noninvasive nature and lower risk for infection.

52.4 DESCRIPTION OF A TRANSCUTANEOUS CARDIAC PACING SYSTEM

A TCP system is an optional feature on some defibrillator-electrocardiogram (ECG) systems. Currently, Medronic (Minneapolis, MN) and Zoll Medical (Chelmsford, MA) both offer optional external cardiac pacing. In addition to the pulse generator, the pacing system requires a good-quality ECG tracing and a pair of disposable transthoracic patch electrodes connected to the pulse generator via pacing leads.

Application of the external pacemaker is simple. Standard ECG leads usually are connected to the footpads of the 217
dog to obtain a good-quality recording. The adhesive pacing patch electrodes are then placed on the left and right 218
hemithorax directly over precordial impulse (Figure 52-1). The fur is shaved over both the left and right precordia, and a small amount of ECG paste is placed on the electrode patches just before adhesion. One may choose to further secure the patch electrodes with an elastic nonadhesive bandaging material to minimize migration and to improve contact. After the patch electrodes are placed, a good-quality ECG recording is obtained. Lead selection and ECG gain are optimized to attain accurate sensing of the patient's intrinsic cardiac rhythm by the demand pacing system (Figure 52-2). After accurate QRS sensing is confirmed by the appearance of the sensing marker on the ECG monitor, the desired pacing rate is chosen and the pacing current is increased gradually until ventricular capture is identified on the ECG (see Figure 52-2) and by palpation of a corresponding arterial pulse. 218
Determination of electrical and mechanical capture can at times be difficult because skeletal muscle is also 219
stimulated, causing motion ECG and palpation artifact, respectively. Ventricular capture is identified by a wide QRS-T complex after the pacing spike on the ECG monitor. The current output is then maintained just above the capture threshold, usually 10 to 20 mA greater than threshold, for the duration of cardiac pacing. In a clinical canine case series, the current required for pacing ranged from 50 to 110 mA.[6]

Figure 52-1 Schematic illustration of a dog under general anesthesia undergoing noninvasive, transthoracic external cardiac pacing. The dog is positioned in lateral recumbency, an electrocardiographic recording is obtained, and after proper sensing of the patient's cardiac rhythm, the pacing stimulus is delivered through the two large patch electrodes placed directly over the precordium on the right and left sides of the thorax. Illustration by Petra Guity. From DeFrancesco TC, Hansen BH, Atkins CE: Noninvasive transthoracic temporary cardiac pacing in dogs, *J Vet Intern Med* 17:663, 2003.

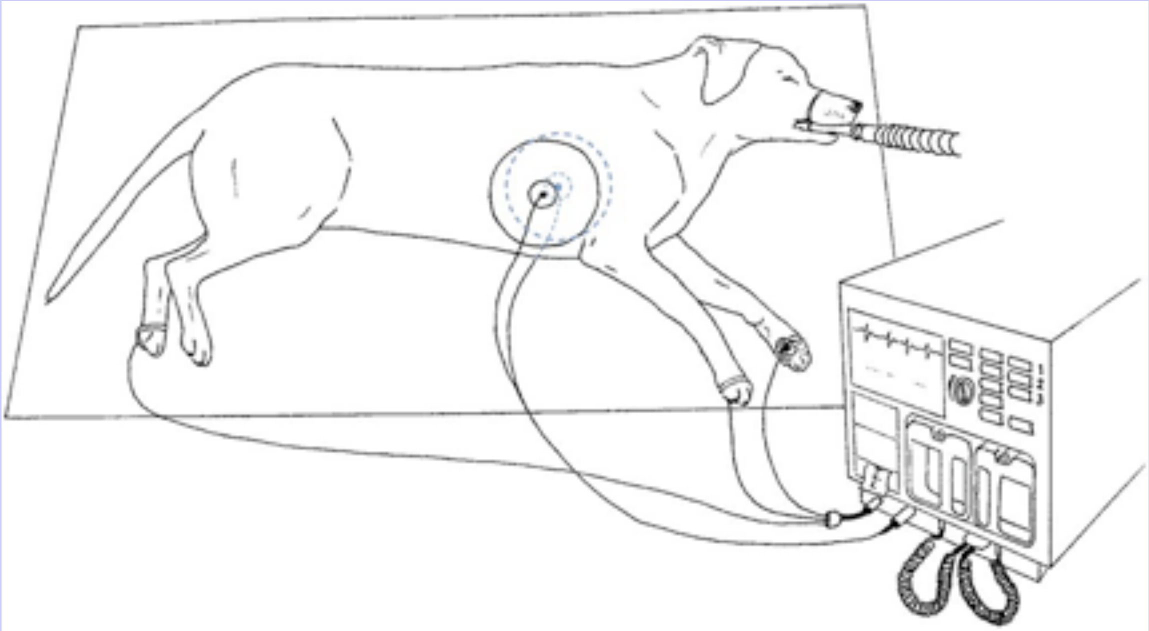

Figure 52-2 **A,** Electrocardiogram from a dog with complete atrioventricular block under general anesthesia for permanent pacemaker implantation. The ventricular rate is 30 beats/min while the atrial rate is 170 beats/min. **B,** Proper sensing of the patient's intrinsic QRS activity is shown with the sensing marker, an inverted triangular symbol on top of the QRS. Once accurate sensing is accomplished, the pacemaker is turned on. **C,** Electrical capture of the ventricle by the pacer is shown by a pacing spike followed by a wide QRS-T complex. Each pacing spike is also denoted by an *arrow* mark just below the paper grid. The ventricular rate is now 70 beats/min (paper speed for all ECG recordings is 25 mm/sec). From DeFrancesco TC, Hansen BH, Atkins CE: Noninvasive transthoracic temporary cardiac pacing in dogs, *J Vet Intern Med* 17:663, 2003.

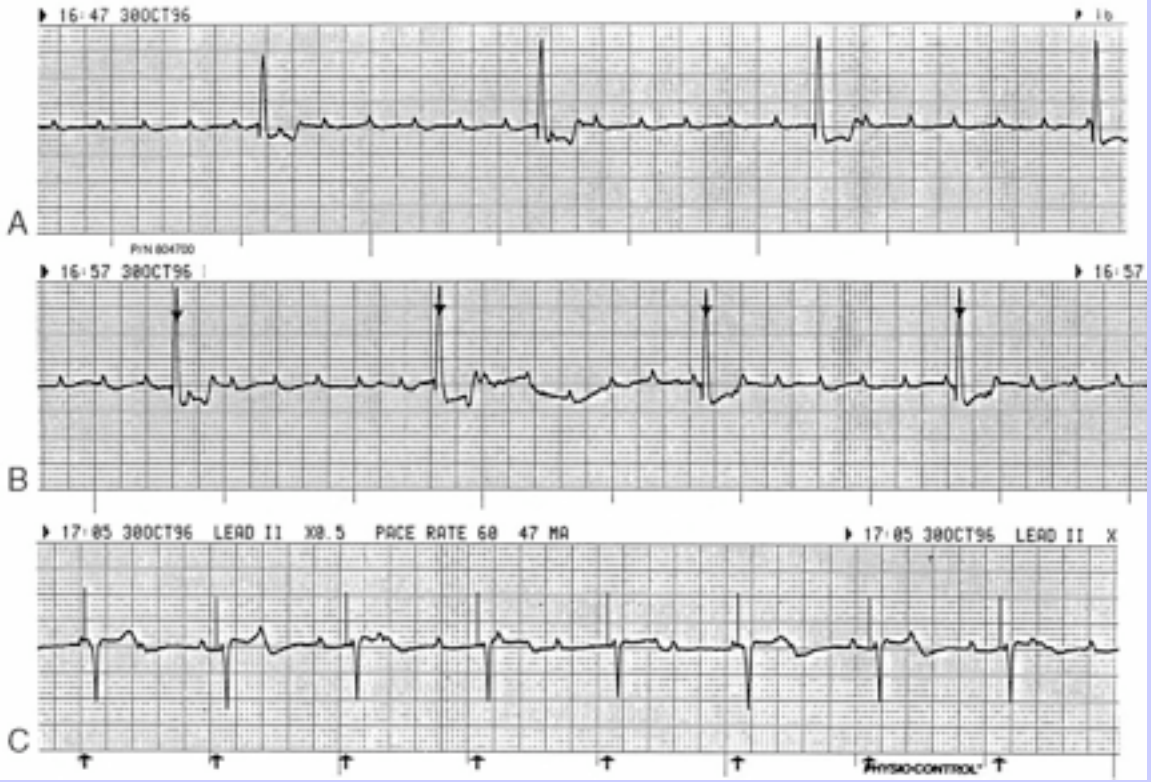

52.5 COMPLICATIONS

Although most humans tolerate external cardiac pacing with no or minimal discomfort, conscious dogs, in the author's experience, do not tolerate TCP. General anesthesia and analgesia are strongly recommended for all dogs in which this technique is employed. In one human case series, the pacing stimulus was described as intolerable by only 10% of patients.[5] These patients described the pacing stimulus as a severe thump or as an intense burning or stinging pain that required termination of pacing. The pain and discomfort associated with noninvasive pacing are increased with higher pacing current outputs, smaller diameter patch electrodes, and presence of any skin abrasions at the electrode site.[5] It is unclear whether dogs truly feel pain with TCP or if the element of surprise, combined with the sudden and repetitive nature of the pacing stimuli and skeletal muscle stimulation, make the technique intolerable.

Despite the requirement for general anesthesia, TCP is a good alternative over temporary transvenous pacing in most veterinary clinical settings in which short-term temporary pacing is indicated, that is, permanent pacemaker implantation, replacement, or lead adjustment.

Skeletal muscle stimulation is another complication associated with TCP. This expected side effect is caused by unavoidable electrical stimulation of the skeletal muscles of the thorax and forelegs, which causes the patient to jerk mildly to moderately with each pacing impulse. These movements, although predictable, can increase the difficulty of surgery, especially in smaller dogs, in which the rhythmic motion of the forelegs can be more pronounced. This skeletal muscle jerking can be eliminated with neuromuscular blockade, which then necessitates mechanical ventilation during anesthesia.

52.6 TROUBLESHOOTING

Despite the ease and speed of noninvasive transthoracic pacing, especially in arrest situations, the primary disadvantage in human patients is inconsistent pacing success rates.[7] In the author's experience, initial failure to pace in dogs with TCP usually results from suboptimal electrode placement. The patch electrodes should be placed directly over the cardiac impulse beat, but not too close to the sternum, so that the current actually courses across the heart and not along the skin. The author has also noted that skin and, subsequently, the patch electrodes tend to move with changes in body position, which can cause loss of capture. The position of the patch electrodes should be checked every time the dog is moved. The user also should be aware that the patch electrodes are available in adult and pediatric sizes, and that the appropriate electrode size should be used for the dog. Other causes of inconsistent pacing include obesity, barrel-shaped chest conformation, and pleural space or pericardial disease. In dogs with physical reasons for inconsistent pacing, increased current, generous use of conducting gel, and chest wrap with a nonadherent bandaging material usually help to achieve capture. In a canine case series, successful pacing was achieved in all dogs, although repositioning of the patch electrodes was needed in several patients.[6]

53 Chapter 53 Cardioversion and Defibrillation

Steven G. Cole, DVM, DACVECC, DACVIM (Cardiology)

53.1 KEY POINTS

- Defibrillation and cardioversion involve the application of an electrical shock to terminate a cardiac arrhythmia.
- Electrical defibrillation is a key component of advanced life support and is the only effective treatment for ventricular fibrillation or pulseless ventricular tachycardia in patients with cardiopulmonary arrest. Chemical defibrillation is not a viable alternative.
- Synchronized cardioversion is used for treatment of unstable or drug-refractory supraventricular or ventricular tachyarrhythmias and delivers the electrical impulse at a specific portion of the cardiac cycle to avoid the vulnerable period during the T wave.
- Defibrillator use poses some risk to staff and should be done by trained personnel following a standard protocol.

53.2 INTRODUCTION

Electrical defibrillation and cardioversion are advanced techniques that involve the application of an electrical shock to terminate a cardiac arrhythmia. Both of these techniques use current generated from a defibrillator to cause simultaneous global depolarization of the myocardium, thereby interrupting rhythms that depend on organized or disorganized reentrant mechanisms for their maintenance.[1] Although defibrillation and cardioversion are very similar, they differ somewhat in their application.

Specifically, *defibrillation* refers to an unsynchronized impulse delivered in an effort to abolish ventricular fibrillation or pulseless ventricular tachycardia and is a key component of advanced life support and cardiopulmonary resuscitation (CPR) (see Chapter 4, Cardiopulmonary Resuscitation). In comparison, *synchronized cardioversion* refers to an impulse that is delivered during a specific portion of the cardiac cycle to terminate a symptomatic supraventricular or ventricular arrhythmia.

It should be noted that defibrillation and cardioversion are used to treat symptomatic and potentially life-threatening arrhythmias. In cardiopulmonary arrest associated with a rhythm of ventricular fibrillation or pulseless ventricular tachycardia, the use of a defibrillator is unquestioned and is likely the only method that may restore spontaneous circulation. For other arrhythmias, including sustained, symptomatic supraventricular or ventricular tachycardia, the role of electrical therapy is not clearly defined for veterinary patients in an emergency or critical care setting. Certainly cardiac arrhythmias are common in critically ill dogs and cats and are associated with primary cardiac disease as well as with a variety of noncardiac conditions. However, most of these arrhythmias, including isolated single ventricular premature complexes or accelerated idioventricular rhythms, do not require specific therapy. When the arrhythmia requires management, drug therapy is the appropriate therapeutic choice for nearly all patients. Only in rare situations is the emergency use of synchronized cardioversion indicated. In all cases, patients that are successfully defibrillated or cardioverted should be monitored intensively and treated aggressively to prevent deterioration of their postshock rhythm.

53.3 EQUIPMENT

Many newer defibrillators have the capability to perform both synchronized cardioversion and defibrillation. Defibrillators are available from many manufacturers in both portable and stand-alone configurations. Ideally, the defibrillator is placed on a crash cart in a centrally located arrest station along with supplies for vascular access, airway management, and resuscitation drugs. Although both defibrillation and cardioversion may be performed with standard paddles, several accessories make the procedures easier to perform in veterinary patients. First, an attachment called a *posterior paddle* (Color Plate 53-1), which is a flat paddle that can be placed under the patient, makes it possible to cardiovert or defibrillate a patient in lateral recumbency. This minimizes the awkwardness and increased danger to staff that arises from defibrillating a patient in dorsal recumbency. Second, many defibrillators can be used with adhesive patches instead of paddles. These patches come in both pediatric and adult sizes for use on both small and large patients and provide similar benefits to a posterior paddle.

53.3.1 Monophasic Versus Biphasic Waveforms

Two types of defibrillators are available: monophasic and biphasic. These differ by the shape of the waveform that is generated by the defibrillator. Monophasic defibrillators generate a single positive current, and biphasic defibrillators generate a positive followed by a negative current (Figure 53-1). The bidirectional energy flow produced by biphasic defibrillators allows lower energy settings to be employed, and there is evidence suggesting that this technology allows for more efficient defibrillation with less myocardial damage.[2] Although biphasic defibrillators are becoming more common in human medicine and recommendations for energy settings have been incorporated into human CPR guidelines,[3] monophasic defibrillators are much more common in veterinary hospitals. Accordingly, guidelines for energy settings in small animal patients are based on defibrillators with monophasic waveforms.[4]

53.4 SAFETY

Electrical defibrillators can be among the most effective, as well as the most dangerous, pieces of equipment in a veterinary hospital. Inadvertent delivery of current to staff can result in painful electrical shocks, burns, and potentially serious cardiac arrhythmias. The risk of injury to staff increases when the animal is in dorsal recumbency, because it is more likely that the patient's limbs will touch nearby personnel. It is also important to recognize that metal surfaces may conduct current, and it is recommended that nonconducting rubber or foam pads be placed on metal tables near the crash cart. Additionally, poor contact between the paddles and the chest may result in arcing of current across the surface of the patient. This can result in fire, especially when alcohol has been placed on the fur. As a result, only contact gel should be used to apply electrocardiogram (ECG) electrodes when defibrillation or cardioversion may be necessary. Because of these potential hazards, it is vital that staff members are educated in the use of the defibrillator and that protocols for cardioversion and defibrillation are followed carefully.

53.5 DEFIBRILLATION

53.5.1 Indications

The indications for defibrillation are clearly defined: ventricular fibrillation or pulseless ventricular tachycardia in a patient suffering cardiopulmonary arrest. Once either of these rhythms is recognized, ongoing CPR should be halted and defibrillation should take place immediately. Other arrest rhythms, including asystole, sinus bradycardia, or slow pulseless electrical activity, are not indications for defibrillation. Although ventricular fibrillation is the initial arrest rhythm in only 20% of small animal patients suffering cardiopulmonary arrest,[5] it often develops during the course of the resuscitation, and the defibrillator should be immediately available if this occurs.

Figure 53-1 Monophasic *(left)* versus biphasic *(right)* defibrillator waveforms.

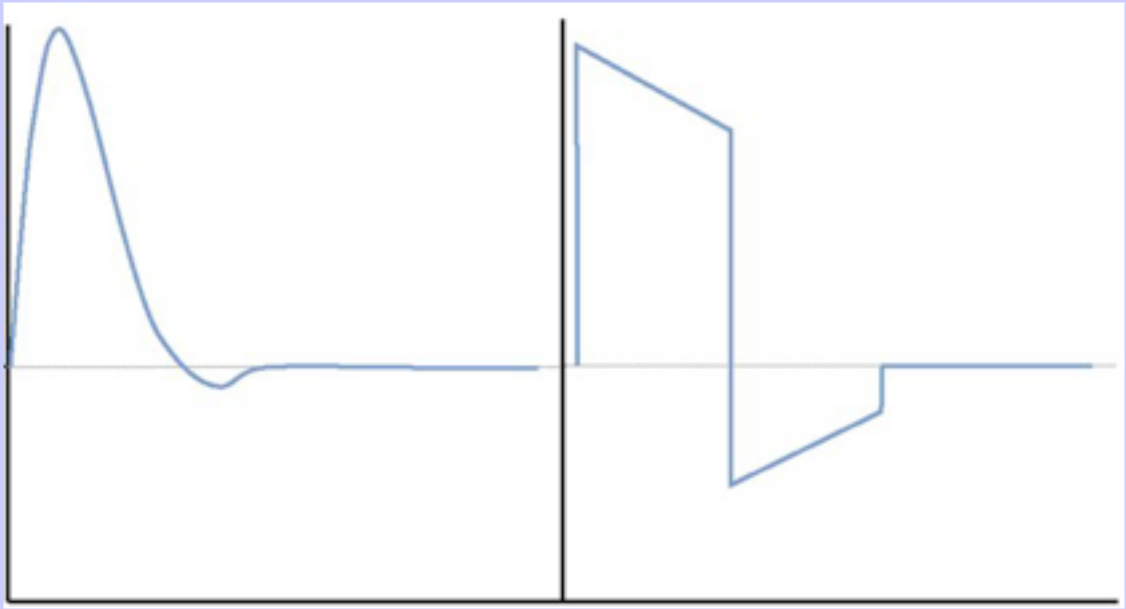

Table 53-1 Guidelines for Initial Defibrillator Settings With Monophasic Waveform Defibrillators

	Weight (lb) Weight (kg)	52.5	10 5	2010	30 15	4020	50 25	60 30	70 35	80 40	90 45	100 50
Dosage												
External defibrillation	2 to 10 J/kg	20	30	50	100	200	200	200	300	300	300	300
Internal defibrillation	0.2 to 1 J/kg	2	3	5	10	20	20	20	30	30	30	30

53.5.2 Technique for Use

Defibrillation may be performed in conjunction with both closed-chest and open-chest CPR techniques. External defibrillation is performed most commonly and, as mentioned above, may be done with standard defibrillator paddles, a standard paddle and a flat posterior paddle, or adhesive defibrillator patches. The author's preferred technique is a standard paddle and a flat posterior paddle, with the patient in lateral recumbency. This eliminates the awkward and dangerous use of dorsal recumbency necessary with two standard paddles and is quicker and more consistent to perform than the use of adhesive patches, which requires clipping of hair and is prone to poor skin contact if traction is applied to the leads. With the patient in right lateral recumbency, the posterior paddle is placed underneath the right side of the chest and a standard paddle is used on the upper side. A generous amount of contact gel is applied to each paddle before use, and care is taken to place the paddles over the heart (as opposed to the dorsal portion of the chest wall).

Before delivering countershocks, it is important that the operator follow a sequence designed to ensure the safety of all personnel participating in the resuscitation effort. First, the ECG rhythm of ventricular fibrillation or pulseless ventricular tachycardia is verified. Second, proper placement of the paddles is confirmed. Third, the operator announces the intention to defibrillate the patient, halt ongoing CPR, and calls “clear.” Fourth, following the call of “clear,” the operator visually confirms that no personnel are in contact with the patient or table. Finally, firm pressure is applied with the paddle and the countershock is delivered. The ECG is then monitored for the efficacy of the countershock, and the patient is immediately reassessed for the return of spontaneous circulation.

An energy setting of 3 to 5 joules/kg (range 2 to 10) is selected for the initial external defibrillation attempt (Table 53-1), with an increase in energy of approximately 50% for each subsequent attempt. It had previously been recommended that a series of three shocks be administered before recommencing CPR (for 1 to 2 minutes) in cases of unsuccessful defibrillation, with pauses between shocks only long enough to monitor the ECG and to recharge the defibrillator.[4,6] More recent human recommendations call for 1 to 2 minutes of CPR between each unsuccessful shock, because this may increase the likelihood of success.[3] It is reasonable to adapt these guidelines to veterinary patients, and the one-shock protocol may be considered an alternative to the established three-shock protocol.

Defibrillation may be performed during open-chest CPR. In this situation, internal paddles are employed to apply current directly to the epicardium. Accordingly, the energy used is significantly less than that used for external defibrillation. An initial energy of 0.2 to 1 joule/kg is selected, and this may also be increased by 50% with subsequent shocks. As with external defibrillation, a one-shock or three-shock protocol may be used, with 1 to 2 minutes of cardiac compression between defibrillation attempts with the one-shock method. Because myocardial burns may occur with internal defibrillation, it is recommended that saline-soaked gauze sponges be placed between the paddles and the epicardium before defibrillation. Although the energy used for internal defibrillation is significantly less than for external defibrillation, it is still important to follow standard protocol to ensure safety of all personnel before discharge of the defibrillator. It should also be mentioned that if internal paddles are not available, the patient may still be defibrillated externally in standard fashion during open-chest resuscitation.

53.6 CARDIOVERSION

53.6.1 Indications

As opposed to defibrillation, the indications for synchronized cardioversion are less well defined in small animal patients. In human medicine, synchronized cardioversion is the emergency treatment of choice for unstable patients with supraventricular or ventricular tachyarrhythmias.[3] Most dogs and cats with sustained tachyarrhythmias can be treated successfully with antiarrhythmic drugs (see Chapter 190, Antiarrhythmic Agents). Although synchronized cardioversion for dogs with “lone” atrial fibrillation has been described,[7] this is not considered an emergency procedure and, if it is considered, should be performed by a veterinary cardiologist.

In patients with atrial fibrillation and a rapid ventricular response rate, management with rate-lowering drugs (calcium channel blockers, β-blockers, digoxin) is more appropriate in an emergency setting.

Synchronized cardioversion is indicated, however, in patients with sustained supraventricular or ventricular tachyarrhythmias that are unresponsive to drug therapy and result in adverse clinical signs. This is especially true if the arrhythmia is compromising perfusion and causing signs of shock or hypotension, because the rhythm may deteriorate rapidly to ventricular fibrillation. In all conscious patients, sedation and analgesia or anesthesia must be provided, because cardioversion is a painful and distressing procedure in an awake patient.

53.6.2 Technique for Use

Synchronized cardioversion, like defibrillation, may be performed with standard defibrillator paddles, with a standard paddle and a flat posterior paddle, or with adhesive patches. Because synchronized cardioversion often is performed in more controlled circumstances than is defibrillation, the author prefers to clip the fur on either side of the thorax and to use adhesive defibrillator patches. Following the administration of sedatives and analgesics or the rapid induction of anesthesia, the patient is placed in lateral recumbency. As with defibrillation, a protocol is followed to ensure the safety of the staff before administering the countershock. The key components are to announce the intention to perform cardioversion, to call “clear,” and to visually verify that all personnel are clear of the patient and table before discharge.

The defibrillator should be placed in synchronization mode, and it should be verified that the QRS complexes are recognized. Most defibrillators display a mark on each recognized complex as it is displayed on the ECG monitor. The energy to be used for synchronized cardioversion is not well defined for veterinary patients. However, because cardioversion requires less energy than defibrillation, it is recommended to begin with 50% of the energy recommended for defibrillation.[4,7] This is similar to guidelines for human medicine and has proven effective in veterinary patients.[3,6,7] Once the countershock has been delivered, the ECG should be monitored for resolution of the arrhythmia and, if persistent, cardioversion may be repeated at the same or sequentially increasing energy levels.

Synchronized cardioversion prevents delivering the countershock during the vulnerable period associated with the mid to late portion of the T wave. The vulnerable period represents the relative refractory period, during which the ventricular myocardium is in various stages of repolarization. During this time, stimulation of reentrant circuits can lead to ventricular fibrillation.[8] Despite the synchronization feature of the defibrillator, it is possible for the rhythm to deteriorate during cardioversion. Because of this, it is important to be prepared to perform immediate defibrillation (at standard energy levels) should ventricular fibrillation develop or to perform CPR should asystole occur. In patients that are cardioverted successfully, appropriate antiarrhythmic therapy should be instituted, and the patient should be monitored intensively for recurrence of the arrhythmia.

53.7 POSTDEFIBRILLATION AND CARDIOVERSION MONITORING

In addition to continuous ECG monitoring and appropriate antiarrhythmic therapy, patients should be monitored for systemic derangements that may result from temporary tissue ischemia. The neurologic status of post-defibrillation or cardioversion patients should be assessed and monitored, because cerebral anoxia or emboli may occur. Respiratory rate and effort, in addition to oxygenation status, should be observed because CPR and central nervous system disease may affect respiratory function and drive, respectively. Arterial blood pressure should be maintained within a normal range to maximize oxygen delivery to the tissues and prevent organ dysfunction. Skin burns should be identified and treated with appropriate wound care.

97 Chapter 97 Coma Scales

Simon R. Platt, BVM&S, DACVIM (Neurology), DECVN, MRCVS

97.1 KEY POINTS

- Coma can result from many causes affecting the intracranial nervous system.
- Severe head trauma is a common cause of coma in veterinary medicine, and victims may have a poor prognosis.
- The prognosis for a patient with head trauma depends on the severity of the neurologic injury at the time of hospital admission.
- Neurologic injury can be categorized numerically based on the abnormalities detected on examination.
- The numeric scoring system developed for animals with head injury is the modified Glasgow Coma Scale.
- The scoring system is based on specific abnormalities of mentation, motor function, and neuroophthalmologic examination.

97.2 INTRODUCTION

Although coma can be caused by an array of direct and indirect neurologic disorders affecting the intracranial structures in small animals. The development of coma scales has focused on dogs and cats with head trauma. These tools can be used objectively to decide when to initiate aggressive treatment, to monitor the success of therapy and, in some cases, provide a prognosis. Such scoring systems are in their infancy in veterinary medicine and are meant to be only a guide to management. They can be used to monitor patients with any cause of coma based on this premise. This chapter is focused on coma scales as they specifically relate to head trauma.

Appropriate therapy for patients with head trauma remains controversial in veterinary medicine (see Chapter 152, Traumatic Brain Injury). Treatment must be immediate if the animal is to recover to a level that is both functional and acceptable to the owner. It is important therefore to be aware of the optimal way to assess these patients; many dogs and cats can recover from severe brain injuries if the clinician is able to identify treatable systemic and neurologic abnormalities in a timely manner.

97.2.1 Intracranial Pressure After Head Trauma

Increases in intracranial pressure (ICP) are often responsible for the clinical decline seen in many animals after head trauma.[1] Following traumatic brain injury, the volume of the brain tissue compartment increases, usually a result of edema or hemorrhage. As this tissue compartment increases, the cerebrospinal fluid (CSF) and blood compartments must decrease to prevent an increase in ICP. Compensation for increased brain tissue volume initially involves shifting of cerebrospinal fluid out of the skull, decreased production of CSF and, eventually, decreased cerebral blood flow.[2] These compensatory mechanisms prevent increases in ICP for an undetermined period. In general, the compensation is more effective when the increases in ICP are slow. Once the capacity for compensation is exhausted, a further small increase in intracranial volume will result in dramatic elevations of

ICP, with the immediate onset of clinical signs.[2] Unfortunately, the clinical signs of significantly increased ICP often become evident too late for any therapy to be effective. A clear understanding of what clinical signs necessitate immediate intervention, those that indicate a grave prognosis, and those that need to be closely monitored will help with the successful treatment of patients following head trauma.

97.3 NEUROLOGIC ASSESSMENT

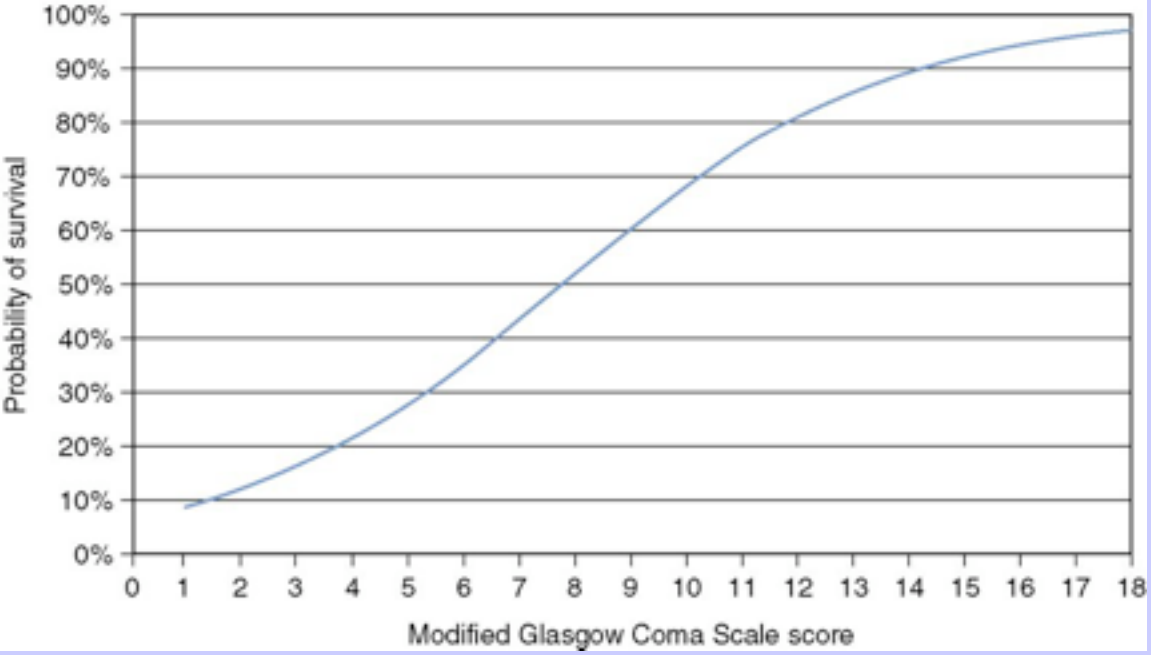
Initial neurologic assessment should include an evaluation of the patient's state of consciousness, breathing pattern, size and responsiveness of pupils, ocular position and movements, and skeletal motor responses. This should be repeated at least every 30 to 60 minutes in patients with severe head injuries to assess for deterioration or to monitor the efficacy of therapy. This would require an objective mechanism to “score” the patient's condition so that treatment decisions could be made logically.

97.4 MODIFIED GLASGOW COMA SCORING SYSTEM

In humans, traumatic brain injury is graded as mild, moderate, or severe on the basis of the level of consciousness or the Glasgow Coma Scale.[3] Mild traumatic brain injury in humans is usually due to a concussion, and full neurologic recovery routinely occurs. A patient with moderate traumatic brain injury is lethargic or stuporous, and a patient with severe injury is comatose. Patients with severe traumatic brain injury have a high risk of hypotension, hypoxemia, and brain swelling.[3] If these sequelae are not prevented or managed properly, they can exacerbate the existing brain damage and increase the risk of death.[3] The clinical point at which to initiate therapy for a veterinary patient with head trauma, the extent of appropriate therapy, and the length of time that such treatment is necessary are poorly documented. The effectiveness of specific treatment and the prognosis for any given animal will always be difficult to assess because of the multifactorial nature of the injury.

A modification of the Glasgow Coma Scale used in humans has been proposed for use in veterinary medicine.[4]
This scoring system enables grading of the initial neurologic status and serial monitoring of the patient. Such a 410
system can facilitate the assessment of prognosis, which is crucial information for both the veterinarian and owner.[4] 411
An almost linear correlation between this scoring system and survival of dogs with head trauma has now been evaluated (Figure 97-1).[5] It should be noted that long-term survival and functional outcome have not been evaluated using these scales in dogs or cats.

Figure 97-1 Probability of survival for patients with head trauma based on their individual modified Glasgow Coma Scale score at admission. Reprinted with permission from Platt SR, Radaelli ST, McDonnell JJ: The prognostic value of the modified Glasgow Coma Scale in head trauma in dogs, *J Vet Intern Med* 15:581, 2001.



Each of the three categories of the examination (i.e., level of consciousness, motor activity, brain stem reflexes) is assigned a score from 1 to 6 (Table 97-1). The level of consciousness provides information about the functional capabilities of the cerebral cortex and the ascending reticular activating system in the brain stem.[6]

97.4.1 Levels of Consciousness

The level of consciousness is the most reliable empiric measure of impaired cerebral function after head injury. Impairment of consciousness is stratified in terms of the responses to external stimuli, and serial records of these responses are an important clinical guide to treatment.

The consciousness level of is also a valuable index of injury severity. In the early evaluation, the depth of impairment can be used as a measure of cerebral impairment. Levels of consciousness range from normal, depressed, or delirious, to stuporous or comatose. Depression is a reduced state of mental function. A delirious animal manifests a reduced state of consciousness with profound disorientation. Stupor is partial or nearly complete unconsciousness, manifested by response only to vigorous or noxious stimulation. Coma is a state of unconsciousness from which the patient cannot be aroused.

Decreasing levels of consciousness indicate abnormal function of the cerebral cortex or interference with transmission of sensory stimuli by the brain stem ascending reticular activating system. Patients that arrive in a state of coma generally have bilateral or global cerebral abnormalities or severe brain stem injury and have a guarded prognosis.[7]

97.4.2 Limb Movements, Posture, and Reflexes

Spontaneous and evoked limb movements are studied as part of the coma scale examination.[5] It is important for the clinician to determine whether spinal cord injury or severe orthopedic abnormalities are present before extensive manipulation of the patient. Motor activity may be affected by the animal's level of consciousness; the best motor response detected is the most important. Animals that are not comatose, but have an altered state of consciousness, usually maintain some voluntary motor activity.

Muscle tone is assessed by putting the limbs through a full range of passive movement, keeping in mind the possibility of a long bone fracture. The tendon reflexes are elicited; these reflexes have very little value in the diagnosis of acute cerebral injuries, but localized absence of tendon jerks may disclose a nerve injury. Exaggerated reflexes can be seen in all four limbs in most patients with cerebral injury (or cervical spinal cord trauma), but severely affected comatose animals lose muscle tone and reflex activity.

Opisthotonus with hyperextension of all four limbs is suggestive of decerebrate rigidity (Color Plate 97-1), whereas variable flexion and extension of the hind limbs is seen in rigidity with cerebellar injury (Color Plate 97-2).[7,8] Decerebrate rigidity, occasionally seen in animals recumbent as a result of craniocerebral trauma, can provide further information about the severity of the brain injury.[4]

97.4.3 Neuroophthalmologic Examination

97.4.3.1 Pupils

This is the basis of the brain stem reflexes category. Pupil size, shape, and reactivity are recorded routinely during the initial examination and should be checked at frequent intervals thereafter. If the pupillary light reflex is impaired on one side, the contralateral light reflex is tested to see whether the impaired pupil reacts consensually. In the unconscious patient, changes in the pupillary light reactions often give diagnostic information regarding the cerebral condition and prognosis.[6] The light reflex may also be the only available test of optic nerve function (Table 97-2). It is necessary to use a strong light source and to shield the opposite eye when testing for a consensual response.

Pupillary abnormalities may be bilateral or unilateral; they may be present from the time of the injury or may appear later. Mild size discrepancy between the two pupils (<3 mm) has not been significantly associated with 411 patient outcome in humans.[9] Pupils that are widely dilated at the time of initial examination may indicate an 412 irreparable primary midbrain lesion or advanced herniation. However, there are other causes that should be ruled out. These include the following: the early postictal period, inadequate cerebral perfusion,[10] local trauma to the iris or its innervation on both sides prior administration of opioid (cats only) or anticholinergic therapy, or the use of a mydriatic agent to view the fundus. Previous ocular disease may be associated with bilateral or unilateral pupillary abnormalities. In humans, bilateral optic nerve injury may result in bilateral fixed or sluggish pupils, sometimes with autonomic balance fluctuations causing spontaneous fluctuations (hippus) in diameter.[10]

Table 97-1 Small Animal Modified Glasgow Coma Scale

Assessment Parameter	Score
Motor Activity	
Normal gait, normal spinal reflexes	6
Hemiparesis, tetraparesis, or decerebrate activity	5
Recumbent, intermittent extensor rigidity	4
Recumbent, constant extensor rigidity	3
Recumbent, constant extensor rigidity with opisthotonus	2
Recumbent, hypotonia of muscles, depressed or absent spinal reflexes	1
Brain Stem Reflexes	
Normal pupillary light reflexes and oculocephalic reflexes	6
Slow pupillary light reflexes and normal to reduced oculocephalic reflexes	5
Bilateral, unresponsive miosis with normal toreduced oculocephalic reflexes	4
Pinpoint pupils with reduced to absent oculocephalic reflexes	3
Unilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	2
Bilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	1
Level of Consciousness	
Occasional periods of alertness and responsiveness to environment	6
Depression or delirium, capable of responding but response may be inappropriate	5
Semicomatose, responsive to visual stimuli	4
Semicomatose, responsive to auditory stimuli	3
Semicomatose, responsive only to repeated noxious stimuli	2
Comatose, unresponsive to repeated noxious stimuli	1

Reprinted with permission from Platt SR, Radaelli ST, McDonnell JJ: The prognostic value of the modified Glasgow Coma Scale in head trauma in dogs, *J Vet Intern Med* 15:581, 2001.

A score is given to each of three categories of the neurologic examination: motor activity, brain stem reflexes, and level of consciousness. Within each category, a score of 1 to 6 exists, representing the most severe to the mildest of clinical pictures. A total score can then be helpful (1) in estimating the severity of the initial condition, which determines the most appropriate level of therapy, (2) assessing the prognosis for survival within the first 72 hours, and (3) assessing the effect of therapy.

Pupils that respond appropriately to light, even if miotic, indicate adequate function of the rostral brain stem, optic chiasm, optic nerves, and retinas. In the absence of concurrent ocular trauma, miosis may indicate a diencephalic lesion, particularly in the hypothalamus, because this area represents the origin of the sympathetic pathway.[4,7,8] In humans who have sustained head trauma, bilateral miosis has also been associated infrequently with pontine lesions.[10]

Table 97-2 Anatomic Interpretation of Pupillary Abnormalities

Injury	Ipsilateral Pupil	Associated Findings
Oculomotor nerve	Dilated and fixed to direct light No consensual constriction from contralateral light but normal consensual constriction in contralateral pupil	Ptosis and ventrolateral strabismus
Optic nerve	Fixed to direct light Absent consensual constriction in contralateral pupil Normal consensual constriction from contralateral light	Spontaneous fluctuations in pupil size
Oculomotor and optic nerve	Dilated and fixed to direct light No consensual constriction from contralateral light and no consensual constriction in contralateral pupil	Ptosis and ventrolateral strabismus
Iris or ciliary body	Dilated and fixed to direct light No consensual constriction from contralateral light but normal consensual constriction in contralateral pupil	Often signs of orbital injury No strabismus
Cervical sympathetic pathway	Constricted and fixed or sluggish to direct light and contralateral light but normal consensual constriction in contralateral pupil	Ptosis

Pupils that are initially miotic and then become mydriatic are indicative of a progressive brain stem lesion, whereas bilateral mydriasis with no response to light is usually indicative of irreversible midbrain damage, herniation of the cerebellum through the foramen magnum, or both.[7] Unilateral mydriasis may indicate unilateral cerebellar herniation or brain stem hemorrhage.[6,7] However, a unilateral mydriasis and loss of direct light reflex in one eye commonly implies a cranial nerve III paralysis, and is commonly accompanied by ptosis and ventrolateral strabismus (see Table 97-2). In humans this can be a sign associated with extradural bleeding and warrants immediate advanced imaging.[11]

97.4.3.2 Eye Movements

In the unconscious patient, spontaneous ocular movements should be assessed.[5] If there are none, the
oculocephalic reflexes (i.e., physiologic nystagmus) are tested by rotating the head in vertical and horizontal 412
planes. This can be done only when a cervical spinal injury has been excluded. Oculocephalic reflexes may be 413
impaired in animals with brain stem lesions as a result of either involvement of cranial nerve nuclei that innervate the extraocular muscles or the interconnecting ascending medial longitudinal fasciculus within the pons and midbrain.[11]

In addition to their localizing value, the eye movements have been considered indices of head injury severity. The ability of the patient to fix its eyes on a target and follow it is a favorable finding, and absence of eye movements is an ominous finding. Absence of eye movements on irrigating the external auditory canal with ice-cold water (oculovestibular reflex) is indicative of profound brain stem failure and is an accepted criteria of brain death in humans.[10] However, such a test should not be performed if there is any suspicion of a craniotaural fistula or a skull base fracture. Between the presence and absence of inducible eye movements, there are many ill-defined disturbances with unknown diagnostic and prognostic implications.[10]

97.5 COMA SCALES AND LONG-TERM FUNCTIONAL OUTCOME

There have been no long-term functional outcome studies in dogs or cats following head trauma, so the use of coma scales for long-term prognosis is not documented. There is an obvious need for an accurate assessment of outcome, because patients surviving head trauma may be left with multiple neurologic deficits that markedly affect the quality of life (or at least the owner's perception of the animals quality of life). Exceptional owner commitment may enable some very disabled patients to return home, but minor neurologic deficits may be viewed by some owners as unacceptable.

A standardized outcome scale used in human medicine is the Glasgow Outcome Scale.[12] This scale is based on the overall social capability of the patient, which takes into account specific mental and neurologic deficits. It was devised for victims of brain damage in general, because it was required for studies both of head injury and of atraumatic coma. Four categories of survival are recognized and are listed as good recovery, moderate disability (independent but disabled), severe disability (conscious but dependent), and vegetative state.[12] There is variation within each category, but much of this may not be applicable to veterinary patients because it is based on the ability of the patient to communicate and be self-sufficient. There is a need, however, for the modified Glasgow Coma Scale to be correlated with an outcome scale in veterinary medicine, because this would truly assist with defining a prognosis in small animal patients. Until this time, coma scales can be used only as a guide of the immediate success of therapy and, more importantly, when to initiate this treatment.

98 Chapter 98 Seizures and Status Epilepticus

Karen M. Vernau, DVM, DACVIM (Neurology)

Richard A. LeCouteur, BVSc, PhD, DACVIM (Neurology)

98.1 KEY POINTS

- Epilepsy refers to recurrent seizures of any type resulting from an intracranial cause and may be subdivided into true epilepsy (inherited, acquired, and idiopathic) and symptomatic epilepsy.
- Seizures are classified as partial or generalized; generalized seizures are the most common.
- Status epilepticus (SE) is a life-threatening neurologic emergency, and a common initial complaint at the emergency hospital.
- SE may cause serious systemic problems such as hypoxia, hyperthermia, systemic lactic acidosis, shock, and acute renal failure.
- Disorders that induce seizures and SE are either extracranial or intracranial.
- A complete history, physical examination, neurologic examination, and minimum database should be done in all animals with a seizure disorder.
- Further investigation of intracranial diseases using electroencephalography, magnetic resonance imaging, or computed tomography imaging, cerebrospinal fluid analysis, serology, and biopsy may be indicated.
- Seizure management is based on control of seizures by selection and appropriate administration of an anticonvulsant drug. When an underlying disease is present, it should be treated concurrently. Seizures associated with SE should be stopped as quickly as possible.

98.2 INTRODUCTION

The epidemiology of seizures in cats and dogs is unknown, despite reports of the rate,[1] prevalence,[2] and incidence.[3] Population-based animal studies are difficult to execute, thus most studies are based on data from groups of veterinary hospitals or referral-based veterinary teaching hospitals.[2] The epidemiology of seizures in groups of purebred dogs or colonies of research dogs[1] with epilepsy has been reported. For example, one population-based study reported the lifetime prevalence of epilepsy in the Danish Labrador as 3.1% (95% confidence interval 1.6% to 4.6%).[4] Although these studies are interesting, the information cannot be extrapolated beyond the research colony, hospital, or specific purebred dog geographic setting.

Despite the lack of prevalence or incidence data, it is accepted that seizure disorders are common in dogs and cats and that seizures occur more frequently in dogs than in cats. Estimates of lifetime seizure frequencies are 0.5% to 5.7% in dogs and 0.5% to 1.0% in cats.[5]

Status epilepticus (SE) is a life-threatening neurologic emergency and a common presenting complaint at an emergency hospital. Although the population prevalence of SE is not known, in one report the prevalence of SE and cluster seizures in dogs was 0.44% of all hospital admissions.[6]

Although many different types of seizures occur in dogs and cats, a classification system that is accepted universally by veterinary neurologists has not been established.[7-9] To effectively diagnose and treat dogs and cats with seizure disorders, including SE, it is important to understand the terminology, pathophysiology, and causes of seizures.

98.2.1 Definitions

A *seizure* is the clinical manifestation of a paroxysmal cerebral disorder, caused by a synchronous and excessive electrical neuronal discharge, originating from the cerebral cortex.[5]

Cluster seizures are two or more seizures within a 24-hour period.[6]

Epilepsy is recurrent seizures of any type resulting from an intracranial cause.[5]

1 *True epilepsy* originates from a nonprogressive intracranial disorder.[5]

  A Inherited epilepsy is caused by a genetically determined intracranial disorder.[5]

  B Acquired epilepsy is caused by a previously active intracranial disorder that is no longer active.[5]

  C Idiopathic epilepsy is a seizure disorder in which the cause and mechanism for the seizures is unknown.[5]

2 *Symptomatic epilepsy* is caused by progressive intracranial disease.

Status epilepticus is a neurologic emergency requiring immediate therapy. A universally accepted definition for SE in humans or animals does not exist.[6,10] The authors recommend the definition, “continuous seizures, or two or more discrete seizures between which there is incomplete recovery of consciousness, lasting at least 5 minutes.”[11]

98.3 CLASSIFICATION

Seizures in dogs and cats may be classified as partial or generalized, based on clinical observations rather than EEG characteristics. Partial seizures originate from a focus in one cerebral hemisphere and usually manifest localized clinical signs. Partial seizures usually have an acquired cause and may be subdivided into simple partial seizures or complex partial seizures. In simple partial seizures there is no alteration in consciousness, and the clinical signs during the seizure are limited to isolated muscle groups (e.g., tonus or clonus of a limb). Additional clinical signs (e.g., autonomic signs) may be present during a simple partial seizure. Complex partial seizures are accompanied by an alteration in consciousness. There may be involuntary or compulsive actions such as chewing, licking, and defensive or aggressive behavior. Complex partial seizures have been referred to as psychomotor seizures. Both types of partial seizures may spread throughout the brain, causing generalized seizures.[5] 414 415

Generalized seizures are the most commonly recognized seizures in dogs and cats. The most common type is the tonic-clonic seizure. Other types of generalized seizures such as tonic, clonic, or myoclonic seizures are recognized. In tonic-clonic seizures, animals lose consciousness. In the tonic phase, increased muscle tone results in limb and head extension, causing the animal to fall to the side. In the clonic phase, alternating extension and flexion of the limbs, and exaggerated chewing movements, occur. The animal usually urinates, defecates, and salivates.[5]

98.4 PATHOPHYSIOLOGY

The normal brain is capable of seizures in response to a variety of intracranial and extracranial stimuli. When the brain's homeostasis is overcome, cerebrocortical excitability is altered and the seizure threshold is decreased. Normal animals with a low seizure threshold may be induced to have a seizure by many factors, including fatigue, fever, estrus, photic stimulation.

Experimentally, repeated stimulation of the rat cerebral cortex by a subconvulsive electrical stimulus caused generalized seizures over time. This phenomenon is referred to as *kindling*. [12] Following establishment of a focal seizure focus, abnormal electrical activity may be recorded over the contralateral cerebral cortex. This secondary seizure focus is termed a *mirror focus*. [13] Either the primary or secondary focus, or both, may cause seizures. The mirror focus may cause seizures even if the primary seizure focus is removed.[14] Although kindling and mirror foci are observed as experimental phenomena, they may be clinically relevant in the therapy of animals with seizure disorders.

In SE, there is failure of the normal brain homeostasis mechanisms that work to stop seizures. Proposed mechanisms for the development of SE include persistent neuronal excitation, inadequate neuronal inhibition, or both.[11] Extrasynaptic factors may be important in spreading and maintaining the seizure. An excess of excitatory neurotransmitters such as glutamate, aspartate, or acetylcholine, or antagonists of γ-aminobutyric acid (GABA) (an inhibitory neurotransmitter) may cause SE.

SE lasting 30 to 45 minutes results in brain injury in experimental animals.[15] However, brain injury probably occurs in clinical patients after a much shorter time. SE may cause neuronal necrosis, particularly in brain regions with high metabolic rates. In one report, neuronal necrosis was most severe in rats that were hypoxemic or exhibited tonic-clonic seizures.[16]

In early SE, an increase in cerebral blood flow may be protective for the brain. In late SE, cerebral blood flow decreases simultaneously as blood pressure decreases, and cerebral metabolic rate (e.g., glucose and oxygen utilization) increases. This leads to adenosine triphosphate depletion and lactate accumulation, which contribute to neuronal necrosis. SE may be associated with systemic problems including hypoxemia, hyperthermia, aspiration pneumonia, systemic lactic acidosis, hyperkalemia, hypoglycemia, shock, cardiac arrhythmias, neurogenic pulmonary edema, and acute renal failure.

98.5 ETIOLOGY

Disorders that induce seizures and SE arise either outside the nervous system (extracranial) or within the nervous system (intracranial). Extracranial causes may be divided into those that originate outside the body (e.g., toxins) and those that originate within the body but outside the nervous system (e.g., liver disease). Intracranial causes of seizures are divided into progressive and nonprogressive diseases.[5]

Extracranial causes may result in generalized seizures, because they affect the brain globally. Causes of progressive intracranial disease include inflammation (e.g., granulomatous meningoencephalitis), neoplasia, nutritional alterations (e.g., thiamine deficiency), infection, anomalous entities (e.g., hydrocephalus), and trauma. Most animals with progressive intracranial disease are clinically abnormal between seizures and usually have progression of clinical signs. However, seizures may be the only clinical sign for a prolonged time, before others become apparent.

Nonprogressive causes of seizures include inherited, acquired, and idiopathic epilepsy. Dogs with inherited epilepsy usually are 6 months to 5 years of age. Many breeds are known or suspected to have inherited epilepsy.[17] In idiopathic epilepsy, seizures are caused by a functional problem of the brain and therefore are generalized and symmetrical.

Very few veterinary studies have evaluated the clinical features of SE; therefore it is not possible to make generalizations concerning underlying causes or concerning short-term and long-term outcomes. One study[18] evaluated a cohort of 50 dogs with SE. Of those, 28% had idiopathic epilepsy, 32% had symptomatic epilepsy, and 12% had seizures secondary to a systemic insult or to physiologic stress. Forty-four percent of the dogs had not had SE previously. Many dogs were euthanized, and thus a mortality rate was not reported.[18] In another study[19] of SE in dogs with idiopathic epilepsy, 59% of the dogs had one or more episodes of SE. Survival time was shorter in dogs with both idiopathic epilepsy and SE than in those with idiopathic epilepsy alone.[19] In another study of SE or cluster seizures in dogs, a poor outcome was reported in dogs with granulomatous meningoencephalitis, poor seizure control after 6 hours of hospitalization, or SE manifest by partial seizures. Fifty-nine percent of the dogs in this study died or were euthanized.[6]

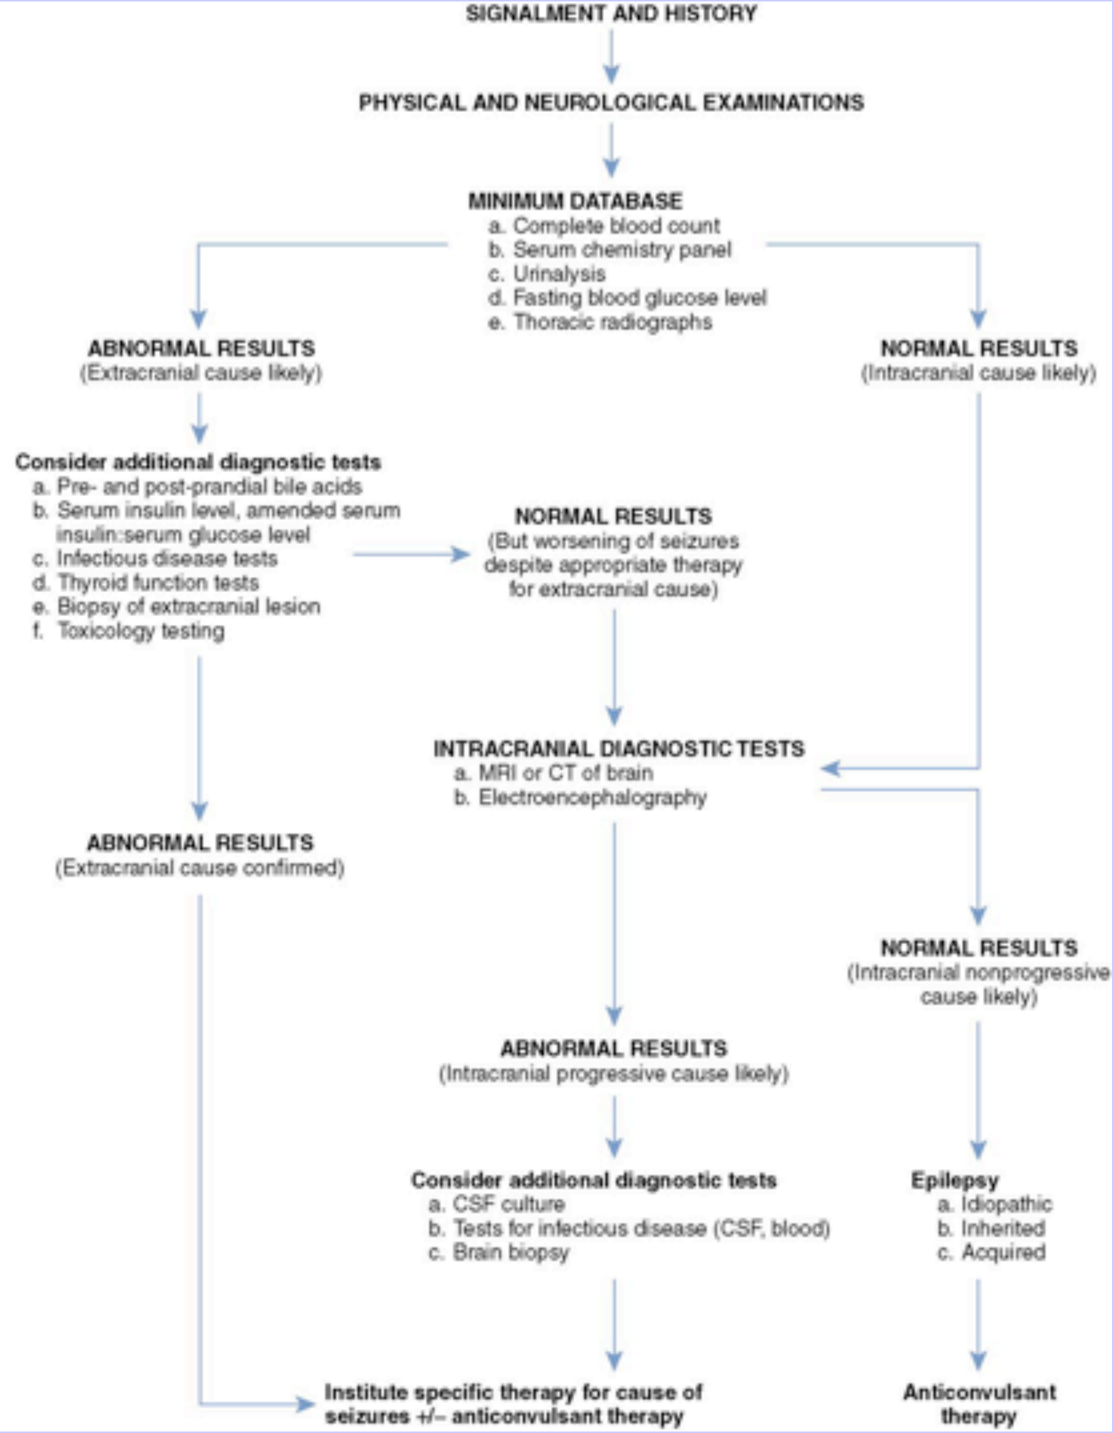
It is essential to distinguish between extracranial and intracranial (progressive and nonprogressive) diseases that cause seizures. Therapy for extracranial and progressive intracranial diseases requires not only control of seizures, but also therapy for the underlying disease.

98.6

DIAGNOSTIC PLAN

A seizure disorder is essentially a manifestation of an underlying disease; therapy is most effective when the underlying disease is diagnosed and treated. Therefore an accurate diagnosis should be established in a timely manner. In some animals an underlying cause may not be identified, as with idiopathic epilepsy. A complete history, physical examination, and neurologic examination should be done in all animals with a seizure disorder (Figure 98-1).

Figure 98-1 Diagnostic approach to seizure disorders in dogs and cats. *CSF,* Cerebrospinal fluid; *CT,* computed tomography; *MRI,* magnetic resonance imaging.



SIGNALMENT AND HISTORY
PHYSICAL AND NEUROLOGICAL EXAMINATIONS
MINIMUM DATABASE
a. Complete blood count
b. Serum chemistry panel
c. Urinalysis
d. Fasting blood glucose level
e. Thoracic radiographs
ABNORMAL RESULTS
(Extracranial cause likely)
NORMAL RESULTS
(Intracranial cause likely)
Consider additional diagnostic tests
a. Pre- and post-prandial bile acids
b. Serum insulin level, amended serum insulin:serum glucose level
c. Infectious disease tests
d. Thyroid function tests
e. Biopsy of extracranial lesion
f. Toxicology testing
NORMAL RESULTS
(But worsening of seizures despite appropriate therapy for extracranial cause)
INTRACRANIAL DIAGNOSTIC TESTS
a. MRI or CT of brain
b. Electroencephalography
ABNORMAL RESULTS
(Extracranial cause confirmed)
NORMAL RESULTS
(Intracranial nonprogressive cause likely)
ABNORMAL RESULTS
(Intracranial progressive cause likely)
Consider additional diagnostic tests
a. CSF culture
b. Tests for infectious disease (CSF, blood)
c. Brain biopsy
Epilepsy
a. Idiopathic
b. Inherited
c. Acquired
Institute specific therapy for cause of seizures +/– anticonvulsant therapy
Anticonvulsant therapy

98.6.1 History

A complete general history should be obtained from the owner, as well as a specific seizure history: age at onset, frequency, and description of seizures, behavior between seizures, and temporal associations (e.g., associated with eating or not eating). A videotape of a seizure may be useful, particularly if the owner's description is insufficient.

98.6.2 Age and Breed

The age at onset is necessary to determine the most likely cause of a seizure disorder. Dogs 5 years and older usually have an acquired seizure disorder, such as a primary brain tumor. The breed is important, because inherited epilepsy is reported in certain breeds such as Beagles, German Shepherds, Poodles, and others.[17] Some breeds may have a higher prevalence of intracranial tumors (Boxers) or inflammatory disease (Maltese dogs).

98.6.3 Physical Examination

A complete physical examination should be done in all animals with seizures, to diagnose systemic problems or local problems (e.g., skull mass) that may affect the brain.

416

417

98.6.4 Neurologic Examination

A complete neurologic examination should be done in all animals with seizures. In animals with inherited or idiopathic epilepsy, neurologic examination findings between seizures most often are normal. Dogs and cats with extracranial or progressive intracranial disease may have neurologic abnormalities between seizures.

Animals may be abnormal neurologically for days after a seizure. Therefore multiple, serial neurologic examinations may be necessary in some animals after a seizure, before neurologic deficits are attributed to extracranial or progressive intracranial disease.

98.6.5 Minimum Database

A minimum database (complete blood count, serum chemistry panel, 24-hour fasting blood glucose, urinalysis) should be done on admission in all animals with seizures. In some animals, serum triglycerides and preprandial and postprandial bile acid levels should be obtained to evaluate the possibility of a portosystemic shunt and hypertriglyceridemia. If systemic disease or intracranial disease is suspected, thoracic radiography and abdominal ultrasonography should be performed to further screen for neoplastic and infectious disease.

98.6.6 Diagnostic Tests for Intracranial Disease

Further investigation of intracranial diseases, including electroencephalography (EEG), MRI, CT, CSF analysis, biopsy (for cytology, histopathology, or both), and serology, may be indicated after a minimum database is completed.

EEG is useful in some animals. When a seizure disorder is suspected, abnormal EEG findings may help to distinguish the presence of seizures from other paroxysmal nonseizure events. EEG may help the clinician to evaluate anticonvulsant therapy, particularly in a patient undergoing treatment for SE, because the external manifestations of seizures may be abolished by drugs.[20] In the future, EEG may be useful in the classification of canine and feline seizure disorders.

MRI is preferred over CT imaging, unless acute head trauma or an acute intracranial hemorrhage is suspected. MRI and CT imaging are noninvasive, and probably yield the most diagnostic information with respect to location and extent of disease in animals with progressive intracranial problems. The results of advanced imaging may help to define a cause of the seizure disorder.

Ideally CSF is collected after MRI or CT imaging has been done. Usually CSF is collected from the cisterna magna (see Chapter 105, Cerebrospinal Fluid Sampling). Because there is risk to the patient undergoing CSF puncture, CSF is not collected in all animals with intracranial disease (see Chapter 100, Intracranial Hypertension). Usually CSF analysis results are supportive of a diagnosis, rather than providing a definitive diagnosis. However, CSF occasionally provides diagnostic information with some infections (e.g., *Cryptococcus neoformans,* bacteria), and with some neoplasms (e.g., lymphoma), and is therefore an essential part of an intracranial workup in most animals.

98.7 TREATMENT PLAN

Regardless of the underlying cause, seizure control is based on selection and administration of an appropriate anticonvulsant drug. Underlying disease, if present, should be treated concurrently. Adverse effects may limit the usefulness of an anticonvulsant drug; therefore knowledge of the mechanisms of action and drug interactions are essential. Selection of an anticonvulsant drug should be based on results of pharmacokinetic studies in the species in which the drug is intended to be used.

The ultimate goal of anticonvulsant therapy is to eradicate all seizure activity; however, this goal rarely is achieved. A more realistic goal is to reduce the severity, frequency, and duration of seizures to a level that is acceptable to the owner, without intolerable or unacceptable adverse effects on the animal. A very general guideline is to consider anticonvulsant drug therapy when the seizure frequency is greater than once every 6 weeks.

Immediate, short-term (acute) anticonvulsant therapy is required to manage SE, cluster seizures, and seizures resulting from some toxicities. Chronic (or maintenance) anticonvulsant therapy is used to manage epilepsy. Seizure control with anticonvulsant drugs is most effective when started early in the course of a seizure disorder, because each seizure may increase the probability of additional seizures secondary to effects such as kindling and mirror focus development.

98.7.1 Status Epilepticus

In SE, the goal of therapy is to stop the seizure as soon as possible. In veterinary medicine, EEG monitoring is not routine in the intensive care unit, so effectiveness of SE therapy is evaluated by the cessation of the outward physical manifestations of a seizure. Therefore, in some animals, although there are no obvious clinical signs of SE, the brain may still have ongoing seizure activity that may negatively affect outcome. As with many disorders in veterinary medicine, there are no controlled clinical trials that may be used to guide therapy. Therefore recommended treatments are guidelines only (Table 98-1).

Treatment should be divided into the (1) immediate emergency evaluation and treatment (such as airway, breathing, cardiovascular function, body temperature, glucose concentration, and blood pressure) (see Chapter 2, Patient Triage) and (2) pharmacologic treatment (see Table 98-1). Animals that are admitted in SE or with cluster seizures, may have cerebral edema, and mannitol administration should be considered (see Chapter 100, Intracranial Hypertension).

98.7.2 Pharmacologic Therapy for Status Epilepticus

98.7.2.1 Benzodiazepines

Diazepam is the first-line agent of treatment of dogs and cats with SE. It is lipid soluble and enters the brain rapidly when given intravenously, intranasally, or per rectum. It binds to the GABA receptor and enhances neuronal hyperpolarization, reducing neuronal firing. The duration of action is short, so a maintenance anticonvulsant (such as phenobarbital) should be administered concurrently, to avoid recurrence of seizures or SE when diazepam levels in the brain decrease. For animals not currently receiving phenobarbital, a loading dosage is administered. Owners may administer PR diazepam to their animals. Midazolam is a water-soluble benzodiazepine and may be used to manage SE. Although the IV route is preferred, midazolam may be given IM if IV access cannot be obtained.

Table 98-1 Anticonvulsant Drugs for Status Epilepticus in Dog and Cats

Drug	Dosage	Comments
Diazepam (first-line)	*IV bolus:* 0.5 to 1 mg/kg may be repeated 2 to 3 times *CRI:* 0.5 to 1 mg/kg/hr *Per rectum:* 0.5 to 1 mg/kg (2 mg/kg if receiving concurrent phenobarbital)	IV injections and infusions should be administered into a central vein
Phenobarbital (maintenance anticonvulsant: use concurrently with diazepam)	2 to 4 mg/kg IV q20-30 min to a total of 18 to 20 mg/kg	Administer concurrently with diazepam to prevent recurrence of seizures once diazepam levels fall in the brain This dose may be repeated every 20 to 30 minutes until a cumulative dosage of 18 to 20 mg/kg has been given Once seizures are controlled a maintenance dosage of phenobarbital is used (3 to 5 mg/kg IV or IM q12h for 24 to 48 hours). Oral anticonvulsant therapy should be resumed or initiated every 12 hours as soon as the animal is able to swallow
Pentobarbital (second-line)	6 to 15 mg/kg IV slow bolus, followed by a CRI of 0.5 to 2 mg/kg/hr to effect	Strict monitoring of physiologic parameters is required
Propofol (third-line)	2 to 8 mg/kg slow IV bolus, given as 25% of the total dose every 30 seconds until desired effect achieved	CRI should be considered (0.1 to 0.4 mg/kg/min) Strict monitoring of physiologic parameters is required (may stop overt manifestations of seizures, but may not stop seizure activity)

CRI, Constant rate infusion; *IM,* intramuscular; *IV,* intravenous.

If SE continues or further seizures occur, additional boluses of diazepam may be given, or a constant rate infusion (CRI) of diazepam may be used. If the SE does not stop, or recurs multiple times, then barbiturates (pentobarbital) are used. The dosage of phenobarbital should be reviewed at this point in time, to ensure that an adequate dose has been administered.

98.7.2.2

Barbiturates

Barbiturates potentiate the action of GABA by interfering with sodium and potassium transmission in the neuronal membrane. Because the half-life of most drugs used to manage SE is short, a maintenance anticonvulsant *must* be part of the treatment regimen. Phenobarbital is the most commonly used maintenance anticonvulsant in dogs with SE because it can be given intravenously.

Pentobarbital is used as a second-line drug if benzodiazepines fail, but it has a limited anticonvulsant effect. Pentobarbital is administered as a bolus, followed by a CRI. Pentobarbital may cause sedation, respiratory depression, hypotension, and death. Animals that are heavily sedated or anesthetized should be intubated so that an open airway is maintained. Other physiologic parameters (such as heart rate, blood pressure, oxygenation, etc.) should be monitored regularly or continuously. Therefore the dosage should be titrated carefully to stop or reduce the motor activity from the seizure, but to avoid anesthesia if possible. During recovery, it may be difficult to determine if the animal is recovering from the pentobarbital or is still having seizures.

98.7.2.3 Propofol

Propofol is a rapid-acting, lipid soluble general anesthetic agent. It is a third-line drug for the management of SE in dogs and cats. The anticonvulsant effect of propofol is likely due to its GABA agonist activity.[21] There are case series describing its use in animals and humans with SE.[21,22] However, propofol use is controversial, because seizures have been associated with its use in humans[23] and in a dog.[24] In one study, humans with SE who were treated with propofol had a higher mortality rate than those treated with midazolam.[22]

98.7.3 Chronic Seizure Disorders

Successful anticonvulsant therapy depends on the maintenance of plasma concentrations of appropriate anticonvulsant drugs within a therapeutic range defined for the species in which the drug is to be administered. Therefore anticonvulsant drugs that are eliminated slowly should be employed. The elimination half-life of anticonvulsant drugs varies considerably between species. Few anticonvulsant drugs used in humans are suitable for use in dogs and cats, largely due to species differences in pharmacokinetics. Pharmacokinetic data for and clinical experience with many anticonvulsant drugs are lacking in cats. Selection should be based on the known pharmacokinetic properties of a drug in the species in which it is to be administered (see Chapter 186, Anticonvulsants).

Phenobarbital and bromide are the first-line of anticonvulsant drugs recommended for chronic seizure disorders in dogs. Phenobarbital is the first-line anticonvulsant in cats.

99 Chapter 99 Spinal Cord Injury

Kersten Johnson, DVM, MS

Charles H. Vite, DVM, PhD, DACVIM (Neurology)

99.1 KEY POINTS

- Spinal cord trauma may result from contusion, compression, or ischemia, or any combination of these events.
- Any animal with suspected spinal cord instability or fractures should be restrained on a flat board or in a small cage until further diagnostic tests are performed.
- An accurate history and lesion localization will lead to a reliable list of differential diagnoses.
- Localization of a lesion should be identified as upper motor neuron (UMN), lower motor neuron (LMN), or a combination of both (i.e., LMN to the thoracic limbs and UMN to the pelvic limbs).
- Prognosis for recovery ranges from excellent to grave, and time is the only certain determinant of the extent of return of function.
- Loss of deep pain for more than 12 to 24 hours following injury and severe luxation or displacement of vertebral bodies carry poor to grave prognoses.

99.2 INTRODUCTION

Injury to the spinal cord is common in domestic animals and may result from vascular, infectious, inflammatory, degenerative, neoplastic, and/or traumatic processes. Animals with disease of the spinal cord may present with only a focal area of spinal pain or with anesthesia and paralysis at the level of and caudal to the lesion. Signs of neurologic dysfunction that fall between these two extremes include spinal ataxia, limping or leg-carrying lameness (a "root signature"), walking paresis, and nonwalking paresis. Animals should be evaluated and their deficits graded using one of several scoring systems[1] (Table 99-1).[2]

This chapter will focus on traumatic spinal cord injuries, including intervertebral disk herniation, and will mention only briefly some other causes of spinal cord disease. It is imperative that the emergency veterinarian be able to recognize neurologic dysfunction, accurately localize the lesion, generate a list of differential diagnoses, perform appropriate diagnostic testing to obtain a definitive diagnosis, institute therapy, and recognize the prognosis of injuries to the spinal cord.

Table 99-1 Neurologic Scoring System

Neurologic Grade	Neurologic Description
Grade 1	No deficits
Grade 2	Paresis, walking
Grade 3	Paresis, nonambulatory
Grade 4	Paralysis
Grade 5	Paralysis, no deep pain

99.3 PATHOPHYSIOLOGY

There are two stages by which the spinal cord is damaged following trauma. Initially there is primary tissue damage from direct mechanical disruption, followed by secondary damage via biochemical and vascular events.[3] When cellular membrane integrity is disrupted, a complex cascade of biochemical reactions is initiated, including the release of excitotoxic amino acids, free fatty acids, oxygen free radicals, and vasoactive agents. N-methyl-D-aspartate (NMDA) receptors are activated, and voltage-sensitive calcium and sodium channels open.[4] These membrane changes result in increased intracellular calcium and sodium, decreased intracellular potassium, and increased extracellular potassium. In addition to changes in ionic concentrations, a decrease in blood flow occurs as a result of direct mechanical compression and/or loss of autoregulation, vasospasm, and hemorrhage, leading to spinal cord ischemia.[3,4] Ischemia results in cytotoxic edema, axonal degeneration, demyelination, abnormal impulse transmission, conduction block, and cell death.[3,4]

99.4 LOCALIZATION

When the animal is presented to the veterinarian, a thorough history should be recorded. If a fracture or luxation is suspected, the goal should be to decrease activity that could further damage the spinal cord. A nonambulatory animal can be placed on a flat board and strapped down. Because some animals object to this, sedation may be required. For an ambulatory animal, placement in a small cage to restrict activity may be all the animal will tolerate. When external trauma to the spinal cord is due to a motor vehicle accident, a fall from a height, or a severe bite wound, it may be necessary to radiograph the entire spinal column immediately following only a limited general and neurologic examination.

A complete neurologic examination should be performed unless it is likely to further injure the patient. The goal of the examination is to identify neurologic dysfunction. Interpretation of the neurologic examination allows the clinician to localize the site of spinal cord injury, because specific signs of dysfunction are seen with injury to certain regions of the spinal cord. For localization of lesions, the spinal cord is often divided into five regions, with disease of each region resulting in a characteristic group of signs. These regions include cervical cord segments one through cervical five (C1-C5), cervical six through thoracic two (C6-T2), thoracic three through lumbar three (T3-L3), lumbar four through sacral one (L4-S1), and sacral one through sacral three (S1-S3). It is important to remember that only spinal cord segments C1, C2, and the last thoracic and first two lumbar segments are located in the vertebral body with the same vertebral number in the dog.[5] More caudally along the spine, the spinal cord segments lie in the spinal canal cranial to the vertebrae with the same number.[6] The presence of spinal cord segments within vertebral bodies of different numbers is important to consider when evaluating images of the spine, particularly in the lower lumbar spine where, for example, spinal cord segments L7, S1, S2, S3, and Cd1 may all be present within the fifth lumbar vertebral body.[7]

If there is no suspicion of a spinal fracture or luxation, the examination should begin with gait analysis. The thoracic and pelvic limbs should be evaluated separately. First, the presence or absence of proprioceptive (spinal) ataxia should be determined. Spinal ataxia is recognized by incoordination that is characterized by an increased stride length, dragging or scuffing the toes, walking on the dorsum of the paw, or crossing over of the limbs. At the same time, the animal is evaluated for paresis (incomplete paralysis often recognized by inability to support weight fully while standing or walking, shuffling of the paws, or trembling when bearing weight) or paralysis (loss of the voluntary ability to move a body part) of one or multiple limbs. Posture is assessed by noting the position of the head and limbs when the animal is at rest and when walking. Once this portion of the examination is completed, postural reactions (replacement of a knuckled over paw, hopping, placing, wheelbarrowing, extensor postural thrust, hemi-standing or hemi-walking) and segmental reflexes (stretch reflexes [extensor carpi radialis, triceps, biceps, quadriceps, cranial tibial, and gastrocnemius] and withdrawal reflexes) should be evaluated. Assessment for the presence of muscle atrophy, sensation (including spinal or limb pain), and normal mental status and cranial nerve function should be performed.

Signs of dysfunction of each of the five the spinal cord regions, beginning caudally and moving cranially, are discussed next.

99.4.1 Spinal Cord Segments S1-S3

The sacral spinal cord segments give rise to the lower motor neurons (LMNs) and sensory fibers that contribute to the sciatic, pelvic, pudendal, and perineal nerves and also connect the caudal spinal cord segments to the spinal cord. General signs of LMN dysfunction are flaccidity, diminished segmental reflexes, and rapidly progressing muscle atrophy (1 to 2 weeks). LMN signs associated with injury to S1-S3 spinal cord segments include paresis/paralysis of the sciatic nerve, anal sphincter, and bladder. If nerve dysfunction is present, the paws of the pelvic limbs may shuffle when walking, a plantigrade posture may be evident (i.e., tarsocrural joint in close proximity to the ground), the knuckled-over paw may fail to be replaced, and the segmental reflexes (i.e., cranial tibial, gastrocnemius, and withdrawal of the distal limb) may be decreased. Note that the femoral nerve is spared with an injury to this area, and therefore the withdrawal will not be completely absent, but instead will manifest with coxofemoral joint flexion without flexion of the tarsocrural joint. Denervation of the anal sphincter and bladder will result in decreased anal sphincter tone and a flaccid bladder. The animal may exhibit fecal and/or urinary incontinence. Additionally, the ability to wag the tail volitionally will be lost (with damage to the caudal spinal cord segments, flaccid paralysis of the tail will result). Sensation may be diminished to the perineum, tail, and lateral and caudal skin of the distal pelvic limbs.

99.4.2 Spinal Cord Segments L4-S1

Spinal cord segments L4-S1 include the lumbar intumescence and give rise to the spinal nerves that contribute to the femoral, obturator, sciatic, pelvic, and pudendal nerves.[2] A lesion of L4-S1 may show dysfunction of the pelvic limbs, tail, and anus with normal thoracic limb function. The pelvic limb gait may be short strided and the paws may shuffle as seen with an S1-S3 lesion. Paresis or paralysis may result in a plantigrade stance or inability to stand or support weight. Other signs include absent to decreased pelvic limb postural reactions, absent to decreased segmental reflexes (femoral, craniotibial, gastrocnemius, perineal, and withdrawal), decreased pelvic limb and anal sphincter tone, urine dribbling, a large flaccid bladder, fecal incontinence, and muscle atrophy of the limbs (if the injury is not acute). Sensation may be decreased at the level of and caudal to the lesion.

99.4.3 Spinal Cord Segments T3-L3

A T3-L3 lesion will result in so-called upper motor neuron *signs* caudal to the level of the lesion. The UMN system originates in the cerebral cortex and brain stem, is confined to the central nervous system, and terminates on the LMN. Strictly defined, the UMN is a *premotor neuron,* because it results in movement and muscle tone only through its actions on the LMN.[8] Diminished UMN influence can result in paresis or paralysis, spasticity, exaggerated segmental reflexes, crossed extensor reflex, and diminished to absent postural reactions. These signs are restricted to the pelvic limbs in animals with a T3-L3 lesion. Additionally, urinary retention, a moderate-sized firm bladder, and fecal incontinence (despite normal anal tone) may occur.

A T3-L3 lesion may also result in incoordination of the pelvic limbs characterized by crossing over of the limbs, increased stride length, abduction or circumduction, or walking on the dorsal surface of the paw. These signs are recognized as proprioceptive (spinal) ataxia and are due to dysfunction of ascending proprioceptive tracts.

Lesion localization can be made more precisely by evaluating the cutaneous trunci reflex and assessing the animal for spinal pain. This cutaneous trunci reflex is tested by pinching the skin lateral to the dorsal midline from the thorax to the level of the L5 vertebral body and observing the movement of the cutaneous trunci muscle. Abnormalities in this reflex will be seen as a lack of muscle movement that is caused by the interruption of sensory input from the stimulated dermatome. The sensory nerve from the dermatome being pinched enters the spinal cord approximately two vertebrae cranial to the level of the stimulated skin. Therefore absence of a cutaneous trunci reflex when the skin is pinched at the level of the L3 vertebral body is consistent with a lesion of the spinal nerves or spinal cord at approximately the L1 vertebral body. If the animal also appears to be in pain when pressure is placed on the L1 vertebral body would also be consistent with a lesion at this location.

A T3-L3 lesion can also result in increased tone to the thoracic limbs. This so-called *Schiff-Sherrington phenomenon* results from a lack of ascending input to the thoracic limbs and originates from originating from neuronal cell bodies of the border cells in the lumbar spinal cord. Border cells are responsible for tonic inhibition of extensor muscle α-motor neurons in the cervical intumescence.[4] Increased thoracic limb tone caused by the Schiff-Sherrington phenomenon is not accompanied by proprioceptive deficits or deficits in voluntary motor function.

99.4.4 Spinal Cord Segments C6-T2

The cervical intumescence gives rise to spinal nerves that make up the subscapular, suprascapular, musculocutaneous, axillary, radial, median, and ulnar nerves.[2] A lesion in the C6-T2 region will cause UMN signs to the pelvic limbs (spastic paresis/paralysis, exaggerated segmental reflexes, and diminished to absent postural reactions) and LMN signs to the thoracic limbs (short-strided gait, flaccidity, diminished segmental reflexes, diminished to absent postural reactions, and rapidly progressing muscle atrophy). The animal may also limp or carry a thoracic limb because of nerve root compression (root signature). This neuropathic lameness often confused with lameness due to orthopedic disease. A neurogenic cause of the lameness can frequently be ascertained by identifying proprioceptive deficits, nonuniform muscle atrophy over the limb or by electrodiagnostic testing. Additional signs may include absence of the cutaneous trunci reflex, Horner syndrome, and decreased thoracic wall movement when breathing. The cutaneous trunci reflex may be absent (unilateral or bilateral) as a result of damage to the LMNs that contribute to the lateral thoracic nerve. Horner syndrome (miosis, ptosis, and enophthalmos) results from damage to the sympathetic fibers that leave the spinal cord at this level. Decreased movement of the thoracic wall with respiration occurs because of the inability of the brain stem to control intercostal nerve function. If only the phrenic nerve is functioning properly, diaphragmatic (abdominal) breathing may be seen.

A characteristic gait can occur with lesions of the C6-T2 spinal cord segments. The pelvic limbs may show spinal ataxia and the thoracic limbs a short-strided gait. This mix of signs is often referred to as a *two-engine gait.*

99.4.5 Spinal Cord Segments C1-C5

Lastly, a lesion of spinal cord segments C1 to C5 may show UMN signs in both the pelvic and thoracic limbs. Respiration may be shallow or absent because of the loss of phrenic and intercostal nerve function. Spinal ataxia of all limbs is seen, characterized by a long-strided or “floating” thoracic and pelvic limb gait.

99.4.6 Spinal Shock

In animals examined soon after spinal cord injury, a phenomenon called *spinal shock* may be present, leading to inaccurate neurolocalization. Spinal shock is a profound depression of segmental reflexes caudal to a lesion, despite reflex arcs remaining physically intact. In dogs, these signs often occur transiently, with evidence of areflexia lasting up to 12 to 24 hours after an injury.[9] This exemplifies the importance of performing serial neurologic examinations after a spinal cord injury to ensure accurate neurolocalization.

99.5 DIAGNOSIS

Once the neurologic examination is completed and a lesion or lesions are localized, a list of differential diagnoses should be formulated.[10] Differential diagnoses for spinal cord lesions include trauma (fracture, luxation, subluxation, bruise, intervertebral disk herniation), vascular diseases (hemorrhage, fibrocartilaginous emboli, infarct), neoplasia, malformations (atlantoaxial subluxation, arachnoid cysts, syrinx) and, less commonly, infectious (toxoplasmosis, Rocky Mountain spotted fever, neosporosis, ehrlichiosis, feline infectious peritonitis, fungal, bacterial), inflammatory (granulomatous meningomyelitis), and degenerative diseases (degenerative myelopathy). History, patient age and breed, onset and progression of signs, and presence or absence of pain help to generate a likely list of differential diagnoses (Table 99-2).

At this point, additional diagnostic tests should be performed. Plain radiographs of the spine, including lateral and ventrodorsal (or dorsoventral) views, should be obtained. These radiographs can show obvious fractures, displacement of vertebrae, narrowing of the intervertebral disk space, articular facets or intervertebral foramen, lytic lesions or sclerotic lesions. If available, myelogram, magnetic reasonance imaging, computed tomography, and cerebrospinal fluid analysis may be required. Thoracic and abdominal radiographs and/or ultrasonography may also be indicated based on the animal's clinical signs or history.

99.6 TREATMENT

Emergency treatment of spinal cord injury may vary depending on the diagnosis. For all acute spinal cord injuries, intravenous fluid therapy is indicated because of presumed compromise of spinal cord vasculature that inhibits the normal autoregulation of arteriolar blood flow (see Chapters 64 and 65, Daily Intra-venous Fluid Therapy and Shock Fluids and Fluid Challenge, respectively). As a result, blood flow to the damaged spinal cord is dependent on mean arterial blood pressure, so cardiovascular stability must therefore be maintained.[3,4]

If a fracture or displacement of the spine is detected, the animal should be heavily sedated or anesthetized in order to place a splint aimed at immobilizing the spine. In the case of a cervical fracture or displacement, the splint should be placed on the ventral aspect of the neck, extending from the rostral portion of the mandible to the manubrium of the sternum. Bandaging material can be used to hold the splint in place and should start just caudal to the ears and extend beyond the caudal aspect of both scapulas. In the case of a thoracic or lumbar fracture or displacement, a V-shaped splint should be placed over the spine and secured firmly with bandage material. It is important to avoid placing the splint so tightly that respiration is impaired.

If the injury requires surgery and consent has been given by the owner, the animal should be referred to an experienced surgeon. Surgical fixation has been indicated as the treatment of choice in animals with atlantoaxial subluxation to prevent recurrence of signs.[11] Fractures can be complicated and, depending on the location of the fracture, surgery may or may not be indicated. If the fracture incorporates the articular facets, the vertebral body, or both, internal fixation is recommended.[12] Luxations or subluxations that have compromised the ventral buttress (vertebral body, dorsal and ventral longitudinal ligaments, and intervertebral disks) are susceptible to rotation and require surgical repair to inhibit this movement.[12] However, for animals in which the neurologic status is not deteriorating, external support and strict rest are the treatments of choice for displaced or unstable fractures of the cervical spine.[13] This is due to the high incidence of mortality (approximately 40%) associated with surgical intervention for cervical fractures.[13] Intervertebral disk disease resulting in moderate to severe neurologic deficits, recurrent episodes, and episodes unresponsive to medical treatment should be treated with surgical decompression.

Pain control for animals with spinal cord injury often requires pure opioid agonists (fentanyl, hydromorphone, oxymorphone, or morphine) or a partial opioid agonist (buprenorphine). If these medications are used, the patient should be closely monitored for respiratory depression (see Chapter 164, Analgesia and Constant Rate Infusions).

Treatment for spinal cord edema and lipid peroxidation is a controversial subject. Methylprednisolone sodium succinate at 30 mg/kg IV has been shown to improve neurologic outcome in humans if given within 8 hours of the injury,[14] although similar studies have not been performed in the dog or cat. Subsequent doses of methylprednisolone sodium succinate at 10 mg/kg IV can be given for 24 hours post injury.[9] Gastrointestinal protectants such as histamine-2 blockers (e.g. famotidine) can be given for 24 to 48 hours post injury to decrease the likelihood gastric irritation or ulcers induced by spinal cord injury and steroid administration (see Chapter 181, Gastrointestinal Protectants).

Table 99-2 Differential Diagnoses for Spinal Cord Lesions Based on Signalment, History, and Physical Examination

	Young	Old	Acute Onset	Insidious Onset	Nonprogressive	Progressive	Nonpainful	Painful
Trauma	++	+	+	–	+	–	–	+
IVDD type 1	+	+	+	–	–	+	–	+
IVDD type 2	–	+	–	+	–	+	–	±
Vascular disease	+	+	+	–	+	–	+	–
Infectious and inflammatory disease	++	+	+	–	–	+	±	±
Degenerative disease	–	+	–	+	–	+	+	–
Anomalous or malformation	+	–	+	+	+	–	++	±
Neoplastic disease	+	++	+	+	–	+	±	±

IVDD, Intervertebral disk disease.

++, More likely; +, yes; –, no; ±, sometimes.

99.7 PROGNOSIS

The prognosis for animals with spinal cord injury is extremely variable and difficult to predict. Many factors play a role in outcome including age, size, and breed of the animal, etiology, onset of clinical signs, severity of signs, and location of disease. Animals with cervical spinal cord injury caused by trauma, atlantoaxial subluxation, and intervertebral disk herniation have differing prognoses. Dogs with cervical spine trauma have been reported to have a good prognosis (recovery rate of 82%) if the animal does not suffer from acute respiratory failure.[13] Atlantoaxial subluxations resulting in severe neurologic deficits that are treated conservatively (i.e., splint stabilization) have been reported to have a good to guarded prognosis for recovery (good outcome in 62.5% of dogs), but approximately 25% relapse at a later date.[11] Surgical stabilization has also been reported to have a good to guarded prognosis for recovery,[11] with success rates ranging from 61% to 91%.[16-18] Cervical intervertebral disk herniation (IVDH) treated via ventral slot in animals with tetraparesis or tetraplegia was present before surgery has been reported in one study to have a 56% chance of recovery in 1 to 6 weeks. Animals with only pelvic limb paresis had a 75% chance of recovery in 3 to 8 weeks.[15] Another study reports a better outcome in patients with high cervical intervertebral disk herniation (C2-C3 and C3-C4), with long-term resolution after ventral decompression seen in 66% of dogs. However, in animals with caudal cervical sites of intervertebral disk herniation (IVDH) (C4-C5, C5-C6, and C6-C7) only 21% had long-term resolution of signs.[19] The most common postoperative complications include vertebral instability and subluxation. Another important complication is hypoventilation requiring ventilatory support. This was seen in 4.9% of dogs that underwent surgery for cervical spinal cord disorders.[21]

Thoracolumbar spinal cord injuries have also had varying reports of success. In a study of nine cases of traumatic injuries (e.g., trauma caused by car accidents or being dropped) that resulted in the loss of deep pain sensation, none of the dogs regained deep pain sensation with treatment (six treated conservatively and the remaining three treated surgically), but two did regain the ability to walk (spinal walking).[22] Another report indicated that loss of deep pain sensation due to thoracolumbar luxation or fracture resulted in a less than 10% recovery rate (i.e., motor ability).[2,23] A loss of deep pain for more than 12 to 24 hours following injury and severe luxation or displacement of vertebral bodies also carries a poor to grave prognosis.[20] Overall, the prognosis for recovery after trauma to the thoracolumbar spinal cord that results in the loss of deep pain sensation is extremely grave.

In cases of thoracolumbar disk herniation, many studies have revealed varying rates of recovery (25% to 76%) for dogs that did not have deep pain sensation in the pelvic limbs.[17,24-28] In contrast, the recovery rate for dogs that have retained deep pain sensation in the pelvic limbs is very good and is reported to be in the range of 86% to 96%.[27,28]

100 Chapter 100 Intracranial Hypertension

Beverly K. Sturges, DVM DACVIM (Neurology)

Richard A. LeCouteur, BVSc, PhD, DACVIM (Neurology)

100.1 KEY POINTS

- Intracranial hypertension (ICH) is the persistent elevation of intracranial pressure (ICP) above the normal range of 5 to 12 mm Hg.
- Causes include trauma, hemorrhage, infarction, ischemia, edema, masses, encephalopathy, and status epilepticus.
- ICH develops when the volume of the intracranial contents exceeds the accommodation of compensatory mechanisms.
- ICH damages the brain through its deleterious effects on cerebral blood flow (CBF) and oxygen delivery causing hypoxia, ischemia, and brain herniation.
- The primary treatment goals are maintenance of CBF and tissue oxygenation without causing or worsening ICH.
- Effective management of ICH includes critical maintenance of cerebral perfusion pressure (CPP) and often requires hyperosmolar therapy.

100.2 PHYSIOLOGY OF INTRACRANIAL PRESSURE

100.2.1 Intracranial Fluid Dynamics

The collective volume of intracranial contents is the major determinant of intracranial pressure (ICP). The cranial space may be divided into four distinct physiologic compartments, each with separately regulated water content: blood, cerebrospinal fluid (CSF), intracellular fluid (ICF), and extracellular fluid (ECF).

100.2.2 Cerebrospinal Fluid Flow

Most CSF is formed by ultrafiltration of fluid from the blood vessels of the choroid plexus lining the ventricles and drains into the subarachnoid space, from where it is absorbed. When ventricular pressure is elevated the flow of fluid may be reversed, back into the brain parenchyma.[2] As compensation for intracranial hypertension (ICH), CSF production falls, absorption increases, and a greater volume of CSF is displaced into the spinal subarachnoid space.[1,3]

100.2.3 Brain Water Movement

The blood-brain barrier (BBB) tightly regulates the entry of solutes into the brain but is permeable to water. Changes in effective osmolality across the BBB are accompanied by water movement to equalize osmolality, but at the expense of changes in cell volume. With increases in the osmolality of intravascular fluid or ECF, ICF may shift to the extracellular environment. With persistence of hyperosmolar conditions in the extracellular fluid for many hours, brain cells, having lost volume, will compensate by generating intracellular osmolytes (idiogenic osmoles) to raise the osmotic pull intracellularly and restore cell volume. Breakdown of these idiogenic osmoles occurs over several days. Rapid decreases in ECF osmolality should be prevented, because the intracellular osmolytes may draw water into the cell, causing cell swelling, membrane disruption, and exacerbation of ICH.[4]

100.2.4 Cerebral Blood Flow

The high metabolic demands of the brain require maintaining cerebral blood flow (CBF) in the normal range at all times. CBF is dependent on cerebral perfusion pressure (CPP), which is calculated as mean arterial pressure (MAP) minus ICP[4-6]:

$$\text{CPP} = \text{MAP} - \text{ICP}$$

The volume of blood in the brain (cerebral blood volume [CBV]) is affected by factors that change CBF, such as altered vascular tone, and those that impair venous outflow, such as head-down posture, jugular vein compression, or increased intrathoracic pressure.[1,4,5] Cerebrovascular vasodilation serves to increase CBF and thereby CBV, leading to increased ICP; cerebral vasoconstriction decreases CBF, CBV, and therefore ICP, but may result in hypoxia and neuronal ischemia.[1,4,5]

100.3 INTRACRANIAL PRESSURE

Intracranial pressure ICP is the pressure inside the cranial vault exerted by the tissues and fluids against the encasing bone. Normal ICP in the dog is 5 to 12 mm Hg, similar to that of humans for whom 20 mm Hg is an arbitrary upper limit beyond which treatment for ICH may be instituted[1,3] (see Chapter 209, Intracranial Pressure Monitoring). The upper limit of ICP above which treatment is indicated for ICH has not been defined in dogs and cats. It seems reasonable to utilize the human guidelines for ICH until species-specific information is available.

100.3.1 Homeostatic Responses of the Brain

Three primary homeostatic mechanisms exist to maintain ICP within a range where the brain is functional. These include volume buffering, autoregulation, and the Cushing response.[1,4-6]

100.3.1.1 Volume Buffering

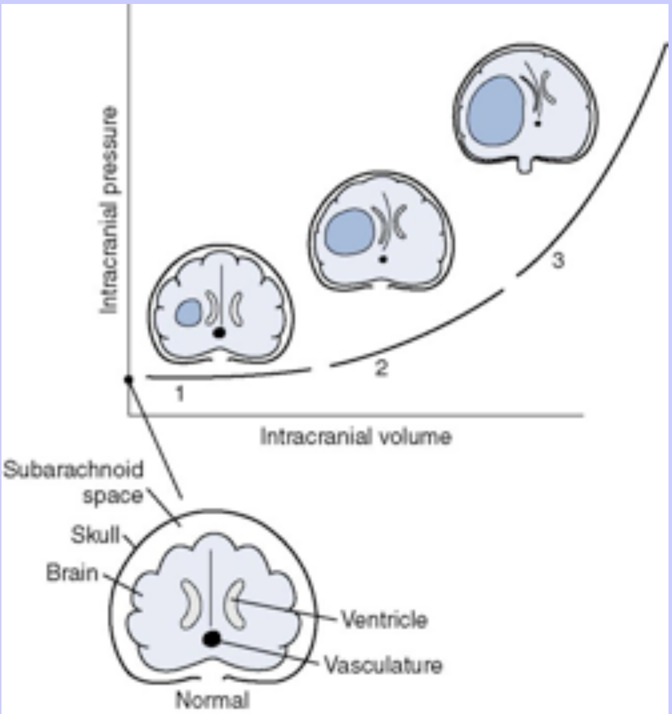
The brain is relatively noncompressible and is encased in bone, causing the volume of the intracranial contents to be fixed. Increase in the volume of one component requires a compensatory decrease in one or more of the others if ICP is to remain unchanged (Monroe-Kellie doctrine). Sources of added volume include hemorrhage, CSF accumulation, vascular congestion, cerebral edema, and decreases in venous outflow (Figure 100-1). Immediate volume buffering responses, specifically displacement of blood and CSF extracranially, are reflected by the pressure-volume curve that relates the temporal change in ICP to expanding intracranial volume.

100.3.1.2 Autoregulatory Mechanisms

100.3.1.2.1 Pressure Autoregulation

Autoregulation of CBF results from a vascular (myogenic) reflex that changes resistance of cerebral arterioles in response to changes in transmural pressure. The purpose is to prevent underperfusion or overperfusion of the brain. Normally this mechanism operates at perfusion pressures between 50 and 150 mm Hg. Outside this range, CBF becomes linear with MAP (Figure 100-2).[1,4,5]

Figure 100-1 Pressure-volume curve. An idealized elastance curve that illustrates changes in intracranial pressure (ICP) accompanying the progressive addition of intracranial volume. First segment: Compliance is high, compensatory mechanisms are functioning well, primarily a result of expansion of the dura mater in the cranial and cervical spinal space, allowing for added volume with no or little increase in ICP. Second segment: As volume is added to the system, displacement of cerebrospinal fluid and blood allow for further volume additions with progressive changes in ICP. Third segment: The vertical portion of the elastance curve shows the high-pressure, low-compliance situation that occurs when the volume buffering capacity is exhausted. Further displacement of intracranial fluids is not possible and addition of more volume causes an exponential rise in ICP. Decompensation is occurring and any volume buffering at this point is due to distention, compression, and eventual herniation of neural tissues.



100.3.1.2.2 Chemical Autoregulation

Chemical regulation of cerebral vascular resistance is influenced by three factors: partial pressure of arterial carbon dioxide ($PaCO_2$), partial pressure of arterial oxygen (PaO_2), and cerebral metabolic rate of oxygen consumption.[1,4,5]

100.3.1.2.2.1 Partial Pressure of Arterial Carbon Dioxide

Cerebral vascular resistance is directly responsive to changes in $PaCO_2$ concentrations, because carbon dioxide combines with water to form hydrogen ions, which when increased in concentration stimulate cerebral vasodilation and when decreased may cause vasoconstriction. Therefore, in the normal brain, hyperventilation decreases $PaCO_2$ causing vasoconstriction, reduced cerebral blood volume, and lowering of ICP.

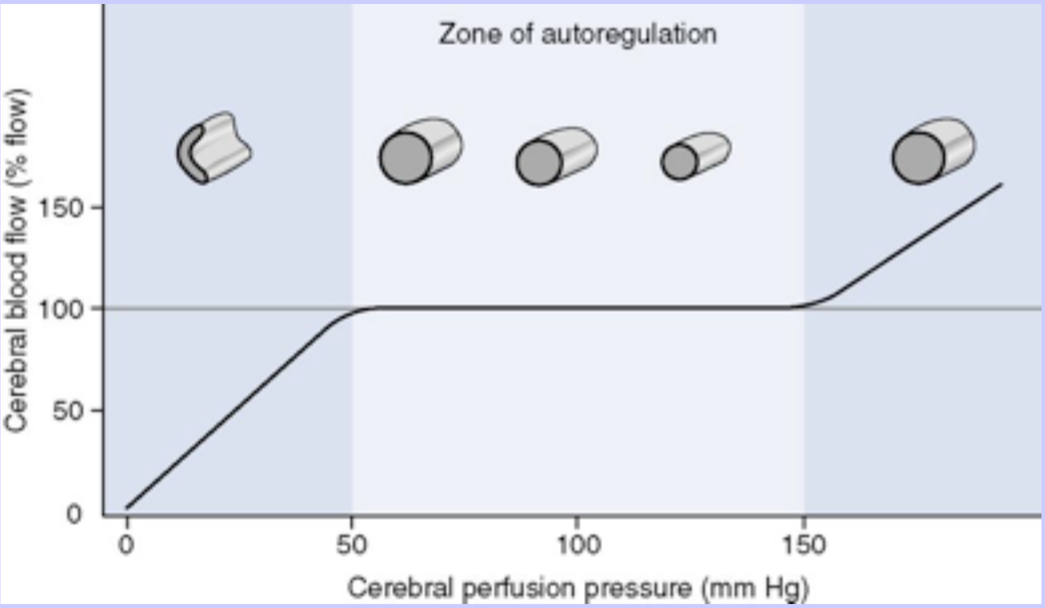
100.3.1.2.2.2 Partial Pressure of Arterial Oxygen

Decreases in PaO_2 cause vasodilation, resulting in increased CBF, CBV, and ICP.

100.3.1.2.2.3 Cerebral Metabolic Rate of Oxygen Consumption

CBF is coupled to local cerebral metabolism. In regions of high cerebral metabolic activity, pH alterations in the perivascular environment will have a direct influence on cerebral vascular tone.
Increased hydrogen ion concentration, as seen with lactic acidosis or accumulation of other acids formed 424
during the course of cerebral metabolism, will cause an increase in CBF. When cerebral metabolic rate of 425
oxygen consumption is decreased, low levels of hydrogen ion concentration will result in decreased CBF locally as a result of arteriolar constriction.

Figure 100-2 Classic cerebral pressure autoregulation curve. Cerebral autoregulation maintains a relatively constant rate of cerebral blood flow across a wide of range of cerebral perfusion pressures as shown (50 to 150 mm Hg). With intact autoregulation, cerebrovascular tone appears to respond to transmural pressure, which is approximately the same as cerebral perfusion pressure. Note the marked rise and fall in cerebral blood flow as cerebral perfusion pressure changes above and below, respectively, the normal limits of autoregulation. With impairment of autoregulation in the injured brain, cerebral blood flow will passively follow systemic arterial blood pressure.



100.3.1.2.2.4

Cushing Response

Autoregulation often is impaired in animals with intracranial disease where pressure autoregulation generally is affected first and chemically mediated regulation is affected more as brain injury progresses. When volume buffering and autoregulatory adjustments are exhausted, ICH will lead to decreased CBF, cerebral ischemia, and accumulation of carbon dioxide. Decreased CBF and elevated carbon dioxide levels can stimulate the release of catecholamines which may cause systemic vasoconstriction and increased cardiac output. Baroreceptors sense this hypertensive state and cause a vagally mediated bradycardia. Hypertension and bradycardia secondary to ICH is known as the *Cushing response*. The catecholamine release also may result in cardiac arrhythmias due to myocardial ischemia, the so-called brain-heart syndrome.

100.4 CAUSES OF INTRACRANIAL HYPERTENSION

In general terms, causes of ICH can be classified as vascular or nonvascular. Vascular mechanisms of ICH include cerebral vasodilation caused by increased $PaCO_2$, distention of cerebral vessels due to loss of vascular tone, or venous outflow obstruction. Nonvascular mechanisms are increased brain water (interstitial edema or intracellular swelling), masses, or obstruction of CSF outflow.

Pressure gradients associated with ICH may result in movement of neural tissues within and between anatomic compartments (brain herniation) that may perpetuate injury and ischemia by distorting or fracturing brain tissue, and by compression and shearing of cerebral vasculature.[1,7]

100.5 CLINICAL ASPECTS OF INTRACRANIAL HYPERTENSION

A complete history and physical examination are essential in the assessment of patients suspected to have ICH. A careful neurologic examination is required for accurate clinical diagnosis, institution of therapy, and determination of a baseline to which results of future examinations may be compared. Aspects of the neurologic examination that are of particular importance include level of consciousness, brain stem reflexes, respiratory pattern, motor responses, abnormal postures, and breathing patterns. Papilledema identified on fundic examination is a reliable sign of ICH.

100.5.1 Level of Consciousness

Four levels of consciousness are recognized:

1 *Alert and responsive:* Normal responses to sensory stimuli; expected behavior

2 *Obtunded (depressed):* Slow or inappropriate response to sensory stimuli

3 *Stuporous (semicomatose):* Generally unresponsive, except to vigorous or painful stimuli

4 *Comatose:* Complete unresponsiveness to repeated noxious stimulation.

The mechanisms responsible for consciousness are located in the rostral brain stem, the ascending reticular activation system (ARAS; reticular formation), and diffusely throughout the cerebrum.

Progression from a higher to a lower level of consciousness often is caused by elevation of ICP. Although focal loss of autoregulation may not be recognized clinically, unconscious animals are likely to have global impairment of autoregulatory responses.[1,4]

100.5.2 Brainstem Reflexes

100.5.2.1 Size and Reactivity of Pupils

The midbrain and efferent parasympathetic fibers of the oculomotor nerve (cranial nerve III; CN III) are responsible for pupillary constriction. In the absence of ophthalmic injury, abnormalities in pupil size or reactivity indicate brainstem dysfunction. Several patterns of pupillary abnormality are commonly recognized in patients with ICH:

1. *Mydriasis* usually denotes a lesion (ipsilateral or bilateral) of the midbrain or the CN III.
2. *Miosis* may occur ipsilateral to severe brainstem injury or as part of Horner's syndrome (ptosis, 425
   enophthalmos, third eyelid protrusion), indicating a lesion affecting the sympathetic pathway to the eye. 426
3. *Severe bilateral miosis* is a sign of acute, extensive brain disturbance and probably occurs as a result of functional disturbance of higher centers, with release of CN III efferents from cerebral inhibition.
4. *Severe, unresponsive bilateral mydriasis* generally indicates a grave prognosis, and it often accompanies brain herniation.

The return of pupils to normal size and responsiveness to light is a favorable prognostic sign.

100.5.2.2 Resting Eye Position, Eye Movements, and Oculovestibular Reflexes

1. Resting eye position and presence of spontaneous nystagmus should be noted. Eye abduction may be caused by medial rectus muscle paresis due to CN III damage. Adduction may be caused by lateral rectus muscle paresis due to abducens nerve (CN VI) damage, or damage to the rostral medulla oblongata or pons.
2. Oculovestibular movements are elicited by moving the head from side to side or vertically. Conjugate oculovestibular movements require integrity of the brainstem pathways from the cranial cervical spinal cord and medulla oblongata rostrally to the nuclei of CN III, CN IV (trochlear nerve) and CN VI, via the medial longitudinal fasciculus. Thus the oculovestibular maneuver is a convenient method for examination of the functional integrity of large areas of the brain stem and the cranial nerves involved in eye movements.

100.5.2.3 Corneal Reflexes

Although evaluation of corneal reflexes alone rarely is useful, findings may corroborate eye movement abnormalities. Touching the cornea with a wisp of cotton should cause bilateral eyelid closure. The corneal reflex may be absent when the afferent trigeminal nerve (CN V), the efferent facial nerve (CN VII), or their reflex connections within the pons and medulla oblongata are damaged.

100.5.3 Respiration

Breathing is regulated principally by respiratory centers in the caudal brain stem between the midpons and cervico-medullary junction. Respiratory patterns have proven useful, but inconsistent, in localizing brain injury.

1. *Cheyne-Stokes respiration* consists of phases of hyperpnea regularly alternating with apnea. Its presence implies a lesion deep in the cerebral hemispheres or in the rostral brain stem.[1]
2. *Central neurogenic hyperventilation* consists of sustained, rapid, fairly deep, and regular respirations at a rate of approximately 25 breaths/min, with hypocapnia. This respiratory pattern may indicate a lesion in the caudal midbrain and pons.[1]
3. *Neurogenic pulmonary edema* may occur almost instantaneously following rostral brain stem injury in the absence of direct pulmonary trauma.[1] ICH occasionally may result in neurogenic pulmonary edema.
4. *Gasping or chaotic respirations* reflect caudal brain stem damage and represent the terminal respiratory pattern of severe ICH. The appearance of, or progression to, abnormal respiratory patterns, strongly suggests that the animal is deteriorating and mandates more aggressive medical therapy or surgery.[1]

100.5.4 Motor Responses

Ataxia and paresis may determined by observing the gait and response to testing of postural reactions. If an animal is non-ambulatory, voluntary movement of the limbs is determined based on response to noxious stimuli.

100.5.5 Posture

Decerebrate rigidity occurs with midbrain lesions and is characterized by unconsciousness, recumbency, opisthotonos, and rigid extension of all limbs. This posture signifies a grave prognosis and must be distinguished from decerebellate posture and the Schiff-Sherrington syndrome, in which extensor rigidity is present in the thoracic limbs but the animal is conscious.

100.6 DIAGNOSIS OF INTRACRANIAL HYPERTENSION

In the absence of direct ICP monitoring, a clinical diagnosis of ICH usually is based on results of serial neurologic examinations. Ultimately, if ICH is not controlled, significant shifts in brain parenchyma will occur, leading to forcible movement of brain tissue, or herniation. CT or MR imaging may be more sensitive than clinical examination in detecting brain herniation in animals. For example, a slow-growing brain tumor may cause significant cerebellar herniation in a patient without clinical signs of ICH.

Brain death usually is indicated clinically by coma, absence of spontaneous respiration, and loss of brain stem reflexes (e.g., fixed, dilated pupils). Additional criteria used in human patients include an isoelectric electroencephalogram and absence of CBF on arteriographic evaluation.[1]

100.7 TREATMENT OF INTRACRANIAL HYPERTENSION

Appropriate treatment of ICH is often more important to the short-term survival of the patient than primary treatment of the underlying brain disease. Treatment goals include reduction of intracranial volume and prevention of secondary brain injury by restoration and maintenance of circulating blood volume, blood pressure, oxygenation, and ventilation[4-6,8] (Box 100-1).

100.7.1 General Supportive Care

The initial step is to recognize and correct life-threatening, nonneural injuries, especially in the case of brain trauma.[8,9] Shock most often is due to tissue damage and blood loss from other organs; intracranial disease alone, including head trauma, rarely results in shock.

100.7.1.1 Prevent Hypoxia

The animal should be placed in an oxygen-rich environment with its head elevated and a clear airway. Oxygen supplementation will not prevent hypercapnia in a hypoventilating animal. Tracheal intubation and mechanical ventilation are indicated in apneic or hypoventilating patients.[8,9]

100.7.1.1.1 Box 100-1 Concepts in Management of Intracranial Hypertension

100.7.1.1.1.1 Reduction of Intracranial Volume

- Reducing brain size and edema
- Reducing CSF volume and obstruction to flow
- Reducing cerebral blood volume
- Reducing the size of pathologic process (tumor, hematoma, inflammation)
- Increasing the space for expansion of structures by decompressive craniectomy

100.7.1.1.1.2 Prevention of Secondary Brain Injury

- Preventing hypoxia
- Preventing hypotension
- Maintaining euvolemia, euglycemia
- Maintaining electrolyte and acid-base balance
- Managing seizures, fever, SIRS, MODS

CSF, Cerebrospinal fluid; *MODS,* multiple organ dysfunction syndrome;

SIRS, systemic inflammatory response syndrome

100.7.1.2 Prevent Hypotension

Prevention and management of hypotension are central to the treatment of ICH; hence, intensive monitoring of arterial blood pressure is essential.[4,8,9]

100.7.2 Guidelines for Specific Therapy of Intracranial Hypertension

After general supportive measures have been completed, medical treatment is instituted to reduce brain edema, decrease ICP, and maintain cerebrovascular perfusion and tissue oxygenation. The patient should be assessed (at least) every 15 to 30 minutes until stabilized. A response to therapy should be seen within 2 hours; if a response does not occur, medical therapy should be reassessed, and surgical therapy considered (Box 100-2).

100.7.2.1 Maintain Adequate Cerebral Perfusion Pressure

Maintenance of adequate CPP is the theoretical basis for managing ICH.[1,10,11] For CPP to remain constant, the MAP must increase when ICP increases. If the ICP cannot be controlled after adequate fluid resuscitation, vasopressors may be considered to increase MAP.[10] However, in the absence of cerebral ischemia, attempts to maintain CPP at over 70 mm Hg with pressors should not be pursued aggressively.[10,11] CPP in dogs and cats ideally is maintained at 50 to 90 mm Hg. When it is not possible to monitor ICP, mean arterial blood pressure should be maintained at or above 80 mm Hg.

100.7.2.2 Decrease Cerebral Venous Blood Volume

Head elevation promotes drainage of venous blood to reduce ICP. Neck wraps, improper positioning of the head and neck, or positive end-expiratory pressure may impair venous drainage, causing an increase in brain volume.

100.7.2.3 Control $PaCO_2$

The most important factor controlling CBF and CBV is $PaCO_2$.[5] Controlled ventilation, used judiciously, can lower ICH by vasoconstriction and reduced CBF. The target $PaCO_2$ is 30 to 35 mm Hg. Lower values may lead to neuronal ischemia and exacerbation of ICH.[5,11,12]

100.7.2.3.1

Box 100-2 Suggested Protocols for Initiating Management for Intracranial Hypertension

100.7.2.3.1.1

Management for ICH

100.7.2.3.1.1.1

All patients with evidence of ICH or at risk of developing ICH

Prevention of hypercapnia with a target $PaCO_2$ of 30 to 35 mm Hg

Oxygen supplementation as needed to maintain a PaO_2 >80 mm Hg

Head elevation (30 degrees) and prevention of jugular compression

Removal of causes of increased intrathoracic pressure

Control of systemic factors

- Prevent hypotension
- Prevent hypoxia
- Prevent electrolyte and acid-base imbalances
- Maintain euvolemia and euglycemia

100.7.2.3.1.1.2

Clinical Evidence of Marked ICH: Deteriorating Neurologic Status

All of the above therapies

Hyperosmolar agents

Ventricular CSF drainage if feasible

100.7.2.3.1.1.3

Clinical Evidence of Severe ICH: Comatose Mental State, or Rapid Neurologic Deterioration

All of the above therapies

Hyperventilation therapy

Barbiturate coma

Decompressive craniectomy

CSF, Cerebrospinal fluid; *ICH,* intracranial hypertension; *$PaCO_2$*, partial pressure of arterial carbon dioxide; *PaO_2*, partial pressure of arterial oxygen.

100.7.2.4 Control PaO_2

CBF begins to increase when PaO_2 falls below 60 mm Hg. However, the brain is even more sensitive to arterial oxygen content. For example, in humans, halving the hematocrit will double the CBF, even if PaO_2 is higher than 60 mm Hg.[5]

100.7.2.5 Reduce Cerebral Edema With Hyperosmolar Fluid Therapy

Reduction of brain water content has long been theorized to be an effective means of controlling ICP. To this end, the misguided practice of dehydrating patients by using diuretics or restricting fluids was used initially to manage ICH. In more recent years, hyperosmolar agents have been used widely.[8,10,11] The patient's fluid and electrolyte balance should be determined before starting hyperosmolar therapy.

100.7.2.5.1 Mannitol

The short-term beneficial effects of mannitol on ICH, CPP, and CBF are widely accepted.[8,10,11,13] Although the mechanism of action is controversial, mannitol probably has two effects: (1) an immediate (within minutes) plasma-expanding effect that reduces blood viscosity, thus increasing CBF and the delivery of oxygen to the brain, and (2) a delayed osmotic effect that occurs 15 to 30 minutes after administration when gradients are established between plasma and cells, causing a reduction in brain water content. An osmotic increase of at least 10 mOsm is thought to be required for this effect to be seen. This delayed effect persists for 1 to 3 hours. It is thought best not to exceed a plasma osmolality of 320 mOsm/kg. However, the authors have routinely used hyperosmolar therapy in animals with blood osmolalities higher than this, without adverse effects, in situations of severe ICH. Strict monitoring and maintenance of fluid and electrolyte balance are essential during mannitol therapy. 427 428

The recommended dosage is 20% mannitol solution 0.5 to 1 g/kg IV over 20 minutes.

Mannitol should be administered as repeated doses, not as a continuous infusion. Dangers of repeated dosage are related to effects on blood volume and electrolytes rather than specific toxicity. Mannitol may accumulate in the brain parenchyma, especially in an injured area, possibly leading to a rebound effect of increasing ICP when it is discontinued. Preventing hypovolemia following mannitol administration may reduce this complication[8,13] (Box 100-3).

100.7.2.5.2

Hypertonic Saline

Hypertonic saline is a useful therapy for ICH.[8,10,14,15] Animal models have shown it to be as effective as mannitol in reducing cerebral water content.[14] It may also have beneficial effects on excitatory neurotransmitters, as well as on the immune system.

Recommended dosage is sodium chloride 7.5% solution 4 ml/kg IV over 5 to 10 minutes.

100.7.2.5.3

Furosemide

In animals in which mannitol fails to control ICP, or if mannitol is not indicated because of cardiac or electrolyte abnormalities, or ongoing intracranial hemorrhage is suspected, furosemide may be given. Furosemide is a loop diuretic that may reduce brain water by promoting a diuresis of hypoosmotic urine, in addition to other undetermined ICP-lowering effects. Administration of furosemide simultaneously with mannitol reportedly has been synergistic in reducing ICP.[4]

Recommended dosage of furosemide is 0.7 to 2 mg/kg IV. Furosemide takes effect within 30 minutes following IV administration. Maintenance of fluid and electrolyte balance is required.

100.7.2.5.4

Glucocorticoids

A beneficial role for glucocorticoids in the treatment of head trauma remains unproven, and their routine use is strongly discouraged by these authors.[11] Until such time as appropriate studies support the use of glucocorticoids in the treatment of ICH caused by traumatic brain injury, their use is not recommended.[11] Primary infectious and non infectious inflammatory diseases and tumor-associated edema may be indications for considering glucocorticoids to treat severe ICH.[16]

100.7.2.5.4.1

Box 100-3 Precautions for Use of Mannitol

1. Maintain euvolemia. Correct hypovolemia before use, but do not overhydrate. A catheter placed in the urinary bladder to monitor urine output facilitates this aspect of treatment.
2. Use a fluid line filter when administering mannitol or dissolve visible crystals in solution before use.
3. Administer as a slow bolus over 20 minutes.
4. If possible, monitor and maintain serum osmolality at or below 320 mOsm/L, particularly when there is concern for renal failure.
5. Monitor serum electrolytes and acid base balance and maintain in normal range.
6. Monitor urine output. If urine is not produced within 15 minutes of mannitol administration, give furosemide to induce diuresis.

7 Do not use when clear evidence of ongoing intracranial hemorrhage is present, for example, imaging evidence.

Recommended dosage is dexamethasone sodium phosphate 0.1 to 0.25 mg/kg IV.

100.7.2.5.5 Other Drugs

While the authors do not recommend usage of additional drugs for the treatment of ICH, several drugs have been recommended. Dimethyl sulfoxide (DMSO) and opioid antagonists (e.g., naloxone) have been used to treat brain edema, although there is no evidence to support their use in place of mannitol. Tirilazad mesylate has shown promise as a neuroprotectant in experimental models of focal cerebral ischemia and subarachnoid hemorrhage. Research is ongoing concerning use of agents such as tromethamine (an alkalinizing agent), superoxide dismutase, allopurinol, thyrotropin-releasing hormone, fluosol, and calcium channel blocking drugs.[13]

100.7.2.6 Cerebral Metabolic Rate of Oxygen Consumption

CBF and cerebral metabolic rate (CMR) are coupled so that an increase CMR is accompanied by a rise in CBF. Reducing the oxygen requirement of the brain may reduce ICP by reducing cerebral blood volume. Hyperthermia, fever, and hallucinogenic drugs (e.g., ketamine) increase the oxygen requirements of the brain. Measures to reduce CMR include sedation with barbiturates, anesthesia, and hypothermia.[10,11]

100.7.2.7 Surgical Therapy

Craniectomy should be considered in animals with ICH refractory to medical decompression. Other indications for surgery include debulking of mass lesions, drainage of intracranial abscesses, and treatment of open skull fractures, depressed skull fractures, or fractures involving a venous sinus or middle meningeal artery.[1,13] Durotomy appears to be significantly more effective than skull removal in lowering ICP experimentally in dogs and cats.[13]

In humans, aspiration of CSF via intraventricular catheterization is used frequently to treat ICH.[10] It may be possible to aspirate CSF from animals with ventriculomegaly, and ultrasound-guided CSF aspiration may be considered in animals with fontanelles.

100.7.2.8 Other Considerations

Intensive supportive care, as discussed in various sections of this manual, is essential. Factors such as frequent turning, prevention of pressure sores, nutritional support, and attention to bladder and bowel function are of paramount importance in preventing complications associated with recumbency. Most animals with ICH have depressed swallowing and gag reflexes, so oral feeding should be avoided, because aspiration pneumonia may result. Alternative methods of nutritional support, such as a feeding tube or total parenteral nutrition, should be considered early in the course of treatment.

100.8 PROGNOSIS

In general, animals with brain stem lesions, especially persistent coma, abnormal respiration, or progressive loss of cranial nerve reflex function, have a poorer prognosis than those with cerebrocortical involvement. Patience and persistence are essential in treatment, because recovery may require a prolonged time for resolution of edema, necrosis, and hemorrhage. Also, compensatory mechanisms of the central nervous system often require many months for maximum development. Even animals with residual deficits may be functional pets. 428 429

101 Chapter 101 Lower Motor Neuron Disease

Charles Vite, DVM, PhD, DACVIM (Neurology)

Kersten Johnson, DVM

101.1 KEY POINTS

- The motor unit is comprised of the lower motor neuron (LMN), the neuromuscular junction (NMJ), and skeletal muscle fibers.
- Disease of the motor unit results in flaccidity, diminished segmental reflexes, and rapidly progressing muscle atrophy.
- In contrast, upper motor neuron (UMN) paresis or paralysis results in spasticity and exaggerated segmental reflexes.
- Clinical signs, clinicopathologic testing, and electrodiagnostic testing can be used to identify the location of the disease within the motor unit.
- Cranial or spinal neuropathies and local or diffuse myopathies result from neoplastic, degenerative, genetic, immune-mediated, metabolic, vascular, toxic, infectious, or idiopathic causes. Botulism, tick paralysis, acquired myasthenia gravis, or aminoglycoside intoxication may cause diffuse junctionopathies.

101.2 INTRODUCTION

The lower motor neuron (LMN) is comprised of the cell body (found in the brainstem or spinal cord) and the axon that contributes to either the spinal or cranial nerves. The LMN terminates on skeletal muscle fibers at the neuromuscular junction (NMJ). The LMN, NMJ, and skeletal muscle fibers together make up the motor unit.[1]

The upper motor neuron (UMN) system originates in the cerebral cortex and brainstem, with axons contributing to the corticospinal, rubrospinal, reticulospinal, or vestibulospinal tracts. The UMN is confined to the central nervous system and terminates on the LMN. Strictly defined, the UMN is a *premotor* neuron because it results only in movement and muscle tone through its actions on the LMN.[2]

The paretic or paralyzed patient may have disease of the brain, spinal cord, nerve, NMJ, or skeletal muscle. The neurologic examination and its interpretation are the first and most important steps in localizing the lesion. The first question asked is whether the clinical signs result from dysfunction of the UMN system or of the motor unit. Disorders of the UMN system typically result in spasticity and exaggerated segmental reflexes. Disorders of the motor unit result in flaccidity, diminished segmental reflexes, and rapidly progressing muscle atrophy (over 1 to 2 weeks). This chapter will describe how to recognize diseases of the motor nerve (neuropathy), NMJ (junctionopathy), and muscle (myopathy), how to confirm an anatomic diagnosis, and how to treat specific disorders of the motor unit.

101.3 IDENTIFYING NEUROPATHIES, JUNCTIONOPATHIES, AND MYOPATHIES

Disease of the motor unit results in flaccid paresis or paralysis. A short-strided gait is apparent when appendicular muscles are involved. Postural reactions and segmental reflexes frequently are diminished. Muscle atrophy is common, although involvement of specific muscle groups may result in specific dysfunction including incontinence, dysphagia, dysphonia, regurgitation, and abnormal facial expressions. In order to generate a list of appropriate differential diagnoses, the location of the lesion (nerve, NMJ, muscle) must first be determined using information from the clinical examination, clinicopathologic tests, electrodiagnostic testing, and/or biopsy.

101.3.1 Clinical Signs

Some clinical signs are specific to involvement of the nerve, NMJ, or skeletal muscle. Because neuropathies may affect sensory neurons in addition to the LMN, proprioceptive deficits and diminished tactile or pain sensation may be recognized with neuropathies, but not with diseases of the NMJ or muscle. In some instances, it can be difficult to distinguish whether an animal does not correct a knuckled over paw due to inability to sense that it is in an abnormal position (diminished proprioception) or due to paresis. If one supports most of the animal's weight and places the dorsal surface of the paw on the floor, a paretic dog may replace the foot promptly, but a dog with significant proprioceptive deficits will not. Additional clinical signs that may suggest the location of the lesion are muscle pain (found with some myopathies) and waxing and waning signs that frequently are made worse with exercise (found with some junctionopathies and myopathies but uncommon with neuropathies).

101.3.2 Clinicopathologic Testing

Serum enzyme activities specific to muscle may help to identify myopathic disease. Large increases in the serum concentrations of the enzymes creatine kinase, serum glutamic aspartate aminotransferase, and lactate dehydrogenase can indicate damage to muscle fibers. Increases in serum activities of these enzymes must be interpreted with caution because damage to muscle may also occur from recumbency and trauma associated with any cause of paresis.

Cerebrospinal fluid (CSF) analysis may be useful to identify neuropathic disease. Many neuropathies, particularly those involving the nerve roots (radiculopathies) due to degenerative, neoplastic, or inflammatory processes can result in elevations in CSF protein and pleocytosis. These elevations are not expected in most myopathies or junctionopathies.

101.3.3 Electrodiagnostic Testing

Electrodiagnostic testing that is useful for evaluating disease of the motor unit includes electromyography (EMG) and evoked response testing. Electromyography can detect electrical discharges of muscle fibers that are independent of neural control. Spontaneous electrical activity known as *fibrillation potentials* and *positive sharp* commonly are recorded from damaged (myopathy) or denervated muscle (neuropathy) but are rarely found in junctionopathies.

Nerve fibers may also be stimulated electrically to produce compound muscle action potentials (CMAPs). The amplitude and duration of these evoked potentials and the conduction velocity along the nerve can be used to identify the location of the lesion. Small-amplitude evoked responses are found in neuropathies where axonal dysfunction is present (axonal neuropathies), and they can also be found with some junctionopathies and myopathies. Repetitive nerve stimulation is useful for identifying junctionopathies because it often causes the evoked CMAPs to have decreasing amplitude in cases of myasthenia gravis and increasing amplitude in animals with tick paralysis and botulism. A prolonged duration of the CMAP and a significant decrease in nerve conduction velocity can occur in neuropathies where myelin dysfunction occurs (demyelination neuropathies).

101.3.4 Nerve and Muscle Biopsy

Nerve and muscle biopsies may be required when electrodiagnostic testing cannot be performed or when the results of these tests are inconclusive. Nerve biopsy may reveal degeneration or inflammation of the axon or myelin associated with the neuropathy. Muscle biopsy may reveal fiber-type grouping, group atrophy, degeneration, inflammation, or infiltration with fat and connective tissue. Fiber-type grouping, the clustering of either type I or type II muscle fibers, and group atrophy (atrophy of adjacent muscle fibers of similar type) can be seen in animals with neuropathies. Myopathies generally are characterized by fibers affected in a more random pattern with muscle necrosis, regeneration, and inflammation commonly found.[2]

101.4 DECISION MAKING

When an animal has signs consistent with disease of the motor unit, the clinician should first determine which nerve and muscle are affected, based on the clinical examination. If a neuropathy is suspected, the distribution of the neuropathy should be ascertained (cranial versus spinal nerves, mononeuropathy versus polyneuropathy, purely motor neuropathy versus concomitant sensory or autonomic neuropathy).[3] The distribution should be determined in a similar fashion in animals with myopathies (localized versus generalized). A list of differential diagnoses can then be generated.

Next, the onset and course of the clinical signs should be considered. Acute disease may be due to metabolic, neoplastic, inflammatory, traumatic, toxic, and vascular causes, with bilaterally symmetric disease resulting more commonly from metabolic, inflammatory, and toxic causes and asymmetric disease resulting more commonly from neoplastic and traumatic causes.

Next, the possible association of the neurologic dysfunction with any past or present diseases should be considered. Hematologic, biochemical, and serologic testing, as well as imaging, may be performed.

Finally, electrodiagnostic testing, nerve biopsy, and muscle biopsy may be done to confirm the distribution of the disease and to determine the nature of the lesion.

101.5 CAUSES OF ACUTE NEUROPATHY, MYOPATHY, OR JUNCTIONOPATHY

101.5.1 Cranial Mononeuropathies

101.5.1.1 Trigeminal Nerve Sheath Tumor

The client frequently recognizes a rapid loss of muscle over one side of the head of the dog, even though the malignant peripheral nerve sheath tumor (MPNST) is slow growing. Unilateral temporal, masseter, pterygoid, and digastric muscle atrophy may occur, the mandible may be directed toward the side of the lesion, and a unilateral loss of facial sensation may occur if sensory fibers are involved. As the mass grows and compresses the brain, signs of brainstem dysfunction may occur with hemiparesis and vestibular system dysfunction being particularly common. Diagnosis generally is made by computed tomography (CT) or magnetic resonance imaging (MRI) of the head. Surgery and radiation therapy have been attempted and may slow the progression of signs.[4]

101.5.1.2 Trigeminal Neuritis

Dogs (common) and cats (rare) with trigeminal neuritis have an acute inability to close the mouth and difficulty eating and drinking due to bilateral paralysis of the mandibular muscles. Decreased sensation of the face, due to involvement of sensory nerve fibers, and Horner syndrome, due to presumed involvement of sympathetic fibers adjacent to the ophthalmic branch of the trigeminal nerve, may also occur. The diagnosis is made by ruling out musculoskeletal causes for a dropped jaw. Other differential diagnoses for mandibular paralysis are rabies encephalitis (the clinician should wear gloves and obtain a complete vaccination history), round cell neoplasia, and early polyneuritis.[5] Treatment is supportive and the animal is fed by placing small meatball-shaped foods in the mouth with the head elevated. Recovery usually occurs in 2 to 4 weeks, although up to 9 weeks is described.

101.5.1.3 Facial Nerve Paralysis

Dogs and cats generally present because of an inability to lift the lip, excessive drooling, and an inability to move the ear or blink the eyelid. Unilateral (common) or bilateral (less common) paralysis may occur. Signs may be due to inflammatory, neoplastic, traumatic, and idiopathic causes.[6] In the idiopathic form, which may be the most common, tear production is preserved and signs may resolve in weeks to months with no specific therapy. Facial nerve paralysis due to otitis media/interna is indistinguishable from the idiopathic form unless accompanied by Horner syndrome or evidence of ear disease identified by otic examination, brainstem auditory evoked response testing, or imaging.

Surgical (bulla osteotomy) or medical therapy (cephalosporins, amoxicillin-clavulanic acid, clindamycin, enrofloxacin) of the ear disease may lead to resolution of the paralysis. Trauma to the nerve may occur following total ear canal ablation and may or may not resolve with time. Lymphosarcoma may also cause unilateral facial nerve paralysis. In these cases, the facial nerve typically is affected intracranially, in which case the major petrosal nerve may also be affected, resulting in decreased tear production.[7] Finally, facial nerve paralysis may be a clinical sign of a polyneuropathy.

101.5.1.4 Laryngeal Paralysis

Dogs and cats with increased inspiratory sounds, dysphonia, gagging, cyanosis, panting, and collapse may have disease of the vagus or recurrent laryngeal nerves. Laryngeal paralysis may be unilateral or bilateral and may be due to trauma, degeneration (hypothyroid, polyneuropathy), toxic (lead, organophosphates) or idiopathic causes, and has a genetic basis in Siberian Huskies, Bouvier des Flandres, Dalmatians, Rottweilers, Bull Terriers, German Shepherds, and Pyrenean Mountain Dogs (IVIS).[8,9]

The diagnosis is made under light sedation, preferably using thiopental, where decreased abduction of vocal folds with inspiration is found. Electromyography may reveal spontaneous electrical activity in the cricoarytenoideus dorsalis muscle, and in many cases evidence of a distal appendicular polyneuropathy that may or may not be clinically apparent is found. Treatment consists of exercise restriction, tranquilization, and cooling the patient. Arytenoid lateralization surgery may eventually be necessary.

101.5.2 Cranial Polyneuropathies

101.5.2.1 Paralysis of Oculomotor, Trochlear, Abducens, and Trigeminal Nerves

Dogs and cats may have unilateral or bilateral internal and external ophthalmoplegia (inability to move the eyes, retract the globe, or move the pupil). Additional signs may include ptosis and diminished sensation to the cornea and the skin around the eye. These signs can occur from tumors or inflammatory disease of the middle cranial fossa involving these nerves where they pass near the cavernous sinus, or from disease of the retrobulbar space.[10] CT or MRI is necessary to further characterize the lesion before therapy is begun.

101.5.2.2 Other Causes of Cranial Polyneuropathy

Animals may occasionally have dysfunction of multiple cranial nerves including the trigeminal, facial, vestibulocochlear, vagus nerves, and others. Signs may be bilaterally asymmetric or symmetric. Progression of signs from a mononeuropathy to a polyneuropathy may occur. In these animals, tumors and inflammation of the brain stem and cranial nerves must be considered. Lymphosarcoma and meningiomas commonly affect several adjacent cranial nerves, and diagnosis is made with CT and MRI of the brain and cranial nerves, in addition to biopsy. Fungal and protozoal meningoencephalitides may also affect several cranial nerves with diagnoses made by CSF analysis or titers in CSF or serum. Rabies encephalitis must also be considered as a cause of acute-onset cranial polyneuropathy.

101.5.3 Spinal Mononeuropathies

Spinal mononeuropathies and multiple mononeuropathies generally are due to trauma (transections, stretching, bite wounds, injections) and may be classified into three categories based on lesion severity. Neurapraxia, the loss of nerve conduction without structural change, occurs from transient loss of blood supply, often due to compression, and usually resolves over weeks to months. Axonotmesis, damage to axons without loss of supporting structures, requires regeneration of the axons in a favorable environment where motion is absent. Regeneration progresses at a rate of approximately 1 mm per day. Neurotmesis is complete severance of the nerve. Clinical signs seen with disease of specific nerves are well described and the lesion severity may be determined by visual inspection, repeated clinical examinations, and electrodiagnostic testing.[1,7,11] Sharp transections may respond well to surgical intervention, but effective therapy for traction injuries has not been described.

Malignant peripheral nerve sheath tumors and round cell tumors may also result in spinal mononeuropathies, multiple mononeuropathies, and polyneuropathies. They are discussed in the section below.

101.5.4 Spinal Polyneuropathies

101.5.4.1 Metabolic Causes

Metabolic causes of neuropathy generally have an insidious onset. Hypoadrenocorticism and diabetes mellitus may cause rear limb paresis in addition to signs of metabolic disease. Dogs with Addison disease may manifest signs ranging from rear limb paresis to recumbency. Diabetic animals may have a plantigrade stance.

In both instances hyporeflexia may occur. Hypothyroid neuropathy is also described with generalized weakness, muscle atrophy, and hyporeflexia with or without diminished facial sensation, facial nerve paresis, laryngeal paralysis, megaesophagus, vestibular system dysfunction, and lameness.[12] Control of metabolic disease commonly results in resolution of neurologic dysfunction.

Serum glucose concentrations of less than 50 mg/dl due to insulin-secreting tumors may result in flaccid paresis or paralysis, hyporeflexia, lethargy, bradycardia, muscle tremors, hypothermia, and disorientation, with or without seizures. Small quantities of food high in protein, fat, and complex carbohydrates may be provided frequently. Diazoxide (10 mg/kg q12h) and prednisone (0.5 to 1.0 mg/kg q24h) may be given, and surgical tumor resection is often beneficial.

101.5.4.2 Malignant Peripheral Nerve Sheath Tumors and Round Cell Tumors

MPNSTs and round cell tumors are the most common tumors to involve peripheral nerves. Both tend to affect proximal motor nerves (near the spinal cord), but although MPNSTs affect adjacent nerves on one side of the spinal cord, round cell tumors may cause bilateral paresis or paralysis. MPNSTs more commonly affect spinal nerves to the thoracic limbs rather than those to the pelvic limbs. Both tumors are sometimes palpable and painful and can be diagnosed with MRI or CT and biopsy. MPNSTs are treated with radical resection of the nerves because a nonresected tumor has a tendency to regrow into and compress the spinal cord.[13] Round cell tumors are treated with radiation or chemotherapy.

101.5.4.3 Toxoplasmosis and Neosporosis

Puppies may manifest flaccid paralysis of the pelvic limbs that progresses to increased extensor tone of such a degree that the joints no longer bend. Signs of neuropathy and myopathy may occur, and retinitis may accompany these signs. Diagnosis is made by finding protozoa on muscle or nerve biopsy or by finding increased serum antibody titers. Trimethoprim-sulfadiazine (15 mg/kg PO or IV q12h for 2 weeks) and clindamycin (10 mg/kg PO or IV q12h for 8 weeks) may result in improvement of clinical signs; however, once hind limb rigidity has developed, improvement will not occur with therapy.[14]

101.5.4.4 Acute Polyneuritis and Polyradiculoneuritis

Affected dogs may have a history of exposure to raccoons, recent vaccination, or neither. Flaccid tetraparesis or paralysis and hyporeflexia develop within 1 to 3 days of the onset of signs. Facial muscle paresis and a change in bark are common. Respiratory paralysis may occur. Tail and neck motion, swallowing, and fecal and urinary continence are often maintained. The animal may be hyperaesthetic to touch. CSF analysis may show an increase in protein, and electromyography may show diffuse fibrillation potentials and positive sharp waves; nerve conduction velocity is slow, and CMAPs may be decreased in amplitude.[15] Biopsy of the nerve or nerve root may show inflammatory cell infiltrates, demyelination, and axonal loss. Titers for *Toxoplasma* and *Neospora* are recommended to rule out these causes of polyneuritis.[16]

Prednisone (1 mg/kg prednisone q12h for 1 to 2 weeks; then 1 mg/kg q24h for 1 month) may be given; however, there is controversy as to whether it has any effect on the progression of this disease. Aggressive supportive care is necessary to prevent and treat decubital ulcers and urinary tract infections. Close observation for respiratory muscle paresis is important. Partial or complete recovery may take 2 to 30 weeks and signs can recur.

101.5.4.5 Aortic Thromboembolism

Animals may have an inability to stand on the pelvic limbs or may have a short-strided, crouched gait with the animal sitting after only a few steps. Peripheral nerves are ischemic and anesthesia may accompany the paresis or paralysis. Limbs are painful and cool, pulses are weak or absent, and muscles are often firm. Abdominal ultrasonography may identify a thrombus in the aorta. Analgesics, intravenous fluids, heparin, vasodilators, and aspirin may be beneficial (see Chapters 117 and 188, Hypercoagulable States and Thrombolytic Agents, respectively). Thromboembolism has been associated with cardiomyopathy in cats and with protein-losing nephropathy in dogs.[17,18]

101.5.4.6 Intoxications

Drugs that may result in neuropathies include vincristine, thallium, and organophosphates. Animals usually manifest an insidious onset of clinical signs and history of drug administration or ingestion.

101.5.5 Localized Myopathies

101.5.5.1 Masticatory Myositis

Animals may have swelling over the head (acute), atrophy of the masticatory muscles (chronic), and trismus. Affected muscles of mastication (temporalis, masseter, pterygoid) may be painful on palpation and the mouth may be difficult to open. Masticatory myositis may be confirmed by muscle biopsy or serum titers for antibodies against type IIM muscle fibers. Treatment with prednisone (1 to 2 mg/kg q12h for 4 weeks and then tapering dosage over several months) results in a resolution of pain and improves mastication. Residual signs of disease including decreased range of motion of the jaw and significant atrophy are common.

101.5.5.2 Megaesophagus

Animals with megaesophagus can present with regurgitation, excessive salivation, and/or aspiration pneumonia (see Chapter 131, Vomiting and Regurgitation). Megaesophagus may occur with neuropathies (lead or organophosphate intoxication, dysautonomia), polymyopathies, and junctionopathies (myasthenia gravis, botulism), although clinical signs of disease elsewhere in the body commonly are found. Idiopathic megaesophagus may be congenital or acquired, and although disease of the vagus nerve is suspected, this has not been confirmed. A diagnosis of idiopathic megaesophagus is made by clinical and radiographic findings and by ruling out obstructive causes, toxic or infectious causes, endocrine disease, and myasthenia gravis. Small, frequent meals offered to an animal with the head and thorax elevated may help food reach the stomach. The smooth muscle prokinetic agents metoclopramide and cisapride have not been helpful in improving esophageal motility in dogs (likely due to the canine esophagus being primarily striated muscle). Reported use in the cat is lacking. Aspiration pneumonia is frequently recurrent and requires long-term management.

101.5.6 Diffuse Myopathies

Dogs and cats of any age may develop polymyositis, which is characterized by generalized weakness that worsens with exercise.[19] The gait is stiff and short-strided. Ventroflexion of the neck, dysphagia, regurgitation, megaesophagus, change in bark, painful appendicular muscles, fever, lethargy, and increases in creatine kinase, serum glutamic aspartate aminotransferase, lactate dehydrogenase, and antinuclear antibody may occur. Electromyography shows fibrillation potentials, positive sharp waves, and complex repetitive discharges in many muscles, and muscle biopsy shows lymphoplasmacytic inflammation and muscle necrosis. Toxoplasmosis and neosporosis should be ruled out with titers and muscle biopsy. 432 433

Prednisone may be given (1 mg/kg q12h initially) and reduced to the lowest dosage necessary to control signs. Pharyngeal and esophageal muscle involvement may result in aspiration pneumonia.

101.5.7 Junctionopathies

101.5.7.1 Botulism

Signs occur in dogs hours to days following ingestion of a toxin produced by *Clostridium botulinum*. The toxin interferes with the release of acetylcholine at the NMJ. A stiff and short-strided gait with muscle tremors (frequently first affecting the pelvic limbs) rapidly progresses to flaccid tetraplegia with diminished to absent spinal reflexes. A decreased ability to blink the eyelids, close the mouth, lift the upper lip, lap water with the tongue, or swallow occurs. Change in bark, mydriasis, regurgitation associated with megaesophagus, constipation, urinary retention, and respiratory paresis or paralysis may occur.

Diagnosis is made by identifying a history of exposure to spoiled meat and by finding other similarly affected animals. Toxin may be identified in food, serum, stomach contents, or feces early in the course of the disease. Supporting the patient may result in complete resolution of signs within 2 to 3 weeks. The patient should be monitored for aspiration pneumonia. A gastrostomy tube or parenteral nutrition may be necessary to provide nutritional support. If acute exposure occurs and signs are progressing, type C antitoxin may be administered.[20]

101.5.7.2 Tick Paralysis

Dogs may have a recent history of ataxia or paresis that may progress to recumbency within 24 to 72 hours. Signs are similar to those found with botulism, but spontaneous nystagmus may be seen and urinary and fecal continence frequently are maintained. A slow nerve conduction velocity may be found in addition to a decreased CMAP amplitude. Signs are due to an unidentified toxin believed to be present in tick saliva that interferes with the release of acetylcholine at the NMJ. In all dogs that develop a sudden onset of flaccid quadriparesis, a thorough examination for ticks should be performed that may include clipping of all hair, bathing the dog, and applying a topical tick treatment. Resolution of clinical signs occurs within 24 to 72 hours of tick removal.[21] Tick paralysis in Australia causes a more severe and prolonged course of disease.

101.5.7.3 Acquired Myasthenia Gravis

Acquired myasthenia gravis has been reported in cats and many breeds of dogs over 8 months of age, with the German Shepherd, Labrador Retriever, and Akita overrepresented. At least three clinical pictures may occur: (1) focal myasthenia gravis, (2) generalized myasthenia gravis, and (3) acute fulminating myasthenia gravis.[22]

Animals with the focal form show facial (decreased palpebral blink with normal sensation), pharyngeal (decreased gag reflex), or laryngeal (voice change, decreased arytenoid and vocal fold abduction, inspiratory stridor) dysfunction without appendicular muscle involvement. Megaesophagus may occur with or without aspiration pneumonia, and the animal may regurgitate within hours after eating. Frequently excessive salivation, dysphagia, change in bark, coughing, and retching are noted.

Generalized myasthenia gravis is characterized by appendicular muscle weakness, with or without signs of facial, pharyngeal, or laryngeal dysfunction. Strength may return following periods of rest, or the animal may show continuous weakness with the rear limbs often more severely affected. The animal has a stiff, short-strided gait, muscle tremors, and may walk “on the toes” of the rear limb. The head and neck may be held low and the dog may pant excessively. Postural reactions are usually normal if the animal is supported. Spinal reflexes and sensation are normal.

Acute, fulminating myasthenia gravis is the most severe form of the disease.[22,23] Signs include a sudden, rapid progression of severe appendicular muscle weakness, resulting in recumbency that is unabated by rest, frequent regurgitation associated with megaesophagus, and facial, pharyngeal, or laryngeal dysfunction. Respiratory dysfunction, thought to be due to aspiration pneumonia and loss of respiratory muscle strength, may be severe.

Definitive diagnosis of acquired myasthenia gravis may be made by identifying increased circulating acetylcholine receptor antibody in blood (>0.6 nm/L in dogs; >0.3 nm/L in cats). Antibodies are detectable in 80% to 90% of dogs with acquired disease. Intercostal muscle biopsy may also be used to identify acetylcholine receptor antibodies at the NMJ. If a more immediate diagnosis is necessary, edrophonium response testing may be performed.

Edrophonium (0.1 to 0.2 mg/kg IV) results in dramatic improvement in gait for 1 to 2 minutes in some animals with myasthenia gravis (anecdotal evidence suggests that improvement is rarely seen in cases of acute fulminating myasthenia gravis). Pretreatment with atropine (0.02 mg/kg IV) is recommended to decrease salivation, defection, urination, bronchial secretion, and bronchoconstriction that may occur following edrophonium administration. The animal may require oxygen and endotracheal intubation if severe dyspnea develops. Electrodiagnostic testing may also be performed. A 10% or greater decremental response of the fourth or fifth compound action potential recorded from the interosseous muscle following repetitive stimulation of the tibial or ulnar nerve at 3 Hz may be found.

Animals affected with generalized myasthenia gravis may be treated with oral pyridostigmine bromide (0.2 to 2 mg/kg q8-12h; IV infusions of 0.01 to 0.03 mg/kg/hr have also been used). Intramuscular neostigmine bromide or methylsulfate (0.04 mg/kg q6-8h) may be given to animals with significant dysphagia and regurgitation. A low dosage is begun and titrated upward over 2 to 3 days until clinical signs resolve or signs of overdose occur (bradycardia, diarrhea, salivation, dyspnea, miosis, and recurrence of weakness). When these signs occur, the dosage is decreased until they are no longer present. The animals should be kept warm and exercise limited. Although appendicular muscle weakness frequently resolves with this care, pharyngeal, laryngeal, and esophageal dysfunction may continue for weeks. 433

434 In animals with focal and generalized myasthenia gravis in whom dysphagia and megaesophagus are marked, pyridostigmine or neostigmine is given; however, management of these patients must include feeding the animal from a raised height and keeping the head elevated for 10 minutes afterward to facilitate passage of food into the stomach. Frequently a gastrostomy tube is necessary to provide nutritional support until dysphagia and regurgitation resolve. Frequent auscultation and radiographs of the thorax are recommended to determine whether aspiration pneumonia is present. If so, a transtracheal wash is performed and broad-spectrum antibiotics are given (see Chapter 23, Aspiration Pneumonitis and Pneumonia). Aminoglycoside antibiotics should be avoided (see Aminoglycoside Intoxication later in this chapter).

Treatment of acquired myasthenia gravis with prednisone is controversial because it may result in a rapid worsening of clinical signs in affected humans. In addition, the immunosuppressive effects of steroid therapy may lead to rapid respiratory deterioration in patients with aspiration pneumonia. Anecdotally, the addition of prednisone to neostigmine improves pharyngeal dysfunction sooner than cholinesterase inhibitors alone. A starting dosage of 0.5 mg/kg/day increased to 2 mg/kg q24h over 1 week has been suggested. Prednisone should be started only in the hospital, where the animal can be monitored for sudden deterioration and for aspiration pneumonia. Additionally, treatment with azathioprine (2 mg/kg PO q12-24h, decrease dosage after 3 to 6 months) and mycophenolate mofetil (10 to 20 mg/kg PO or IV q12h) has proven useful and may minimize side effects of steroid administration.[24,25]

The acquired disease is usually a temporary state and may resolve over many months of supportive care. The most common cause of death or euthanasia is aspiration and pneumonia. In nine cases of acute, fulminating myasthenia gravis reported in the literature, eight died or were euthanized because of respiratory failure and aspiration despite anticholinesterase inhibitor therapy in some cases.[22,23] Plasmapheresis and intravenous γ-globulins may, in the future, prove useful in treating acute, fulminating disease.

In approximately 15% of dogs with acquired myasthenia gravis, the disease is related to a thymoma. In these cases, thymectomy may resolve clinical signs. Other inciting causes include osteogenic sarcoma, biliary carcinoma, and reaction to exogenous antigens. One paper describes an association between hypothyroidism and myasthenia gravis in dogs and suggests that testing for hypothyroidism be performed in cases of the latter. Thyroid supplementation should be instituted if necessary.[26]

101.5.7.4 Aminoglycoside Intoxication

Animals may have a history of recent parenteral aminoglycoside exposure. Affected animals are tetraparetic and clinical signs generally resolve following discontinuation of aminoglycosides. It is important to note that clinical signs due to many of the diseases listed in this chapter may worsen following therapy with aminoglycosides.

102 Chapter 102 Tetanus

Simon R. Platt, BVM&S, DACVIM (Neurology), DECVN, MRCVS

102.1 KEY POINTS

- Tetanus is the result of a bacterial infection by *Clostridium tetani* following a skin wound, surgery, or even parturition.
- The clinical signs are due to the effects of an exotoxin produced by the bacillus that prevents neurotransmitter release.
- Common signs include spasms of the masticatory, pharyngeal, and facial muscles, but the whole body can be involved.
- Definitive diagnosis is difficult in many cases unless serum antibodies can be associated with the bacterial toxin.
- Treatment is initiated immediately on suspicion of the disease based on clinical signs.
- Tetanus antitoxin can prevent further deterioration of the patient from unbound toxin at time of treatment, but improvement relies on regrowth of axons and nerve terminals.
- Broad-spectrum anaerobic antibiotics, wound cleansing, muscle relaxants, and sedatives are the important constituents of medical management.
- A quiet environment and intensive nursing care are essential for the success of treatment regimens.

102.2 ETIOLOGY

Tetanus is caused by the neurotoxins released by *Clostridium tetani,* a motile, gram-positive, nonencapsulated, anaerobic, spore-forming bacterium. The toxin is produced during vegetative growth of the organism in a suitable environment.[1] The deoxyribonucleic acid for this toxin is contained in a plasmid and is antigenically homogenous. The organism's resistant spores are ubiquitous, with a natural habitat in moist fertile soil; however, they can survive indefinitely in dusty indoor environments. Resistance of the spores has been proven to boiling water and an autoclave temperature of 120°C for up to 20 minutes.[2] However, the vegetative phase of this bacterium is susceptible to chemical and physical inactivation. Organisms can be isolated from the feces of dogs, cats, and humans, but presence of the organism does not indicate infection because not all strains possess the plasmid.[1]

Cats and dogs are considered to be relatively resistant to infection by the bacterium, especially when compared with horses and humans. In part the resistance in these species is due to the inability of the toxin to penetrate and bind to nervous tissue.[2]

102.3 PATHOGENESIS

Tetanus develops when spores are introduced into wounds or penetrating injuries. Most cases develop after skin wounds, but infection can follow parturition or ovariohysterectomy.[3-5]

Under anaerobic conditions found in necrotic or infected tissue, the tetanus bacillus secretes two exotoxins: tetanospasmin and tetanolysin. Tetanolysin is capable of locally damaging otherwise viable tissue surrounding the infection and optimizing the conditions for bacterial multiplication.[1]

Tetanospasmin leads to the clinical syndrome of tetanus. This toxin may constitute more than 5% of the weight of the organism.[1] It is a two-chain polypeptide of 150,000 daltons that is initially inactive, made up of a light and a heavy chain. The light chain acts presynpatically to prevent neurotransmitter release from affected neurons. Tetanospasmin binds to the membranes of the local motor nerve terminals. If toxin load is high, some may enter the bloodstream from where it diffuses to bind to nerve terminals throughout the body, and may even enter the central nervous system (CNS) through an intact blood-brain barrier. The toxin is then internalized and transported intraaxonally and in a retrograde fashion to the cell body at a speed of 75 to 250 mm per day.[1,2] Transport occurs first in motor and later in sensory and autonomic nerves. Further retrograde intraneural transport occurs with toxin spreading to the brain stem in a bilateral fashion, up the spinal cord. This passage includes retrograde transfer across synaptic clefts by a mechanism that is unclear.

It is after internalization in inhibitory neurons that the light chain becomes activated; at this stage the toxin is no longer accessible for neutralization by antitoxin.[6,7] It prevents neurotransmitter release by cleaving and inactivating synaptobrevin, a membrane or “docking” protein necessary for the export of intracellular vesicles containing the neurotransmitter.[8] In addition to disrupting docking proteins, the toxin may lead to cross-linking of synaptic vesicles to the cytoskeleton, further preventing neurotransmitter release.[9]

The toxin predominantly affects inhibitory interneurons, inhibiting release of glycine and γ-aminobutyric acid (GABA).[1,7] Interneurons inhibiting α-motor neurons are first affected, and the motor neurons lose inhibitory control. The disinhibitory effect on the motor neuron may cause diminution of function at the neuromuscular junction, so the clinical effect is dissimilar to that of the related botulinum toxin. Medullary and hypothalamic centers may also be affected. Disinhibited autonomic discharge leads to disturbances in autonomic control, with sympathetic overactivity and excessive plasma catecholamine levels.

Neuronal binding of toxin is thought to be irreversible. Recovery requires the growth of new nerve terminals, which explains the long duration of tetanus.[10]

102.4 CLINICAL PRESENTATION

Clinical signs can take up to 3 weeks from the onset of infection to be apparent, although most cases exhibit

symptoms within 5 to 12 days.[11] The clinical signs initially can be localized or generalized, with the former possibly being more common in dogs and cats. A study of 38 dogs with tetanus revealed that ocular and facial changes were the most common initial signs. Localized signs begin proximal to the site of introduction of the infection and can include single muscle rigidity, entire limb rigidity, and facial muscle spasms. The clinical signs may progress with more extensive muscle involvement.[12] Generalized signs include a stiff gait affecting all limbs, increased muscle tone, dyspnea, an elevated tail and a “sawhorse stance,” although the animal may become uncomfortable standing with such excessive muscle activity. At least 50% of dogs will progress within a median of 4 days (range 0 to 14 days) to recumbency with severe muscle spasms.

Involvement of the head can lead to spasms of the masticatory and pharyngeal muscles, causing trismus (lockjaw) and dysphagia. This can be functionally exacerbated by increased salivation, increased bronchial secretions, and increased respiratory rate resulting from involvement of the parasympathetic and somatic cranial nerve nuclei. Regurgitation and gastroesophageal reflux can result rarely from esophageal hiatal hernia and megaesophagus, which may lead to aspiration pneumonia when combined with the problems described earlier.[13] Excessive contraction of the facial muscles causes erect ears and a wrinkled forehead (Color Plate 102-1), and gives the animal a characteristic sneering of the lips known as *risus sardonicus,* or the *sardonic grin* (Color Plate 102-2).[7] Additionally, the patient can exhibit protrusion of the third eyelid and enophthalmos, resulting from retraction of the globe from hypertonus of the extraocular muscles.[12] Reflex muscle spasms can occur in animals with generalized tetanus or intracranial involvement; these may be painful and resemble seizure activity, affecting agonist and antagonist muscle groups together.[12] Severe progression of signs can cause recumbency, opisthotonus, seizure-like activity, respiratory paralysis, and central respiratory arrest, potentially causing death if not rapidly recognized and managed.[7] Death was reported in 18% of dogs (7 of 38) in one retrospective study, and 6 of these dogs demonstrated concurrent autonomic signs.

It is possible to see an effect on the autonomic system evidenced by episodes of bradycardia and tachycardia, hypertension, marked vasoconstriction, and pyrexia.[12,14,15] A study of 38 dogs with tetanus revealed that 37% demonstrated abnormalities of blood pressure or rectal temperature, or both, consistent with autonomic disturbance. In the mild generalized cases, autonomic involvement may be manifested by dysuria and urinary retention, constipation, and gaseous distention. In humans, “autonomic storms” occur, causing marked cardiovascular instability, severe hypertension alternating with profound hypotension, and even recurrent cardiac arrest.[1] During these “storms,” plasma catecholamine levels are raised up to 10-fold, similar to levels seen in animals with a pheochromocytoma.[1]

A neurologic examination of these patients can reveal normal initiation of a response to postural reaction testing but a stiff and reduced motor response.[2] Myotatic reflexes are generally accentuated and flexor reflexes depressed, but both may be difficult to assess because of the extreme rigidity of the limbs. Although a complete neurologic examination is always ideal, it should be emphasized that animals can become very sensitive to tactile, visual, or auditory stimulation that can exacerbate clinical signs, occasionally causing a mild, generalized form of the disease to progress to a crisis situation.

102.5 DIAGNOSIS

The patient history and clinical signs are usually sufficient to make a presumptive diagnosis of tetanus. If general anesthesia is used for diagnostic tests such as cerebrospinal fluid acquisition, the muscle spasms can be reduced but rarely are abolished. Intubation may be difficult in patients with trismus, and a stylet-assisted intubation should be anticipated in severely affected animals (see Supportive Intensive Care).

A complete blood count may suggest an infectious process from a wound, whereas serum biochemistry (with the exception of muscle enzymes) and cerebrospinal fluid analysis findings are normal.[12] Muscle enzymes may be elevated in patients with tetanus because of the persistent muscle spasticity. Radiographs may be helpful to identify involvement of the esophagus, diaphragm, and secondary changes in the lungs resulting from aspiration pneumonia.

Electrodiagnostic abnormalities of tetanus are nonspecific and consist of prolonged electric discharges following needle insertion on electromyography; nerve conduction velocities are normal.[11]

Measurement of serum antibodies to tetanospasmin can be performed by some laboratories and may be used for a definitive diagnosis.[7] Values need to be compared with those of control animals.

Attempts to isolate *C. tetani* from wounds often fails because of the low concentration of organisms and the requirement for strict anaerobic culture conditions at 37°C for at least 2 weeks.[7] Performing a Gram stain on a smear from an open wound may identify gram-positive rods and dark-staining spheric endospores, but the morphology of the bacterium is similar to that of many other bacteria.[12]

102.6 TREATMENT

Treatment strategies involve three principles: organisms present in the body should be destroyed to prevent further toxin release; toxin present in the body outside of the CNS should be neutralized; and the effects of the toxin already in the CNS should be minimized.

102.6.1 Neutralization of Unbound Toxin

Antitoxin neutralizes any toxin that is unbound to the CNS or is yet to be formed. Therefore the timing of administration in relation to the onset of the disease is essential to its efficacy. The antitoxin used can be either antitetanus equine serum or human tetanus immune globulin. The latter may be more likely to produce reactions if given intravenously.[16] Early intervention has been recommended as a matter of routine, but there are no studies objectively evaluating antitoxin use in dogs or cats, and its efficacy in cases with no evidence of a recent wound is unknown.

The recommended dosage of equine antitoxin for dogs and cats is 100 to 1000 U/kg (maximum 20,000) IV, SC, or IM.[2] Intravenous administration is preferred to intramuscular or subcutaneous administration. However, intravenous use of antitoxin is associated with a high incidence of anaphylaxis.[2] To reduce this risk, a test dose (0.1 to 0.2 ml of 1:10.000 solution) should be administered intradermally 15 to 30 minutes before the intravenous dose.[2] A wheal at the site of injection may indicate that an anaphylactic reaction will develop. Epinephrine (0.1 ml/kg IV of the 1:10,000 dilution), glucocorticoids, and an antihistamine should be readily available in case of an adverse reaction (or even given on a prophylactic basis). Repeated doses of antitoxin are more likely to cause adverse reactions and are not recommended or necessary because therapeutic levels persist for approximately 14 days.

436

437

Intramuscular injection at and proximal to the wound site (1000 U) may be helpful in localized forms of tetanus.[2] Although intrathecal administration of antitoxin has not been proven to be effective,[16] experimental studies have suggested that it may be of use in dogs, reducing both the morbidity and mortality in affected patients.[2] It is considered potentially advantageous, because it need not penetrate the blood-brain barrier when given intrathecally and may partially neutralize bound toxin.[2] However, because of the lack of thorough clinical evaluation and risks associated with administration, the intrathecal route should be reserved for severely affected cases.

102.6.2 Removal of Source of Infection

Any obvious wounds should be radically debrided after the administration of antitoxin. Flushing the wound with hydrogen peroxide increases oxygen tension, which inhibits anaerobic organisms, although wound healing may also be impaired[2] (see Chapter 157, Wound Management).

Antibiotics are essential to kill vegetative *C. tetani* organisms and thereby reduce the amount of circulating toxin. Although local administration of antibiotics at a wound site has been advised, parenteral administration is recommended more routinely.[2] Classically, penicillin G has been the management of choice, either intravenously as an aqueous potassium or sodium salt or intramuscularly as the procaine salt (20,000 to 100,000 U/kg q6-12h for 10 days in both cats and dogs). However, metronidazole (10 mg/kg PO or IV q8h for 10 days) has been shown to be superior to penicillin G in clinical tetanus because it achieves bactericidal therapeutic concentrations in anaerobic tissues.[2] Other options include clindamycin (10 mg/kg PO, IV, or IM q8-12h) and tetracycline (22 mg/kg PO or IV q8h).[2]

102.6.3 Control of Rigidity and Spasms

See Anesthesia and Pain Management section and Chapter 184, Narcotic Agonists and Antagonists, for more details on specific therapies.

Prevention of unnecessary stimulation is mandatory, but the mainstay of treatment is sedation with a benzodiazepine. Benzodiazepines augment GABA agonism at the $GABA_{\alpha}$ receptor. Diazepam (0.5 to 1 mg/kg PO q8h in dogs [maximum 10 mg], 0.25 to 0.5 mg/kg in cats [maximum 5 mg], or a continuous intravenous infusion of 0.1 to 1 mg/kg/hr in dogs and cats) or clorazepate (0.5 to 1 mg/kg PO q8h in dogs; 0.2 to 0.5 mg/kg PO q12-24h in cats) can be used in this regard, although both may cause oversedation in some patients.

Additional sedation can be provided by anticonvulsants, particularly phenobarbital (1 to 4 mg/kg PO or IV q12h or IM q6h), which further enhances GABAergic activity. Phenothiazines appear to be highly effective in controlling the hyperexcitable state; chlorpromazine (0.5 to 2 mg/kg IM, IV, or PO q6-12h) is the drug of choice, although acetylpromazine (0.005 to 0.05 mg/kg IV q2h as needed [maximum 3 mg in any dog]) is a useful substitute.

With severe signs such as generalized tonic-clonic seizure activity, generalized body stiffness, and opisthotonus, barbiturate or propofol infusions may be necessary, but cardiovascular parameters should be monitored closely and careful consideration should be given as to whether the patient should be intubated and placed on positive-pressure ventilation. Sedation with propofol has been shown to assist with muscle spasm and rigidity control in humans, without the use of neuromuscular blocking drugs.[17] Neuromuscular blocking agents may be an option for the most severely affected veterinary patients, but assisted ventilation is imperative.

Narcotics and parasympatholytics such as atropine should be used with caution. In severe human forms of tetanus, atropine infusions have helped to control autonomic dysfunction.[18]

102.6.4 Supportive Intensive Care

Intensive nursing care is essential for successful treatment of patients with tetanus. The dog or cat should be isolated in a dark and quiet environment, with cotton wool balls placed in the external ear canals (Color Plate

102-3). Minimal handling is optimal, and all treatments should therefore be coordinated to occur together at set times through the day. A recent study of 10 dogs with tetanus documented the complications that occurred in these dogs during treatment; these included aspiration pneumonia, upper respiratory tract obstruction requiring tracheostomy, and coxofemoral luxation.[i]

Weight loss and dehydration are common in patients with tetanus resulting from poor prehending, mastication, and swallowing capabilities, reduced gastrointestinal function in the presence of autonomic dysfunction, increased metabolic rate, and hyperthermia from the muscular activity and prolonged critical illness. Nutrition and fluid therapy should therefore be established as early as possible. Enteral nutrition may be associated with a lower incidence of complications and is cheaper than parenteral nutrition, but the latter may be necessary in select cases. The risk of vomiting and subsequent aspiration pneumonia must be considered when making this decision (see Chapters 13 and 14, Enteral Nutrition and Parenteral Nutrition, respectively).

Percutaneous gastrostomy may prevent the complications associated with nasogastric tube feeding, particularly the stress that may be associated with an indwelling intranasal tube. Gastrostomy- or gastrojejunostomy-assisted feeding can also reduce the risk of aspiration pneumonia, a potential complication in dogs with severe forms of tetanus and those that are recumbent for a prolonged period.

If airway constriction due to laryngeal spasms, a buildup of saliva or tracheal secretions, or the need for artificial ventilation are concerns, tracheostomy usually is performed after intubation (see Chapter 18, Tracheostomy). A stylet may be inserted into the airway and the endotracheal tube fed over the stylet for intubation of dogs with severe laryngospasm. A tracheostomy requires meticulous care to prevent introduction of infection, but it will allow intermittent tracheal suction to be performed with little stress to the animal. Oxygen supplementation may be administered via tracheostomy flow-by, intratracheally, or with mechanical ventilation.

Urinary and fecal retention occur in some patients with hypertonic anal and urinary sphincters. An indwelling urinary catheter may be beneficial in these patients, although the urine should be analyzed regularly for evidence of infection.

Pressure sores or decubital ulcers should be prevented with appropriate soft or padded bedding and frequent turning and physiotherapy. However, the balance between frequent physiotherapy and isolated rest is difficult to achieve, and pharmacologic sedation may be necessary before physical manipulation is possible in some patients.

102.7 PROGNOSIS

Most patients that recover will show some improvement within 7 days, unless autonomic abnormalities are noted, which are poor prognostic indicators. Median length of hospitalization has been reported to be 13 days (range 6 to 42 days). One study estimated the mortality rate to be approximately 18% in affected dogs. Dogs with surgical wounds manifest a more severe clinical course than those with external wounds, and young dogs are also more likely to develop more severe treatment. There is no documented association between earlier wound treatment, antibiotic administration, or antitoxin administration and either progression of signs or survival. A prospective trial will be necessary in the future to further investigate the value of these therapeutic options. A full recovery may not be possible in at least 15% of dogs that survive, but continued improvement may be seen for 3 to 5 months.[11]

103 Chapter 103 Hepatic Encephalopathy

David Holt, BVSc, DACVS

103.1 KEY POINTS

- Hepatic encephalopathy (HE) is associated with moderate to severe liver insufficiency and may be secondary to a portosystemic shunt(s), end-stage liver disease, or congenital urea cycle enzyme deficiencies.
- The pathophysiology of HE is complex and incompletely understood; however, the importance of elevated levels of ammonia have been reemphasized.
- Symptoms may include depression, dementia, stupor, coma, muscle tremors, motor abnormalities, excessive salivation, and focal or generalized seizures.
- Medical management includes strategies to minimize ammonia absorption from the intestine and control seizure activity, if present.
- Definitive therapy involves correcting underlying causes, such as surgical management of a portosystemic shunt.

103.2 INTRODUCTION

HE comprises a spectrum of neurologic abnormalities associated with moderate to severe liver insufficiency. In dogs and cats, it occurs most commonly with portosystemic shunting of blood. Fulminant hepatic failure is an important cause of HE in humans but is seen less commonly in veterinary medicine. Congenital urea cycle enzyme deficiencies may also lead to HE.

103.3 CAUSES

In dogs and cats, congenital extrahepatic or intrahepatic portal-to-systemic venous communications are the most frequent cause of HE; up to 95% of affected animals demonstrate neurologic symptoms.[1] These communications are generally a single vessel, but multiple extrahepatic[2] and intrahepatic[3] congenital portosystemic shunts have been reported. Hepatic arteriovenous malformations cause portal hypertension, multiple extrahepatic portosystemic shunts, and ascites, and may cause symptoms of HE. In young dogs, hepatic microvascular dysplasia[4] and, rarely, congenital urea cycle deficiencies[5] can also cause symptoms of HE. In older animals, portosystemic shunts develop secondary to portal hypertension that results from chronic liver disease. In cats, hepatic lipidosis often is associated with symptoms of HE. Other causes of chronic and acute hepatic failure that can result in symptoms of HE are discussed in Chapter 127, Hepatic Failure.

103.4 PATHOPHYSIOLOGY

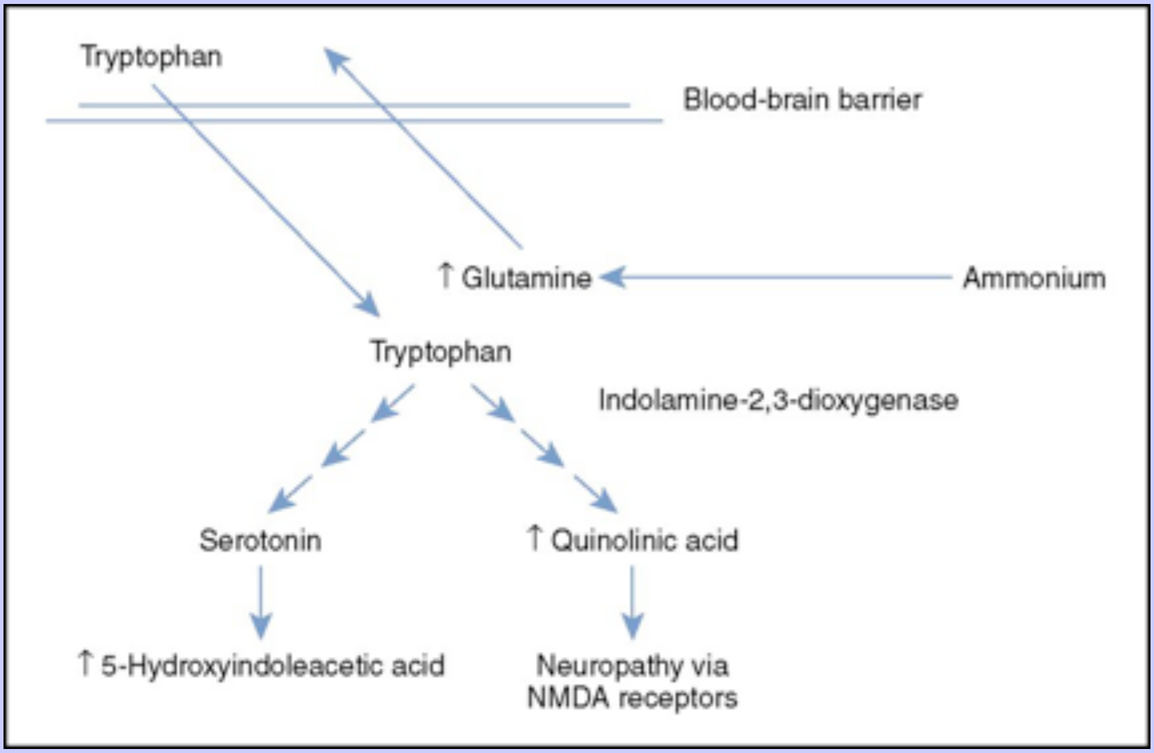
In 1893, Marcel Nencki and Ivan Pavlov described the physiologic consequences of a surgically created, end-to-side portocaval shunt (Eck fistula) and showed that clinical signs in this canine model worsened after a meat meal, linking HE to the concept of "meat intoxication."[6] Ever since this description, HE has been thought of as a condition caused by gut-derived toxins that are not metabolized by a diseased or failing liver. Research over the last century has elaborated on this concept and demonstrated the complexity of this condition. However, recent work on several aspects of HE including cerebrospinal fluid amino acid alterations,[7,8] glutamate neurotoxicity,[9] the generation of reactive oxygen species,[10] and the mitochondrial permeability transition[11] emphasizes the central role of elevated blood ammonia concentrations in animals with HE. Other substances that are considered synergistic with ammonia toxicity include mercaptans, free fatty acids, phenols, and bile salts[12] (see Chapter 127, Hepatic Failure, Table 127-2 for a summary of toxins implicated in HE).

Ammonia is produced in the intestinal tract as the end product of amino acid, purine, and amine breakdown by bacteria, the metabolism of glutamine by enterocytes, and the breakdown of urea by bacterial urease.[13] It is then absorbed into the portal blood and rapidly converted to urea or glutamine in the normal liver. In animals with portosystemic shunting of blood or significant liver disease, high levels of ammonia are present in the systemic circulation. The permeability of the blood-brain barrier to ammonia increases in animals with HE, and experimental studies suggest that HE coma is associated with brain ammonia concentrations in the low millimolar range.[14] These concentrations of ammonia decrease excitatory neurotransmission, in part by down-regulating the N-methyl-D-aspartate (excitatory) receptors,[9] yet at the same time block chloride extrusion from the postsynaptic neuron, decreasing inhibitory neurotransmission.[15]

The brain has no urea cycle; consequently, ammonia in the central nervous system (CNS) is removed by transamination of glutamate into glutamine in astrocytes.[16] Glutamine concentrations in the cerebrospinal fluid are elevated in dogs with HE[8] and often are an accurate indicator of the degree of neurologic dysfunction in humans with HE.[9] Glutamine is exchanged across the blood-brain barrier for tryptophan, leading to increased levels of tryptophan and tryptophan metabolites in the CNS (Figure 103-1).[7] The tryptophan metabolites serotonin and quinolinate are important agonists of inhibitory and excitatory neurotransmission, respectively, although the exact alterations in both of these systems in patients with HE are complex and incompletely understood. Glutamine is also transported from astrocytes into neurons, where it is converted to glutamate.[17] Overstimulation of the N-methyl-D-aspartate receptors by both glutamate and ammonia can cause seizures and neurotoxicity, in part as a result of free radical formation.

γ-Aminobutyric acid (GABA) is the most important inhibitory neurotransmitter in the CNS, and alterations of GABA neurotransmission have been proposed as an important component of HE. In spite of several different observations implicating “increased GABAergic tone” in HE, studies have excluded the possibility of increased amounts of GABA in the CNS and changes in the number of GABA receptors or affinity of the receptor for its ligands in patients with HE.[18] It is likely that if increased GABA neurotransmission exists in animals with HE, it is due to increased brain concentrations of endogenous GABA ligands, including endogenous benzodiazepines and neurosteroids. Increased levels of endogenous benzodiazepine receptor ligands have been found in the portal blood and systemic circulation of some dogs with portosystemic shunts.[19] Elevated levels of ammonia and manganese (also seen in liver disease) increase expression of the peripheral-type benzodiazepine receptor, a heterooligomeric protein complex on the outer mitochondrial membrane of astrocytes. Activation of the peripheral-type benzodiazepine receptor increases mitochondrial cholesterol uptake and the synthesis of neurosteroids that may then act on GABA receptors.[20]

Figure 103-1 Diagram of the proposed effect of ammonia on tryptophan metabolism. Ammonia is metabolized to glutamine, which shares an antiport transport mechanism across the blood-brain barrier with tryptophan. An increase in tryptophan transport leads to an increased flux through the serotonin and quinolinic acid pathways.



There is also evidence that amino acid imbalances play a role in patients with HE. Dogs with portocaval shunts have a decreased ratio of branched chain (valine, leucine, isoleucine) to aromatic (phenylalanine, tyrosine, tryptophan) amino acids.[21] Because these classes of amino acids compete for transport across the blood-brain barrier, the increased relative concentration of the aromatic amino acids means that they will be preferentially transported. This leads to an increased synthesis of false neurotransmitters and a reduction in the synthesis of dopamine and norepinephrine. Coma was induced in normal dogs infused with the aromatic amino acids tryptophan and phenylalanine; addition of the branched chain amino acids to the infusion prevented coma.[22]

103.5 CLINICAL SIGNS

The clinical signs associated with HE are often subtle and episodic initially. A new puppy may be mildly lethargic or depressed and first-time owners may not recognize this as abnormal behavior. Other clinical signs may include disorientation, personality change, stupor, pacing, head pressing, "star gazing," amaurotic blindness, coma, and occasionally seizures. In general, signs of CNS depression predominate over signs associated with hyperexcitability. In cats, ptyalism is common, and is often the only clinical sign associated with HE. In dogs, polydipsia and polyuria are also common clinical findings, presumed secondary to hypercortisolemia and the subsequent partial inhibition of vasopressin's action on the renal tubules.[23] Clinical signs of gastrointestinal (GI) (vomiting, anorexia) and urinary tract (stranguria and hematuria secondary to ammonium biurate calculi) disease can also occur in animals with portosystemic shunting of blood. Although these signs are not unique to HE per se, it is important that they alert the veterinarian to investigate the possibility of moderate to severe liver disease.

Clinical signs HE can be precipitated or worsened by the ingestion of a high-protein meal, GI bleeding, systemic infection, and several medications, including narcotics and other anesthetic agents. Other precipitating factors include electrolyte imbalances (hyponatremia, hypokalemia), hypoglycemia, acidosis or alkalosis, and constipation.

103.6 DIAGNOSIS

The diagnosis of HE is made when an animal has clinical signs compatible with the condition and alterations on a biochemical panel and liver function tests confirming moderate to severe liver disease (see Chapter 127, Hepatic Failure). At the same time, none of the clinical signs described are specific for HE and other potential diagnoses, including other metabolic disorders, toxin or drug ingestion, and intracranial lesions, should be excluded. Routine laboratory analysis (complete blood count, biochemical profile, urinalysis) and liver function testing are often indicated. Possible liver function tests include preprandial and postprandial serum ammonia or bile acid levels, ammonia tolerance test (may potentiate seizure activity and therefore us contraindicated in patients with HE), and sulfobromophthalein dye retention test. It is important to note that samples for blood ammonia concentrations are useful only if processed immediately. Canine samples for blood ammonia determination that are stored frozen for any length of time give erroneous results.[24] Additional diagnostic testing that might be necessary include rectal portal scintigraphy and liver histopathology.

103.7 TREATMENT

See Chapter 127, Hepatic Failure, Table 127-3 for a summary of treatments.

Animals that have or develop focal or generalized seizures will require immediate intervention to stop them (see Chapters 98 and 186, Seizures and Status Epilepticus and Anticonvulsants, respectively). The use of diazepam (Valium) is controversial because of the possibility of endogenous benzodiazepine agents (see Pathophysiology earlier in this chapter). The dosage is typically 0.5 mg/kg IV. Alternatively, the seizure activity may be managed with propofol (0.5 to 1 mg kg IV bolus, then 0.05 to 0.1 mg/kg/min constant rate infusion). Mannitol therapy may also prove beneficial if cerebral edema is present (0.5 to 1 g/kg IV over 30 minutes). Potassium bromide can be administered in an attempt to prevent further seizure activity by loading the animal initially with 400 to 600 mg/kg q24h divided into 4 doses on day 1, then maintenance therapy at 40 mg/kg q24h PO or rectally. Sodium bromide has been suggested as a parenteral antiepileptic formulation in dogs and cats, although there are few data to support its clinical use. The drug is generally administered at 15% of the potassium bromide dosage, including the loading dose on day 1. Phenobarbital may also be used as a parenteral antiepileptic, and a loading dose is typically given on day 1 at 16 mg/kg IV divided into 4 doses, followed by 2 to 4 mg/kg IV q12h thereafter. Both the bromide drugs and phenobarbital may lead to excessive sedation, and close monitoring is therefore essential.

In animals with hepatic coma or seizures, any predisposing factor should be treated. For example, in the case of benzodiazepine sedation, flumazenil (0.02 mg/kg IV) is administered. Intubation of comatose animals or those recovering from seizure activity may be necessary to protect the airway from aspiration and to maintain ventilation. IV fluids are often necessary, but the animal's serum albumin, glucose, electrolyte, and acid-base status should be evaluated carefully before and during administration. Affected animals are often hypoproteinemic and hypoglycemic; alkalosis increases ammonia diffusion into the CNS and hypokalemia stimulates renal ammonia production. Colloid administration (synthetic or fresh frozen plasma) and potassium and glucose supplementation are often necessary. Should a transfusion be necessary, fresh whole blood or packed red blood cells are used, because storage of red blood cell products increases the ammonia concentration.[25] A lactulose enema is administered to prevent ammonia production in, and absorption from, the colon. Lactulose (β-galactosidofructose) is a nonabsorbable disaccharide that exerts an osmotic cathartic action. In addition, intestinal bacteria hydrolyze lactulose-producing organic acids that lower colonic pH. Acidification traps ammonia in its NH_4^+ form, preventing absorption by nonionic diffusion, and also results in the net movement of ammonia from the blood into the bowel lumen.

Fulminant hepatic failure is uncommon in animals but may be fatal. Death in humans with fulminant hepatic failure is often associated with cerebral edema, hemorrhage, and sepsis. Therapy is similar to that described for hepatic coma and seizures. Assisted ventilation is used to prevent hypoventilation and minimize changes in intracranial pressure. Twenty-five percent mannitol (0.5 to 1 g/kg IV) is administered to minimize cerebral edema. Glucose is supplemented as necessary. Animals with fulminant hepatic failure may be coagulopathic, and fresh frozen plasma (10 to 20 ml/kg IV) is administered to supplement coagulation factors, if needed. Bacterial cultures (blood, urine) are obtained and broad-spectrum antibiotics are administered in animals with suspected bacterial sepsis (see Chapter 106, Sepsis). 440 441

General treatment goals for stable animals with HE or those that have been stabilized after treatment for emergent conditions include reducing ammonia levels, decreasing GABA, and lowering endogenous benzodiazepines. Clinical signs of HE can typically be treated with diet modification, oral administration of lactulose, and antibiotic therapy. The diet should be moderately protein restricted (14% to 17% protein on a dry matter basis in dogs; 30% to 35% protein in cats) and high in carbohydrates. The protein should be of high quality and have a high level of branched chain amino acids. The diet should be a low-residue, easily digestible food to minimize the amount of material reaching the colon. It must contain adequate amounts of arginine for cats, because this is an essential amino acid that is necessary for the urea cycle.

Lactulose is an osmotic cathartic that increases transit time through the GI tract, thereby decreasing the availability of glutamine sources (ingested and endogenous) for metabolism. The pH of the intestinal contents is also reduced, which decreases the numbers of urease-producing colonic bacteria and traps ammonia within the GI tract as ammonium ions. Lactulose (1 to 3 ml/10 kg q6-8h) is administered orally or rectally (diluted to 30% with warm water and retained for 30 minutes), and the dosage rate and interval are titrated to produce two to four moderately soft stools daily.

Antibiotics are administered to decrease numbers of urease-producing bacteria in the intestines. Neomycin sulfate (20 mg/kg PO q6-8h) is generally considered nonabsorbable, but it should be avoided in animals with concurrent renal disease. Metronidazole (10 to 20 mg/kg PO or IV q12h) is a reasonable alternative, but neurotoxicity may occur more commonly in animals with hepatic disease. Rifaximin is a commonly used antibiotic for the treatment of HE in humans, but its use in small animals is limited at this time. The effect of long-term antibiotic therapy on the intestinal flora of dogs and cats is not clear. Because the therapeutic effect of lactulose depends on its metabolism by colonic bacteria, the benefit of combined lactulose and antibiotic therapy is open to question in small animals. Although the two treatments often are considered synergistic, oral neomycin inhibits lactulose metabolism in 25% to 30% of human patients.

Enemas have also been used to decrease the colonic bacterial numbers and substrates. The following types of enemas have been recommended:

- Warm water enemas at 10 ml/kg q4-6h until signs improve
- Lactulose enemas at 5 to 15 ml diluted 1:3 with warm water and administered q6-8h
- Neomycin enemas at 15 to 20 ml of 1% solution q8-12h
- Metronidazole enemas at 7.5 mg/kg (systemic dose) mixed with water q12h
- Povidone-iodine (Betadine) enemas given by diluting 1:10 with warm water and giving 10 ml/kg q8h and flushing out with warm water after 10 to 15 minutes
- Activated charcoal enemas using the liquid suspension q8h (can be administered and retained in crisis)
- Vinegar enemas made by diluting the vinegar 1:4 with warm water and administering at 10 ml/kg q8h

Other therapies that have been studied in humans but not companion animals include ornithine aspartate, intestinal repopulation with lactose fermenting, non–urease-containing bacteria, zinc supplementation, branched chain amino acid solutions, and flumazenil and levodopa administration.[26] Inhibitors of the glutamine synthetase enzyme and serotonin receptor antagonists have been associated with a high rate of side effects and are not used for treatment of clinical HE in humans.

In cases of HE secondary to portosystemic shunting of blood, correcting the portosystemic shunt surgically often resolves the clinical signs of HE permanently in dogs. In cats, a variable percentage may have residual or recurrent neurologic signs.[27] Treatment of extrahepatic shunts usually involves either complete suture ligation or placement of either an ameroid ring or cellophane band to occlude the shunting vessel more slowly. Intrahepatic shunts are treated either surgically or with interventional radiographic techniques. All of these procedures require general anesthesia; the metabolism of anesthetic agents and their effects on the CNS are far from clear in animals with HE. Although controlled clinical trials are lacking, general opinion favors a period of medical treatment to stabilize animals with HE before anesthesia induction.

Animals with liver insufficiency commonly experience clinical or subclinical GI hemorrhage, and the digested blood serves as another protein source protein that may cause or contribute to HE. It is therefore recommended that these animals receive GI protectant therapy (see Chapter 181, Gastrointestinal Protectants). Drugs such as famotidine (0.25 to 1 mg/kg PO or IV q12-24h), omeprazole (0.5 to 1 mg/kg/day PO q12h), misoprostol (2 to 3 µg/kg PO q8h), and sucralfate (0.25 to 1 g/25 kg PO q6-8h) are commonly used.

104 Chapter 104 Vestibular Disease

Simon R. Platt, BVM&S, DACVIM (Neurology), DECVN, MRCVS

104.1 KEY POINTS

- Patients with vestibular disease have dysfunction of the vestibular system and are often presented for treatment on an acute emergency basis.
- The vestibular system is comprised of a peripheral component within the structures of the inner ear and central components in the brain stem and cerebellum.
- The common clinical signs of vestibular disease include head tilt, ataxia, and nystagmus.
- Peripheral vestibular disease can be accompanied by Horner's syndrome and facial nerve paresis.
- Central vestibular disease typically is accompanied by loss of proprioceptive and motor function, in addition to multiple cranial nerve deficits and mentation changes.
- The differential diagnosis for the cause of vestibular disease depends on the localization of the lesion to the peripheral or central components.
- Treatment of vestibular disease is determined by the underlying etiology, but supportive care is extremely important to the speed of individual patient compensation.

104.2 INTRODUCTION

Dogs and cats have the ability to control posture and movements of the body and eyes relative to the external environment. The vestibular system mediates these activities through a network of receptors and neural elements. Disease leading to dysfunction of the vestibular system can lead to dramatic signs of disequilibrium. The investigation, treatment, and prognosis of the cause of the disequilibrium can differ depending on whether the peripheral or central components of the system are affected.

This chapter outlines the relevant anatomy of the vestibular system and how this influences the clinical signs of its dysfunction, in addition to the diseases that are most commonly responsible for the acute onset of clinical signs constituting an emergency.

104.3 NEUROANATOMY OF THE VESTIBULAR SYSTEM

The vestibular system can be divided into peripheral components located in the inner ear and central nervous system (CNS) components. Three major CNS areas receive projections from the peripheral sensory receptors of the vestibular system: the cerebral cortex, the spinal cord, and the cerebellum. The projection to the cerebral cortex incorporates extensions to the extraocular muscles.

104.3.1 Nerve Pathways to the Extraocular Muscles

Two neurons make up the pathway responsible for the sensory input of the head to the cerebral cortex (Figure 104-1).

104.3.1.1 Neuron 1

The cell location for the first neuron is within the vestibular ganglion of the eighth cranial or vestibulocochlear nerve, and the axon projects into the ipsilateral vestibular nuclei. These neurons receive input from the vestibular receptors in the membranous labyrinth contained within a bony labyrinth in the petrous temporal bone. The sensory neurons are incorporated into the vestibulocochlear nerve, which leaves the petrous temporal bone via the internal acoustic meatus, along with the facial nerve, and enters the medulla of the brain stem.[1]

104.3.1.2 Neuron 2

The cell location for the second neuron is in the vestibular nuclei, which are situated in the medulla oblongata. From these nuclei, axons travel in the medial longitudinal fasciculus within the brain stem. The ascending axons within the fasciculus give off numerous side branches to the motor nuclei of cranial nerves III, IV, and VI, thereby providing coordinated conjugated eyeball movements associated with changes in position of the head. Some axons project from the nuclei into the reticular formation and go on to provide afferents to the vomiting center located there.[1]

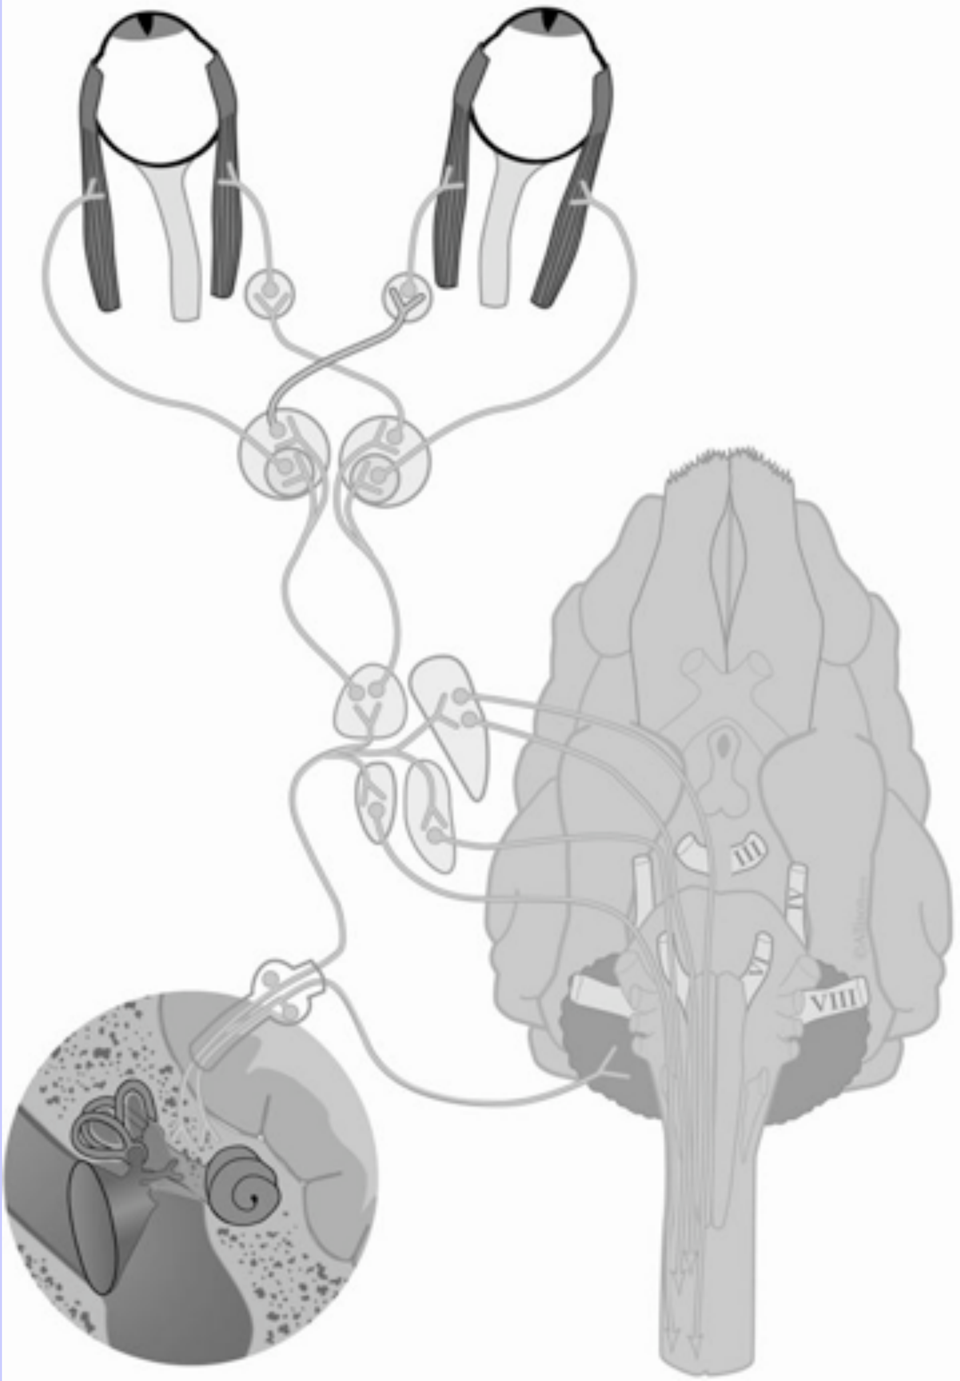
104.3.2 Nerve Pathways to the Spinal Cord

The vestibulospinal tract descends from the vestibular nuclei and projects mainly onto α-neurons or extensor motor neurons throughout the length of the cord via interneurons in the ventral grey column.[1] This pathway is strongly facilitatory to the ipsilateral alpha and gamma motor neurons to extensor muscles.

104.3.3 Nerve Pathways to the Cerebellum

The vestibular nuclei project directly to the cortex of the ipsilateral flocculonodular lobe (the flocculus of the hemisphere and the nodulus of the caudal vermis), as well as the fastigial nucleus of the cerebellum.[1] The return pathway from a cerebellar nucleus to the vestibular nuclei is also ipsilateral; this is an extremely large projection, providing the cerebellum with a strong influence over the activity of the vestibular nuclei. These pathways between the cerebellum and the vestibular nuclei travel in the caudal cerebellar peduncle.

Figure 104-1 Diagrammatic overview of the neuroanatomy of the vestibular system. From Platt S, Olby N, editors: *Manual of canine and feline neurology,* ed 3, Gloucester, 2004, British Small Animal Veterinary Association.



104.4 CLINICAL SIGNS

Unilateral vestibular disease produces asymmetric signs, often on or toward the side of the disease. The most common clinical signs of vestibular disease are head tilt, nystagmus, and ataxia; these may be single entities or a combination of signs.[2] The primary aim of the neurologic examination is to determine if these vestibular signs are due to a peripheral vestibular system (inner ear) disease or a central vestibular system (brain stem and cerebellum, or both) disease. Localization of the disease determines the most appropriate diagnostic tests, the differential diagnoses, and the prognosis.

The essential determination of whether these signs are due to a peripheral or central disease may be possible by the identification of associated neurologic signs that are present only with central disease.[2] Signs of central vestibular syndrome suggest damage to the brain stem and are not present in patients with inner ear disease unless there has been extension of the inner ear disease into the brain stem, such as can be seen with otitis media, otitis interna, and neoplasia.[3]

104.4.1 Specific Signs of Vestibular Dysfunction

Signs of vestibular dysfunction are outlined in Table 104-1.

104.4.1.1 Head Tilt

Loss of equilibrium is most commonly represented clinically as a head tilt that may be present with either central or peripheral vestibular disease. The head tilt is always toward the side of the lesion with peripheral disease but may be toward either side with central disease. When the head tilt is opposite to the side of the lesion, it is termed *paradoxical*. [2] This can be seen with lesions of the flocculonodular lobe of the cerebellum or the supramedullary part of the caudal cerebellar peduncle, with sparing of the vestibular nuclei in the rostral medulla; the head tilt often is accompanied by ipsilateral cerebellar signs, paresis, and proprioceptive deficits.[3]

Table 104-1 Neurologic Examination Findings in Animals With Peripheral and Central Vestibular Dysfunction

Clinical Signs	Peripheral Vestibular Disease	Central Vestibular Disease
Head tilt	Toward the lesion	Toward the lesion, or away from the lesion with paradoxical disease
Spontaneous nystagmus	Horizontal or rotatory with the fast phase away from the side of the lesion Rarely positional	Horizontal, rotatory, vertical and or positional with the fast phase toward or away from the lesion
Paresis and proprioceptive deficits	None	Commonly ipsilateral to the lesion
Mentation	Normal to disoriented	Depressed, stuporous, obtunded, or comatose
Cranial nerve deficits	Ipsilateral CN VII deficit	Ipsilateral CN V, VII, IX, X, and XII
Horner's syndrome	Common ipsilateral to the lesion	Uncommon
Head tremors	None	Can occur with concurrent cerebellar dysfunction
Circling	Infrequent but can be seen toward the side of the lesion	Usually toward the side of the lesion

CN, Cranial nerve.

Bilateral peripheral vestibular disease does not produce asymmetric lesions such as a head tilt. A characteristic side-to-side head movement is seen instead.

104.4.1.2

Nystagmus

Pathologic or spontaneous nystagmus is an involuntary rhythmic oscillation of both eyes, occurs when the head is still, and is a sign of altered vestibular input to the neurons that innervate the extraocular eye muscles.[2] This is in contrast to physiologic nystagmus, which can be induced in normal animals. Pathologic nystagmus may be horizontal, rotatory, or vertical. Vertical nystagmus implies a central vestibular lesion but it is not a definitive localizing sign. If nystagmus of any direction is induced only when the head is placed in an unusual position, it is known as *positional nystagmus,* which may be more common with, but not specific for, central disease; this term may also refer to nystagmus that changes its predominant direction with altered head positions.[2]

443

444

Nystagmus occurs with the fast phase away from the damaged side and with the slow phase commonly directed toward the affected side. In acute and or aggressive nystagmus, the eyelids may be seen to contract at a rate corresponding to that of the nystagmus. Nystagmus may disappear with chronicity of the underlying lesion, particularly with peripheral disease, but its presence usually indicates an active disease process within the vestibular apparatus. Animals with bilateral vestibular disease do not have pathologic or physiologic nystagmus.[4]

104.4.1.3 Ataxia

Ataxia is a failure of muscular coordination or an irregularity of muscle action. It is generally associated with a cerebellar, vestibular, or proprioceptive pathway abnormality. Animals with vestibular dysfunction assume a wide-based stance and may lean or drift toward the side of a lesion if the dysequilibrium is not too severe.[4]

104.4.2 Signs That May Be Associated With Vestibular Dysfunction

104.4.2.1 Facial Paresis, Paralysis, and Hemifacial Spasm

Cranial nerve VII, the facial nerve, is commonly involved in the same disease processes that cause peripheral vestibular disease.[5] The resulting signs are those of facial paresis, paralysis or, more rarely, spasm.

104.4.2.2 Horner's Syndrome

Horner's syndrome (miosis, ptosis, enophthalmos, and protrusion of the third eyelid) of the ipsilateral eye may be present with either middle or inner ear disease causing peripheral vestibular dysfunction.[6] This association is seen because the vagosympathetic trunk synapses in the cranial cervical ganglion deep to the tympanic bulla. Horner's syndrome rarely is associated with central vestibular disease.[1]

104.4.2.3 Hemiparesis or Tetraparesis

Paresis suggests abnormal neurologic function (weakness) without complete paralysis, which implies that some voluntary motion remains. Locomotion is thought to be initiated in the brain stem of animals, so paresis usually is seen with any lesion within the neuraxis caudal to the level of the red nucleus in the midbrain.[3] With unilateral focal central vestibular diseases, paresis of the ipsilateral limbs (hemiparesis) may be seen if the motor pathways in the medulla oblongata are also affected. A large lesion or multifocal lesions may cause an asymmetric tetraparesis. Paresis does not occur with peripheral vestibular disease.

104.4.2.4 Altered Mental State

Disorders causing central vestibular dysfunction may be accompanied by altered mentation. The reticular activating system of the brain stem facilitates the alert and awake state in animals.[1] Damage to this area may cause the animal to become disoriented, stuporous, or comatose.[3] Although peripheral vestibular disease will not cause stupor or coma, it may cause disorientation, which can make the assessment of the animal's mental status difficult.

104.4.2.5 Multiple Cranial Nerve Dysfunction

Central vestibular syndrome may be accompanied by other cranial nerve dysfunction as well. Clinical signs can include ipsilateral facial hypalgesia, atrophy of the masticatory muscles, reduced jaw tone, facial paralysis, tongue weakness, and loss of the swallow or gag reflex.

104.4.2.6 Circling, Leaning, and Falling

With unilateral vestibular dysfunction, dogs or cats may exhibit an ipsilateral reduction in extensor tone, and contralateral hypertonicity, causing them to lean, fall, and circle toward the side of the lesion.[2] Falling may occur when the animal shakes its head if there is aural irritation.

104.4.2.7 Decerebellate Posturing

In severe forms of central vestibular dysfunction, the underlying disease may also cause decerebellate posturing or rigidity; this is characterized by opisthotonus with thoracic limb extension, normal mentation, and flexion of the pelvic limbs.[3] This posture can occur intermittently and be accompanied by vertical nystagmus, the combination being confused by owners as some type of seizure activity. Dorsiflexion of the neck will sometimes elicit this posture.

104.4.2.8 Vomiting

The vomiting center is located within the reticular substance of the medulla, and there are direct connections to it from the vestibular nuclei.[1] Vomiting may be seen in animals affected acutely by vestibular disease.[2]

104.5 DIFFERENTIAL DIAGNOSIS OF ACUTE VESTIBULAR DISEASE

Tables 104-2 and 104-3 outline the overall etiology and infectious etiologies, respectively of acute vestibular disease.

104.6 DIAGNOSTIC APPROACH TO THE ANIMAL WITH ACUTE VESTIBULAR DISEASE

The approach to an animal with vestibular disease can depend on whether a peripheral or central lesion is suspected (Figure 104-2). To determine this, a complete history and a thorough physical and neurologic examination are essential.

The following tests can be performed in sequence, advancing in expense and invasive nature until satisfactory information is acquired. All of the tests may be necessary if central disease is suspected, whereas cerebrospinal fluid (CSF) analysis and advanced imaging may not be necessary if peripheral disease is responsible for the vestibular dysfunction.

104.6.1 Minimum Database

Hematology, a comprehensive serum biochemistry, thyroid function analysis, urinalysis with culture and sensitivity, thoracic radiographs, and abdominal ultrasonography or radiographs should be analyzed in all cases of acute vestibular dysfunction to evaluate the patient for multisystemic or concurrent disease.

104.6.2 Otoscopy and Pharynx Examination

General anesthesia is necessary to thoroughly examine the ears and pharynx for abnormalities such as exudates
and soft tissue masses. Both ears should be examined with an otoscope. The tympanum should be examined for 444
color, texture, and integrity; it is usually dark gray or brown in cases of otitis. An intact tympanum does not rule 445
out otitis media, and diagnosing otitis media on the sole basis of a ruptured tympanum is also unreliable.[5]

Table 104-2 Etiologies of Peripheral and Central Vestibular Diseases[1]

	Specific Diseases	
Disease Mechanism	**Peripheral Disease**	**Central Disease**
Degenerative	—	Cerebellar cortical abiotrophy Lysosomal storage diseases
Anomalous	Congenital vestibular disease	Hydrocephalus Intracranial intraarachnoid cysts
Nutritional	—	Thiamine deficiency
Neoplasia	Squamous cell carcinoma Fibrosarcoma Osteosarcoma Ceruminous gland or sebaceous gland adenocarcinoma	Meningioma Oligodendroglioma Medulloblastoma Lymphoma Extension of middle ear neoplasia Metastasis
Inflammatory or infectious	Bacterial otitis interna or labyrinthitis Cryptococcosis Nasopharyngeal polyps (cuterebral larval migration)	See Table 104-3
Idiopathic	Idiopathic vestibular syndrome	—
Toxic	Aminoglycosides Furosemide Chlorhexidine 10% Fipronil solution (aural administration)	Metronidazole Lead
Traumatic	Iatrogenic: External middle ear flushing or bulla osteotomy Bulla fracture or hemorrhage	Head trauma
Vascular	—	Infarction or hemorrhage Feline ischemic encephalopathy Cuterebral larval migration

104.6.3 Radiography

Radiography is useful for evaluating the osseous tympanic bulla. Skull radiographs should be performed under general anesthesia to achieve adequate positioning. This may not always be possible, particularly in the trauma patient. Lateral, dorsoventral, or ventrodorsal, lateral-20 degree ventral-laterodorsal oblique, and rostral-30 degree ventral-caudodorsal open-mouth oblique radiographs are advised for the assessment of tympanic bulla.[7]

Table 104-3 Infectious and Inflammatory Central Nervous System Disorders That May Cause Vestibular Dysfunction [1]

Class of Etiologic Agent	Disease
Viral	Feline infectious peritonitis Feline immunodeficiency virus Feline leukemia virus Rabies Pseudorabies Borna disease virus Distemper virus
Protozoal	Toxoplasmosis, neosporosis Encephalitozoonosis
Bacterial	Aerobes Anaerobes
Rickettsial	*Rickettsia rickettsii* *Ehrlichia* spp
Fungal	Cryptococcosis Blastomycosis Histoplasmosis Coccidioidomycosis Aspergillosis Phaeohyphomycosis
Parasitic	*Angiostrongylus vasorum* Cuterebral larval myiasis Dirofilaria immitis
Agent unknown	Nonsuppurative meningoencephalomyelitis (presumed viral) Eosinophilic meningoencephalitis Granulomatous meningoencephalitis Necrotizing meningoencephalitis (Pug, Maltese Terrier) Necrotizing leukoencephalitis (Yorkshire Terrier)

104.6.4 Myringotomy

Myringotomy is the deliberate puncture or incision of an intact, although not necessarily healthy, tympanic membrane.[8] Needle puncture and subsequent aspiration through the ventrocaudal part of the tympanic membrane allows for collection of fluid from the tympanic cavity for cytologic examination and microbial culture and sensitivity testing.

104.6.5 Brain Stem Auditory Evoked Potentials

Brain stem auditory evoked potentials testing, also known as *brain stem auditory evoked response testing,* can be used to assess the integrity and function of the peripheral and central auditory pathways, which allows for indirect evaluation of the vestibular pathways because of their close association.[9] Brain stem auditory evoked potentials are recordings of sound-evoked electrical changes in portions of the auditory pathway between the cochlea and the auditory cortex. Because of the level of patient cooperation required, sedation or a light plane of general anesthesia is often needed for this test to be performed and interpreted properly.[9]

104.6.6 Cerebrospinal Fluid Analysis

CSF analysis is a useful adjunctive test for determining the cause of central vestibular disease, although results 445 are rarely specific. Although serum and CSF antibody titers have been used previously to diagnose infectious 446 diseases, polymerase chain reaction analysis of CSF can now be performed in specialized laboratories to evaluate for the presence of infectious antigens rather than antibody titers.[10] The risk of iatrogenic CNS trauma or cerebellar herniation following cisterna magna puncture with space-occupying lesions should not be underestimated. It is preferable to obtain advanced imaging studies of the brain (see Advanced Imaging section next in this chapter) before performing CSF tap, especially if a caudal fossa lesion is suspected.

Figure 104-2 Algorithm detailing the approach to the patient with acute vestibular disease. *CNS,* Central nervous system; *CSF,* cerebrospinal; *CT,* computed tomography; *MRI,* magnetic resonance imaging.

Polyp/ neoplasia/ abscess
Idiopathic vestibular syndrome
Treat for otitis media/interna; consider toxicity
Surgical treatment

104.6.7 Advanced Imaging

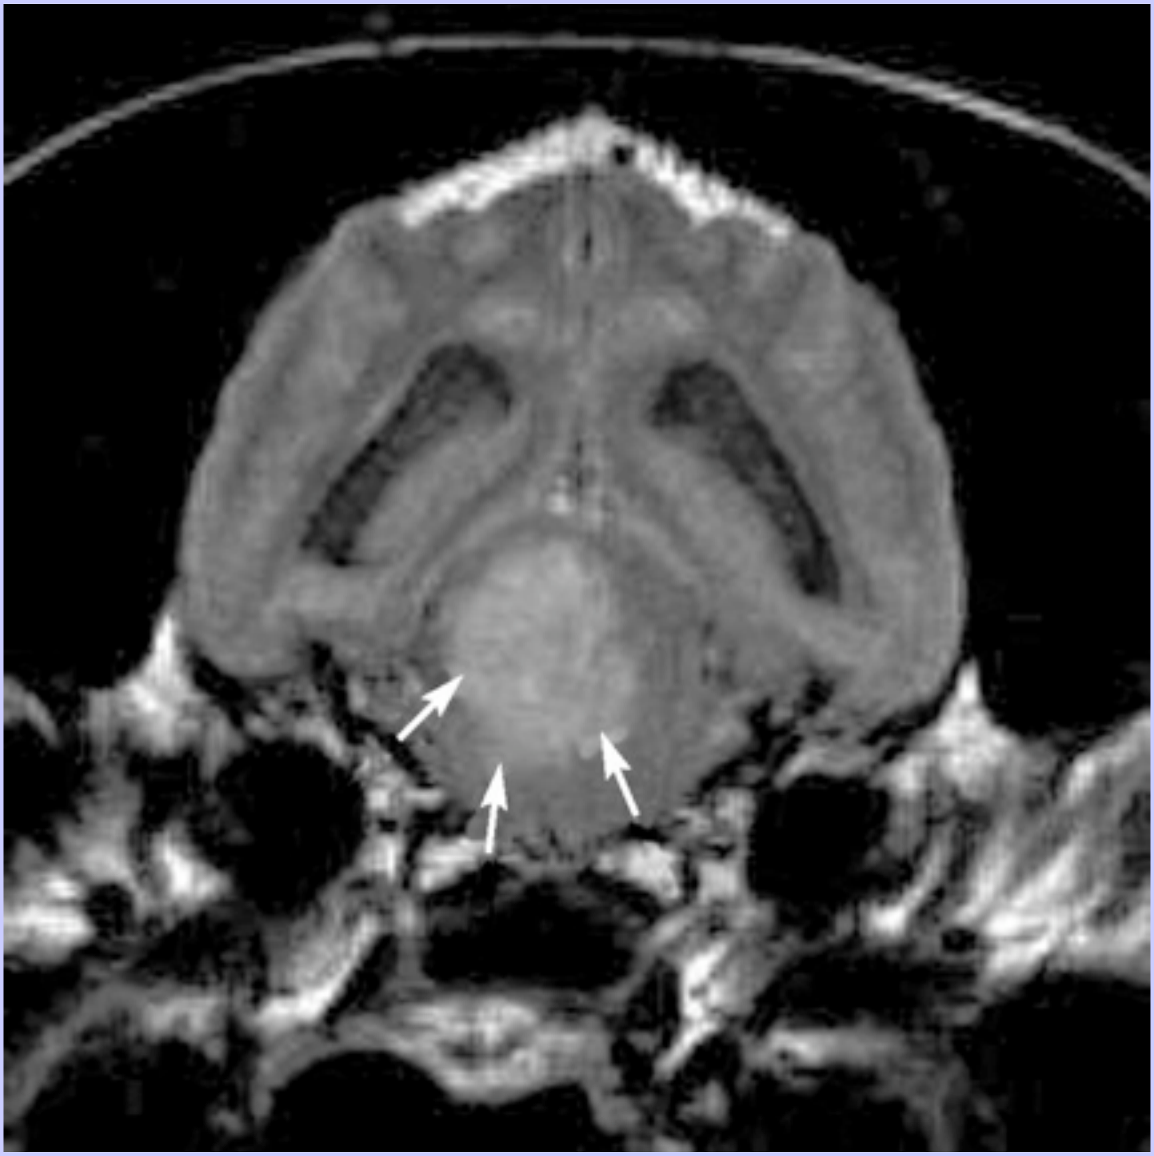
Computed tomography (CT) and magnetic resonance imaging (MRI) have revolutionized the diagnosis of vestibular diseases. CT evaluation of the peripheral vestibular system is particularly useful if radiographs have not determined an underlying cause, if nasopharyngeal polyps and neoplasia are considerations, or if the animal is a potential surgical candidate. CT evaluation for central vestibular diseases may be less helpful because of the artifacts relating to the density of the petrous temporal bones surrounding the medulla (e.g., beam hardening).[11]

MRI of the peripheral and central vestibular systems provides excellent multiplanar soft tissue resolution when compared with CT.[11] The improved soft tissue contrast provided by this modality allows better assessment of neoplastic and inflammatory conditions that result in vestibular dysfunction (Figure 104-3). A typical MRI study consists of T1-weighted, T2-weighted, and proton density–weighted transverse images made before contrast medium administration.[11] Postcontrast sequences have been recommended if a mass is present in the tympanic bulla or the external ear canal.

104.7 TREATMENT AND PROGNOSIS

The damaged vestibular system can compensate over time with central reprogramming of eye movements and postural responses, as well as reliance on visual and other sensory input that replaces lost vestibular input.[2] If the underlying disease process can be targeted, the prognosis for a functional recovery can be good. Residual signs, such as a head tilt, are always possible. Recurrences can occur at times of stress, recurrent disease, or following anesthesia.

Figure 104-3 Transverse T2-weighted fluid-attenuated inversion recovery magnetic resonance study of a 4-year-old mixed breed dog with central vestibular disease and multiple cranial nerve involvement. A large irregular lesion hyperintense to the surrounding brain stem is identified *(arrows)*. Pathologic examination confirmed granulomatous meningoencephalomyelitis.



Supportive care can be essential, especially because these animals are frequently anorexic; feeding tubes and fluid therapy can be vital initially until the patient can self-maintain. Vomiting, salivation, and nausea associated with vestibular disease can be treated with antiemetic medications. Drugs commonly used include the phenothiazine derivative chlorpromazine (0.2 to 0.5 mg/kg SC q8h), serotonin receptor antagonists dolasetron (0.6 to 1 mg/kg SC, IV, or PO q24h) and ondansetron (0.1 to 0.1 mg/kg PO q12-24h or 0.1 to 0.5 mg/kg IV slowly q6-12h), metoclopramide, an antidopaminergic serotonin receptor antagonist and chemoreceptor trigger zone inhibitor (0.1 to 0.5 mg/kg IV, SC, or PO q6h or as an IV infusion of 1.1 to 2.2 mg/kg q24h), or the antihistamines diphenhydramine (2 to 4 mg/kg PO or IM q8h) and meclizine (12.5 mg PO q24h) (see Chapter 182, Antiemetics).[2]

105 Chapter 105 Cerebrospinal Fluid Sampling

Beverly K. Sturges, DVM, DACVIM (Neurology)

105.1 KEY POINTS

- Cerebrospinal fluid (CSF) analysis can rapidly provide information that may be useful in making a diagnosis, deciding on a treatment protocol or further diagnostic tests, and monitoring response of central nervous system (CNS) disease to medical treatment.
- The most common indication for CSF analysis in the emergency or intensive care unit setting is suspicion of infectious or inflammatory disease of the CNS.
- In collecting CSF, correct patient positioning and a good understanding of regional anatomy are essential.
- CSF findings uncommonly yield a definitive diagnosis and should be interpreted in light of the patient history, neurologic signs, and other diagnostic results. In addition, they may be normal in spite of significant CNS disease.
- Risks versus benefits of a CSF collection should be considered carefully in patients with elevated intracranial pressure.
- CSF cell counts and cytology study may be done in-house with minimal investment in equipment and will give the emergency clinician the most useful information for making a diagnosis.

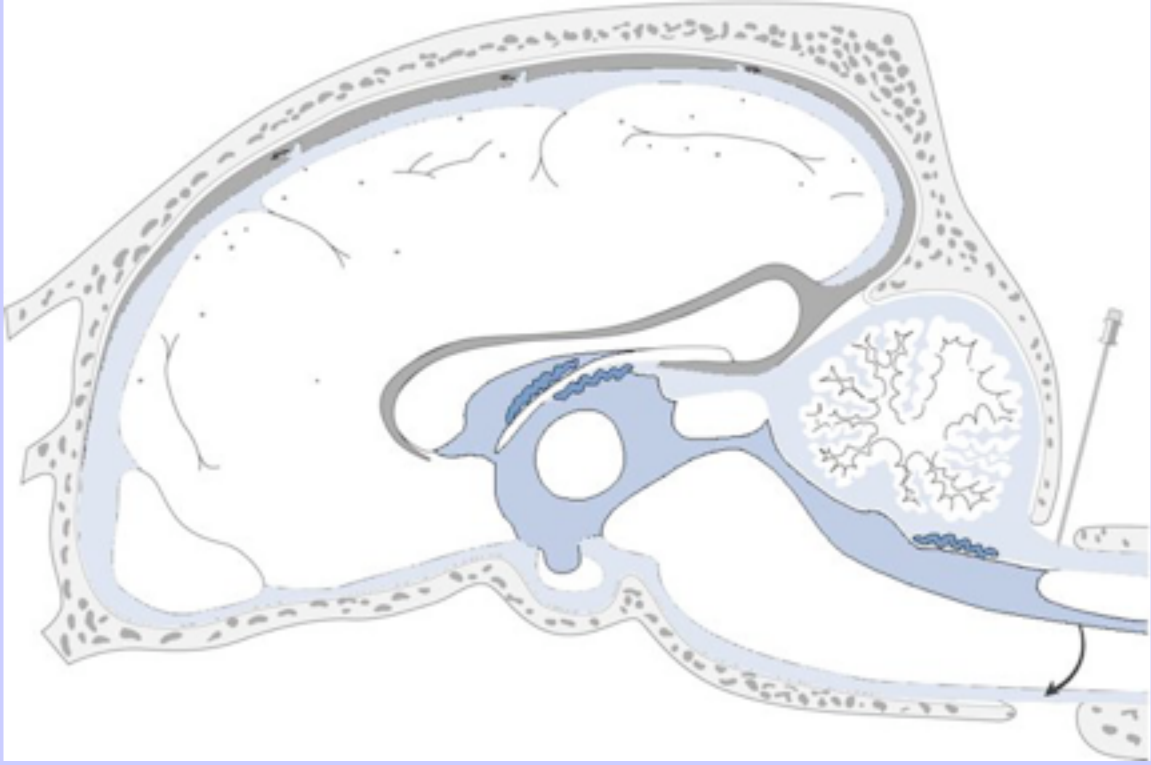
105.2 INTRODUCTION

Cerebrospinal fluid (CSF) collection and analysis may provide rapid information to the clinician investigating a disease affecting the central nervous system (CNS).[1,2] It is particularly useful for confirming the presence of inflammatory and infectious diseases affecting the brain, spinal cord, or nerve roots, especially when the meninges are involved.[1-3] However, CSF analysis should be considered only after an accurate history, physical, and neurologic examination has localized a lesion to the CNS and a logical list of differential diagnoses has been considered carefully.[1,2] In most situations, the results of a CSF analysis provide the clinician with a “piece of the puzzle” that must be used in conjunction with the results of other diagnostic tests, especially magnetic resonance imaging (MRI), to arrive at a correct diagnosis.

105.3 CEREBROSPINAL FLUID FORMATION AND FUNCTIONS

The presence of CSF in the subarachnoid space reduces mechanical trauma to the nervous tissue and serves to remove the products of brain metabolism (Figure 105-1). It is also an intracerebral transport medium for nutrients, neuroendocrine substances, and neurotransmitters.[4] Most CSF is formed by the choroid plexus in the ventricles via ultrafiltration of plasma and the active transport of selected substances across the blood-brain barrier.[4] The CSF flows caudally through the ventricular system; the majority exits via the fourth ventricle to circulate cranially around the brain and caudally around the spinal cord in the subarachnoid spaces.[4] Absorption of CSF occurs primarily through the arachnoid villi that penetrate the major dural venous sinuses in the cranium.[4]

Figure 105-1 Cerebrospinal fluid (CSF) pathway and location of cisternal puncture. CSF, secreted by the choroid plexus *(dark blue),* flows through the ventricular system *(medium blue)* from rostral to caudal: lateral ventricles, third ventricle, mesencephalic aqueduct, and fourth ventricle. From there, most of the CSF exits via the lateral apertures of the fourth ventricle and flows cranially and caudally in the subarachnoid space around the brain and spinal cord *(light blue)*. The remainder of CSF flows caudally down the central canal of the spinal cord. CSF from the cranial subarachnoid space enters the venous system via arachnoid villi. Cisternal puncture is performed by placing a needle in the dorsal subarachnoid space at the craniocervical junction. This space usually becomes accessible when the head is ventroflexed.



105.4 INDICATIONS FOR CEREBROSPINAL FLUID COLLECTION AND ANALYSIS

CSF analysis is indicated when a patient has neurologic signs consistent with disease affecting the CNS, including the brain, spinal cord, and nerve roots.[1-3] Advanced imaging (e.g., MRI, computed tomography [CT]) before CSF collection is usually recommended, whenever possible, to help define the underlying neurologic disease.[5] It gives valuable information relating to the exact location of the lesion, the amount and distribution of associated edema, and any structural evidence of intracranial hypertension (ICH). However, regardless of findings on advanced imaging, animals that are showing rapid neurologic deterioration are most likely to benefit from a diagnostic CSF analysis. Common indications for CSF collection in the emergency or critical care setting include the following:

1. Suspected infectious or inflammatory disease affecting the CNS.[6] Conditions causing meningitis, encephalitis, and myelitis are often moderate to severe in nature by the time these animals are showing neurologic signs and CSF analysis should be done as soon as possible. It is always preferable to collect CSF before treating with medications that may influence the content and, subsequently, the interpretation of the findings.
2. Suspected neoplastic disease affecting the CNS.[1,2,6] With the exception of CNS lymphoma, CSF findings alone are rarely specific for neoplastic disease. However, an analysis is often done to rule out the possibility of inflammatory disease that may also be on the differential list, especially if advanced imaging is not available.
3. Animals having cluster or continuous seizures in which underlying infectious or inflammatory disease or neoplasia is likely.[1]
4. Acute, ascending lower motor neuron signs. Because the prognosis and treatment vary widely depending on the underlying cause of these signs, CSF findings may help to differentiate diseases such as acute polyradiculopathy from infectious, inflammatory, or neoplastic disease (e.g., lymphoma).[1]

CSF analysis occasionally may be indicated to monitor short-term response to treatment when an obvious response to therapy is not evident or cannot be monitored. This may be especially applicable to animals that are systemically ill, heavily sedated, or being mechanically ventilated. CSF evaluation, or “the CBC of the CNS,”[1] may be particularly helpful in guiding the clinician in further treatment and prognosis in such cases.

105.5 CONTRAINDICATIONS AND RISKS

CSF collection requires general anesthesia, the risks of which are inherently higher in animals that might have elevated intracranial pressure (ICP).[3,5] Risks of anesthesia are minimized by the following measures:

1. Using an anesthetic protocol that reduces ICP
2. Treating patients with mannitol, ventilation, and control of partial pressure of arterial carbon dioxide before anesthetizing if severe ICH is suspected (see Chapter 100, Intracranial Hypertension)

The emergency clinician should also be aware of the following situations in which the risks of performing a CSF collection are very likely to outweigh benefits, and therefore the procedure is not recommended[1,2]:

- Acute traumatic brain injury
- Rodenticide toxicity, aspirin ingestion, serious coagulopathies
- Severe, progressive ICH

- Atlantoaxial luxation or cranial cervical fracture or luxation

Although CSF analysis is one of the easiest and most direct methods for evaluating the CNS, the proximity of important neural structures makes it possible to penetrate these structures inadvertently during needle placement, especially if there is pathology affecting the subarachnoid space.[1]

The most common injury is trauma to the cerebellum, brainstem, or cervical spinal cord. It produces a vestibular syndrome that is apparent when the animal recovers from anesthesia.[1] A rarer, but more serious, consequence is iatrogenic trauma that produces apnea. Immediate treatment with hyperosmolar therapy, mechanical ventilation, and possibly glucocorticoids, may save the life of the apneic patient.[1] Patients with vestibular signs will usually recover without treatment in a few days to a couple weeks. The incidence of these complications is rare in the hands of a careful, trained individual.

In cases of ICH, herniation of the brain may occur from a rapid reduction of ICP (e.g., pop-off valve effect), producing apnea and unresponsiveness.[1] Usually mydriatic pupils are apparent even while the animal is still anesthetized. Although immediate aggressive treatment for ICH is indicated, these animals have a grave prognosis.

105.6 CEREBROSPINAL FLUID COLLECTION TECHNIQUES

105.6.1 Preparation

For CSF collection and examination it is necessary to puncture the subarachnoid space in the cerebellomedullary cistern or in the lower lumbar spine.[1,3,5,6] Small animals must be anesthetized to ensure complete immobility. A propofol infusion with midazolam or fentanyl, or both, provides excellent anesthesia for performing CSF collection in patients with ICH. The site must be shaved, surgically prepared, and draped with a small fenestrated sterile drape. Sterile surgical gloves should be worn. All equipment should be assembled and ready to use before positioning the patient. The following items are necessary:

1. Sterile gloves and drape or sterile field
2. Disposable spinal needles with stylets

   A 22-gauge, 1½-inch spinal needle is used in most cisternal punctures regardless of size of the dog; it may also be used for cisternal puncture in cats and for lumbar puncture in small dogs and cats.

   A 22-gauge, 2½-inch spinal needle is occasionally necessary for doing a cisternal puncture in giant breed dogs or in large breed dogs with heavy cervical musculature; it is also commonly used in lumbar punctures of most dogs weighing more than 5 kg.

   A 22-gauge, 3½-inch spinal needle is used for lumbar punctures in large and giant breed dogs.

   A 25-gauge, 1-inch spinal needle may be used in small cats and toy breed dogs. These needles are more easily supported by the surrounding tissues in very small animals, and the bevel on the needle is less likely to cause trauma to the brain stem or spinal cord. However, CSF flow is considerably slower through this needle, which should be remembered when watching for the flash of CSF in the hub identifying the subarachnoid space.

3 Red-top glass blood collection tubes (Vacutainers)

105.6.2 Cerebrospinal Fluid Collection Sites and Techniques

CSF collection can be done from the cisterna magna, the lateral ventricle (rarely), or the lumbar region.[1,3,5,6] When focal CNS disease is suspected, CSF findings are more likely to be abnormal and representative of the underlying pathology when they are collected caudal to the lesion. In multifocal or diffuse CNS disease, CSF collection at both cisternal and lumbar sites is recommended.

105.6.2.1 Cisternal Puncture

105.6.2.1.1 Positioning

The subarachnoid space enlarges to form the cerebellomedullary cistern in the dorsal atlantooccipital region (see Figure 105-1).[1,3,5,6] This site is used when the patient's signs suggest brain or cranial cervical spinal cord disease. During cisternal puncture the neck is flexed and a patent airway must be maintained under anesthesia by use of an endotracheal tube. The animal is placed in lateral recumbency (right lateral is usually easiest for a right-handed person) and an area from the occipital protuberance to the level of C3 is surgically prepared.

With the assistant standing opposite the person doing the puncture, the neck is flexed moderately (90 to 100 degrees) at the cisternal region while holding the ears out of the way. It is important to make sure that the midline of the neck and the head (from the nose to the occiput) are perfectly parallel to the tabletop. If the neck sags, as is common in larger dogs, place a small pad under it. Then palpate the wings of the atlas and make sure they are superimposed, eliminating axial rotation. Positioning is critical in making the puncture exactly on midline.

Palpate all landmarks before inserting the needle: external occipital protuberance, spinous process of C2 vertebra, the dorsal arch of C1 vertebra (do this by slipping rostrally off of C2 spine), and the wings of the atlas. Either of the following methods for finding the correct point of insertion may be used:

1. Using the external occipital protuberance and the spine of C2, the puncture is made on midline halfway between the occiput and the cranial end of the spinous process. If the dorsal arch of C1 can be palpated, the puncture is made on the midline just cranial to it.
2. Using the wings of the atlas, the puncture is made in the center of the triangle formed by the occiput and the wings of the atlas.

With either method, a natural indentation can usually be palpated on midline where the needle is most likely to enter the subarachnoid space.

105.6.2.1.2

Needle Insertion

Place the spinal need perpendicular to the plane of the vertebral column and advance it slowly at a 90-degree angle through the skin and underlying tissues. Extremely tough skin, as in cats, may need to be tented and penetrated before the landmarks are identified for puncture into deeper tissues. Every time a layer of tissue is penetrated, detected by a sudden decrease of resistance at the needle tip, remove the stylet and observe the hub of the needle for a few seconds for the appearance of CSF. In small dogs and cats, the tissue planes are not as easily ascertained by feel and the stylet should be removed and checked every 1 to 2 mm. This prevents inadvertent penetration of neural tissue. When the dura is penetrated, resistance decreases and CSF appears in the hub of the needle when the stylet is removed. Occasionally a twitch may be seen or felt when the dura is penetrated, especially if it is inflamed.

105.6.2.2

Tips for Trouble-Shooting Cerebrospinal Fluid Puncture

1. If pure blood drips from the hub, most likely the needle is slightly off midline and into the vertebral venous plexus, outside of the dura. This poses no harm to the patient and the needle should be removed and discarded. Recheck landmarks and patient alignment and try another puncture.

2. If bloody CSF appears in the hub, most likely the needle has traumatically ruptured vessels in the pia. Replace the stylet for a minute, let any blood-tinged CSF flow out, and collect CSF after it clears. CSF that remains uniformly blood tinged may reflect hemorrhage within the CNS. If the tip of the needle is hitting bone, determine if it is hitting C1 or the occipital bone. Pull the needle out slightly and redirect cranially or caudally along the sagittal plane. If bone is encountered repeatedly, it is best to start over with a new needle after rechecking landmarks and patient positioning.

In cats and small dogs, 1 to 2 ml of CSF can be safely collected by free flow into a sterile glass tube; 6 ml or more may be collected in larger dogs.[1-3] It is best not to aspirate fluid from the hub of the needle, because it may collapse the CSF space or initiate hemorrhage.[1] Once enough CSF has been collected, remove the needle. Historically, the opening pressure of the CSF was measured by attaching a stopcock and manometer to the needle before collecting fluid. However, this practice has largely been abandoned for safer, more accurate ways of measuring CSF pressure and is not recommended.[5] If there is concern of life-threatening ICH, it may be safer to attempt a lumbar puncture instead of a cisternal puncture.

PRECAUTION: Especially important in the emergency and critical care setting is to exercise caution when collecting CSF from patients with very high pressures from meningoencephalitis, CNS edema, or an intracranial mass. In these cases it may be dangerous to remove or allow escape of very much CSF. The sudden release of pressure may lead to brain herniation. If CSF flows out of the needle at a high rate, or if flow is initially very good and then suddenly diminishes, a minimal amount of CSF should be collected. Also, in animals with suspected ICH, extreme care should be taken not to severely flex the animal's head or place any compression on jugular veins during CSF collection.

105.6.2.3 Lumbar Puncture

105.6.2.3.1 Positioning

In animals with thoracic, lumbar, or sacral spinal cord disease, CSF should be collected from the lumbar region.[1,6] Additionally, lumbar CSF is usually preferred in animals with ascending lower motor neuron disease or suspected polyradiculopathies. Because of the proximity of the puncture site to the diseased cord and the craniocaudal flow of CSF, lumbar fluid is more likely than cisternal CSF to reflect the disease process. In animals that are too ill to undergo general anesthesia or are comatose, a lumbar puncture (and occasionally a cisternal puncture) can be done with a local anesthetic and a tranquilizer if needed.

The technique of lumbar puncture for collection of CSF is the same as that used to place a needle for injection of contrast material into the subarachnoid space for myelography. CSF analysis should always be done before myelography to rule out meningitis or myelitis, because injecting contrast media when there is inflammation or infection may further damage an injured cord and possibly disseminate infection. If need be, after lumbar spinal needle placement and CSF collection, the patient can be kept under anesthesia with the needle in place for the few minutes needed to do a cell count and differential; then the myelogram can be done if marked inflammation is not present. The patient is positioned in lateral recumbency with the right side down (for a right-handed person). The lumbar spine may be gently flexed to open up the interarcuate space between L4-5 (large breed dogs preferred site), L5-6 (small breed dogs preferred site), or L6-7 (cats preferred site). An area from the midlumbar to the sacral region is clipped and surgically prepped; sterile technique is used as described above.

Palpating the spinous process caudal to the desired interarcuate space, insert the spinal needle through the skin at the caudal lateral edge of the spinous process. With the needle directed cranially and following the spinous process down, insert it until the vertebral arch is encountered. Then "walk" the needle cranially until the interarcuate space is felt. Push the needle gently through the ligament and spinal canal until the floor of spinal canal is encountered. The animal will often twitch when the needle penetrates the dura. If spinal fluid is not seen in the hub of the needle within a few seconds, the needle can be rotated or retracted slowly, or both, until the subarachnoid space is entered and fluid appears. Fluid should be allowed to drip into the collection tube by free flow and not aspirated from the needle. If blood is present in the hub, the needle should be withdrawn and discarded and another puncture attempted at a different site.

NOTE: Although the cauda equina is penetrated in the process of performing the puncture, this usually produces no ill effects.

105.7 ANALYSIS OF CEREBROSPINAL FLUID

Many tests can be done on CSF. To perform all possible tests costs money, requires larger volumes of CSF, and rarely gives additional information except in specific situations. For a complete list of these tests and their normal values, the reader is directed to a clinical pathology textbook or the indicated references at the end of this chapter. The parameters that follow are recommended for routine analysis of CSF samples.

105.7.1 Specimen Handling and Examination

CSF should be collected in sterile red top Vacutainer tubes and analyzed cytologically within 30 to 60 minutes of collection.[1,3,5,6] If it is not possible to evaluate the sample soon after collection, it should be preserved by refrigeration and the addition of 1 drop of fetal calf serum or autologous serum per 0.25 ml of CSF. An aliquot of CSF should be saved in a separate tube for protein measurement. This portion of the sample may be kept refrigerated or frozen until protein analysis is performed. Most commercial laboratories require a total of about 0.5 ml for routine CSF analysis.

105.7.2 Physical Characteristics

The color and clarity of the CSF should be observed by the clinician at the time of collection (Table 105-1).[1-3,6] Normal CSF is a crystal clear, colorless fluid comparable in appearance to that of distilled water. Common abnormalities include cloudiness or turbidity, caused by significant pleocytosis, and xanthochromia, a yellow discoloration caused by the breakdown of RBCs due to recent hemorrhage in the CNS.

Table 105-1 Normal Characteristics of CSF

Characteristic	Findings in Normal CSF
Color	Colorless
Clarity	Transparent, clear
Refractive index	1.3347 to 1.3350
Protein concentration	*Cisternal:* <25 mg/dl
	Lumbar: <40 mg/dl
Total cell count	*RBCs:* 0/µl
	WBCs: <3/µl cisternal; <5/µl lumbar
WBC differential count	Mononuclear cells
	Small mononuclear cells: 60% to 70% Large mononuclear cells: 30% to 40% Polymorphonuclear cells
	Neutrophils: <1%
	Eosinophils: <1% Others
	Ependymal lining cells: rare
	Nucleated RBCs: Rare in lumbar puncture specimens

CSF, Cerebrospinal fluid; *RBC,* red blood cell; *WBC,* white blood cell.

105.7.3 Total Cell Count and Differential

Red and white blood cell (RBC and WBC) counts can be performed in private practice using the chamber of a standard hemacytometer (see Table 105-1).[1,3] One to two drops of CSF are placed on each side of the hemacytometer from a standard microhematocrit tube (without anticoagulant) that has first been coated with new methylene blue stain. The nuclei of the nucleated WBCs in the sample will be stained and readily differentiated from the RBCs. The RBCs and WBCs in the 9 large squares on each side of the hemacytometer are counted. The mean value of the counts from both sides are multiplied by 1.11 to get the total number of cells per cubic millimeter (μl) of spinal fluid.

A differential count is done next, noting polymorphonuclear cells and mononuclear cells. Normal spinal fluid should have fewer than 3 WBCs/μl (slightly higher in lumbar fluid) with no neutrophils, plasma cells, or macrophages. RBCs should not be present in cisternal fluid; however, small numbers are usually considered normal in lumbar fluid. Slight contamination of CSF with blood does not severely affect the counting results.

Higher numbers of RBCs from the peripheral blood may affect the total WBC count, and the following rule of thumb is often used to make a “ballpark” correction estimate. Because the normal ratio of red cells to white cells in blood is about 500:1, 1 WBC is subtracted from the total CSF WBC count for every 500 RBCs present in the CSF, if the patient's peripheral blood count is in the normal range. For more in-depth explanation on interpreting blood contaminated CSF, the reader is referred to the reference list.

105.7.4 Cytology

Most CSF samples contain low numbers of WBCs, and therefore most samples will need to be concentrated before microscopically examining morphology (see Table 105-1).[1,3] Commercial labs use a cytocentrifuge to concentrate the cells in a single drop of CSF on a microscope slide. Membrane filtration and sedimentation are 451 alternative methods of 452 cytologic analysis. In-house sedimentation chambers can be constructed easily and used in private practice (see reference list). The slides made using a sedimentation chamber may be examined in-house or submitted to a commercial laboratory for morphologic evaluation.

105.7.5 Protein

Total protein may be measured by several methods, although quantitative protein determinations performed by commercial laboratories are the most accurate (see Table 105-1).[1,3,5,6] Normal values vary among species, laboratories, and site of collection. Most diseases of the CNS will cause changes in the CSF protein concentration; elevated protein concentration in the CSF often is used as evidence that neurologic disease is within the CNS. The degree of protein elevation is used, along with information on the total and differential WBC count, to determine the most likely differential(s) for the abnormalities seen in the sample. Blood contamination of the CSF (>500 RBC/μl) may influence protein concentration and should be taken into account. A 1 mg/dl increase in CSF protein can be estimated for every 1000 RBCs in the sample if the serum protein concentration of the patient is in the normal range. For more in-depth discussions on protein concentration and interpretation, see the reference section.

105.7.6 Other Tests

Many other diagnostic tests may be done on CSF samples depending on the interpretation of the cytology findings and protein concentration. These include bacterial culture, antigen-antibody titers, polymerase chain reaction (PCR), immunocytochemistry, and enzyme, metabolite, and neurotransmitter assays.[1,6]

105.8 INTERPRETATION OF COMMON FINDINGS

Although CSF results are usually not specifically diagnostic, certain types of cellular responses can be strongly suggestive of particular diseases.[1-3,5,6] There are many exceptions to the general guidelines presented below, especially when adding the complexity of evaluating CSF from animals that have chronic disease or have been treated with medications that may affect the cellular content or distribution of cells. It must also be kept in mind that normal CSF findings do not rule out the presence of CNS disease.

1 Mild to moderate predominantly mononuclear pleocytosis typically is seen with inflammatory diseases, especially viral and rickettsial infections (e.g., canine distemper, ehrlichia). It may also occur with noninfectious inflammatory brain diseases as well as compressive lesions affecting the spinal cord (intervertebral disk disease [IVDD]).

2 Moderate to marked predominantly neutrophilic pleocytosis most commonly is seen with infectious or inflammatory diseases such as bacterial meningoencephalomyelitis, steroid-responsive meningitis or vasculitis, and feline infectious peritonitis.

3 Moderate to marked predominantly mononuclear pleocytosis classically is seen with granulomatous meningoencephalomyelitis and breed-related forms of necrotizing encephalitis seen in Pugs, Maltese, Yorkshire Terriers, Chihuahuas, and others. Lymphoma in the CNS often causes significant mononuclear pleocytosis as well.

4 Marked pleocytosis with a predominance of eosinophils most commonly is caused by eosinophilic meningitis (idiopathic). Other less common conditions, such as parasitic migrations (e.g., *Angiostrongylus*) and protozoal and fungal disease, should also be considered.

5 Mild to marked mixed pleocytosis most often is associated with inflammatory diseases, especially fungal or protozoal meningoencephalomyelitis. Mixed pleocytoses are also commonly seen in infectious or inflammatory disease that is “aging” or being managed with medications that are altering the typical pattern of cells seen. Necrosis of the CNS occurring secondary to vascular infarction, trauma, or neoplasia may also produce a mixed pleocytosis.

6 Albuminocytologic dissociation occurs when the total nucleated cell count is in the normal range (although the distribution of cells may be abnormal) but the protein is elevated. This finding is very nonspecific and may be seen with virtually any CNS disease, but it is most often indicative of degenerative or demyelinating diseases (degenerative myelopathy), chronically compressive lesions (IVDD, neoplasia, stenoses), and intramedullary pathology (neoplasia or syringohydromyelia).

54 Chapter 54 Sodium Disorders

Jamie M. Burkitt, DVM, DACVECC

54.1 KEY POINTS

- Most disorders of plasma sodium concentration result from abnormalities in the handling of water rather than sodium.
- Plasma sodium concentration is the major determinant of plasma osmolality.
- Hypernatremia or hyponatremia can cause central nervous system (CNS) disturbance resulting from changes in neuronal cell volume and function.
- Overly rapid correction of hypernatremia or hyponatremia can cause severe CNS dysfunction.
- Patients with hypernatremia or hyponatremia that require intravascular volume expansion should be treated with intravenous fluids that match their plasma sodium concentration.

54.2 INTRODUCTION

Sodium concentration is expressed as milliequivalents (mEq) of sodium per liter of serum or plasma. In the vast majority of cases, disorders of sodium concentration in dogs and cats result from abnormalities in water handling rather than an increased or decreased number of sodium molecules. To understand what determines plasma sodium concentration and how changes in plasma sodium concentration alter cellular function, one must understand the distribution of body water and the concept and determinants of osmolality.

54.2.1 Distribution of Total Body Water

Water makes up approximately 60% of an adult animal's body weight; two thirds is intracellular and one third is extracellular. Extracellular water is distributed between the interstitial and intravascular compartments, which contain approximately 75% and 25% of the extracellular water, respectively (see Figure 64-1). The endothelium, which separates the intravascular fluid compartment from the interstitial space, and the cell membrane, which separates the interstitial and intracellular compartments, are freely permeable to water molecules. Therefore, in a closed system (no urinary or gastrointestinal (GI) output), when 1 L of free water (water containing no other molecules) is added to the animal, 666 ml will be distributed to the intracellular space and 333 ml to the extracellular space. Of the 333 ml added to the extracellular space, 250 ml will remain in the interstitial fluid space and 83 ml will be distributed to the intravascular compartment.

54.2.2 Osmolality and Osmotic Pressure

An *osmole* is one mole of any fully dissociated substance dissolved in water. *Osmolality* is the concentration of osmoles in a mass of solvent. In biologic systems, osmolality is expressed as mOsm/kg of water. *Osmolarity* is the concentration of osmoles in a volume of solvent, and in biologic systems is expressed as mOsm/L of water. Every molecule dissolved in the total body water contributes to osmolality, regardless of size, weight, charge, or composition. The most abundant osmoles in the extracellular fluid are sodium and potassium (and their accompanying anions chloride and bicarbonate), glucose, and urea. Hence, these molecules are the main determinants of plasma osmolality in healthy dogs and cats.

Plasma osmolality in healthy animals is approximated by the equation:

$2(\mathrm{Na}^{+} + \mathrm{K}^{+}) + (\mathrm{BUN}\,[\mathrm{mg} / \mathrm{dl}] \div 2.8) + (\mathrm{glucose}\,[\mathrm{mg} / \mathrm{dl}] \div 18)$ where Na^{+} = sodium, K^{+} = potassium, and BUN = blood urea nitrogen.

The blood urea nitrogen (BUN) and glucose concentrations are divided by 2.8 and 18, respectively, to convert them to mOsm/kg. As this equation shows, plasma sodium concentration is the major determinant of plasma osmolality.

Osmoles that do not cross the cell membrane freely are considered *effective osmoles,* whereas those that do cross freely are termed *ineffective osmoles*. The water-permeable cell membrane is functionally impermeable to sodium and potassium. As a result, sodium and potassium molecules are effective osmoles and they exert osmotic pressure across the cell membrane. The net movement of water into or out of cells is dictated by the osmotic pressure gradient. Osmotic pressure causes water molecules from an area of lower osmolality to move to an area of higher osmolality until the osmolalities of the compartments are equal.

When sodium is added to the extracellular space at a concentration greater than that in the extracellular fluid, intracellular volume decreases (the cell shrinks) as water leaves the cell along its osmotic pressure gradient. Conversely, cells swell when free water is added to the interstitial space and water moves intracellularly along its osmotic pressure gradient.

54.2.3 Regulation of Plasma Osmolality

Hypothalamic osmoreceptors sense changes in plasma osmolality, and changes of only 2 to 3 mOsm/kg induce compensatory mechanisms to return the plasma osmolality to its hypothalamic setpoint.[1] The two major physiologic mechanisms for controlling plasma osmolality are the antidiuretic hormone (ADH) system and thirst.

54.2.3.1 Antidiuretic Hormone

ADH is a small peptide secreted by the posterior pituitary gland. There are two major stimuli for ADH release: 224
elevated plasma osmolality and decreased effective circulating volume. Increased plasma osmolality causes 225
shrinkage of a specialized group of cells in the hypothalamus called *osmoreceptors*. When their cell volume decreases, these hypothalamic osmoreceptors send impulses via neural afferents to the posterior pituitary, leading to ADH release.[2] When effective circulating volume is low, baroreceptor cells in the aortic arch and carotid bodies send neural impulses to the pituitary gland that stimulate ADH release.

In the absence of ADH, renal tubular collecting cells are relatively impermeable to water. When ADH activates the V_2 receptor on the renal collecting tubular cell, aquaporin-2 molecules are inserted into the cell's luminal membrane. Aquaporins are channels that allow the movement of water into the renal tubular cell. Water molecules cross through these aquaporins into the hyperosmolar renal medulla down their osmotic gradient. If the kidney is unable to generate a hyperosmolar renal medulla because of disease or diuretic administration, water will not be reabsorbed, even with high concentrations of ADH. Thus, circulating ADH concentration and ADH's effect on the normal kidney are the primary physiologic determinants of free water retention and excretion.

54.2.3.2 Thirst

Hyperosmolality and decreased effective circulating volume also stimulate thirst. The mechanisms by which hyperosmolality and hypovolemia stimulate thirst are similar to those that stimulate ADH release. Thirst and the resultant water consumption are the main physiologic determinants of free water intake.

54.2.4 Prioritization of Osmolality and Effective Circulating Volume

Under normal physiologic conditions, the renin-angiotensin-aldosterone system monitors and fine tunes effective circulating volume, and the ADH system maintains normal plasma osmolality. However, maintenance of effective circulating volume is always prioritized over maintenance of normal plasma osmolality. Therefore patients with poor effective circulating volume will have increased thirst and ADH release regardless of their osmolality. The resultant increased free water intake (from drinking) and water retention (from ADH action at the level of the kidney) can lead to hypoosmolality in patients with poor effective circulating volume. An example of the defense of effective circulating volume at the expense of normal plasma osmolality is seen in patients with chronic congestive heart failure that present with hyponatremia.[3]

54.2.5 Total Body Sodium Content Versus Plasma Sodium Concentration

Plasma sodium concentration is different than, and independent of, total body sodium content. Total body sodium content refers to the total number of sodium molecules in the body, regardless of the ratio of sodium to water. Sodium content determines the *hydration status* of the animal. As it is used clinically, *hydration* is a misnomer, because findings such as skin tenting and moistness of the mucous membranes and conjunctival sac are determined by the sodium content and the water that those sodium molecules hold in an animal's interstitial space.

When patients have increased total body sodium, an increased quantity of fluid is held within the interstitial space and the animal appears overhydrated, regardless of the plasma sodium concentration. Overhydrated patients may manifest a gelatinous subcutis, peripheral, or ventral pitting edema, chemosis, or excessive serous nasal discharge.

When patients have decreased total body sodium, a decreased quantity of fluid is held within the interstitial space and the animal appears dehydrated, regardless of the plasma sodium concentration. Once a patient has lost 5% or more of its body weight in isotonic fluid (≥5% dehydrated), it may manifest decreased skin turgor, tacky or dry mucous membranes, decreased fluid in the conjunctival sac, or sunken eye position. Patients that are less than 5% dehydrated appear clinically normal. Patients with dehydration can become hypovolemic as fluid shifts from the intravascular space into the interstitial space as a result of decreased interstitial hydrostatic pressure.

The sodium-to-water ratio is independent of the total body sodium content: patients may be normally hydrated, dehydrated, or overhydrated (normal, decreased, or increased total body sodium content) and have a normal plasma sodium concentration, hypernatremia, or hyponatremia.

54.3 HYPERNATREMIA

Hypernatremia is defined as plasma or serum sodium concentration above the reference interval. Hypernatremia is common in critically ill dogs and cats.

54.3.1

Etiology

Most dogs and cats with hypernatremia have increased free water loss rather than increased sodium intake or retention.

54.3.1.1

Free Water Deficit

Normal animals can become severely hypernatremic if denied access to water for extended periods. Animals with vomiting, diarrhea, or polyuria of low-sodium fluid may also develop hypernatremia. Diabetes insipidus (DI), a syndrome of inadequate release of or response to ADH, can cause hypernatremia (see Chapter 70, Diabetes Insipidus). Animals with DI become severely hypernatremic when they do not drink water, because they cannot reabsorb free water in the renal collecting duct. Acute or critical illness can unmask previously undiagnosed DI.[4] A syndrome of hypodipsic hypernatremia has been reported in Miniature Schnauzers,[5-7] one of which was diagnosed with congenital holoprosencephaly.[5] This syndrome is most likely due to impaired osmoreceptor or thirst center function. In other dog breeds and cats, hypodipsic hypernatremia has been associated with hypothalamic granulomatous meningoencephalitis, hydrocephalus, and other central nervous system (CNS) deformities and CNS lymphoma.[8-12]

Diagnostic differentiation between central DI, nephrogenic DI, and hypodipsic hypernatremia can be complex and is outside the scope of this chapter. The reader is referred to more detailed texts for further information.[13-15]

54.3.1.2

Sodium Excess

Severe hypernatremia can also occur with the introduction of large quantities of sodium in the form of sodium bicarbonate, sodium phosphate enemas,[16] seawater, beef jerky, and salt-flour dough mixtures.[17]

54.3.2

Clinical Signs

Hypernatremia causes no specific clinical signs in many cases. If it is severe (usually >180 mEq/L) or occurs rapidly, it may be associated with CNS signs such as obtundation, head pressing, seizures, coma, and death. All cells that have Na^+/K^+-ATPase pumps shrink as a result of hypernatremia as water moves out of the cell down its osmotic gradient to the relatively hyperosmolar extracellular compartment, but those of the CNS are clinically the least tolerant of this change in cell volume.

An experimental study found decreased myocardial contractility during injection of hypernatremic or hyperosmolar solutions in dogs.[18] Hypernatremia has also been associated with hyperlipidemia, possibly a result of the inhibition of lipoprotein lipase.[10] Artifactual hemogram changes in the blood of two hypernatremic cats have been reported with a specific hematology analyzer.[19]

54.3.3

Physiologic Adaptation to Hypernatremia

Hypernatremia causes free water to move out of the relatively hypoosmolar intracellular space into the hyperosmolar extracellular space, leading to decreased cell volume. When the cell shrinks, intracellular mechanisms sense the decreased cell volume and build *idiogenic osmoles,* or *osmolytes,* such as inositol to increase intracellular osmolality, which causes water to move back into the cell and restores cell volume to normal. Generation of these idiogenic osmoles begins within a few hours of cell shrinkage, but full compensation takes approximately 24 hours. This restoration of intracellular volume is important for cellular function and is an important consideration during treatment of hypernatremia, as discussed later.

54.3.4 Treatment of the Normovolemic, Hypernatremic Patient

Hypernatremia should be treated, even if no clinical signs are apparent. Patients with hypernatremia have a free water deficit, so free water is replaced in the form of fluid with a lower effective osmolality than that of the patient. Treatment must be cautious, and close monitoring of plasma or serum sodium concentration and CNS signs is imperative.

In patients with mild to moderate hypernatremia ($[Na^+]_p$ <180 mEq/L), sodium concentration should be decreased at a rate of 1 mEq/L/hr. In those with severe hypernatremia ($[Na^+]_p$ ≥180 mEq/L), it should be decreased at a maximum rate of 0.5 to 1 mEq/L/hr. This slow decrease in plasma sodium concentration ($[Na^+]_p$) is important to prevent cellular swelling. Idiogenic osmoles are broken down slowly, so rapid drops in plasma sodium concentration (and thus plasma osmolality) cause free water to move back into the relatively hyperosmolar intracellular space and can lead to neuronal edema.

Free water deficit can be calculated by the formula:

$$\text{Free water deficit} = ([\,\text{current}\,[\text{Na}^+]_p \div \text{normal}\,[\text{Na}^+]_p\,] - 1) \times (0.6 \times \text{body weight in kg})^2$$

This formula gives the total volume of free water that needs to be replaced. This volume of free water, usually 5% dextrose in water, is infused over the number of hours calculated for safe reestablishment of normal plasma sodium concentration. This rate of free water replacement may be inadequate in cases of ongoing free water loss, as seen with diuresis of electrolyte-free water in patients with DI or unregulated diabetes mellitus, but it is a safe starting point in most cases.

Plasma sodium concentration should be monitored no less frequently than every 4 hours to assess the adequacy of treatment, and CNS status should be monitored continuously for signs of obtundation, seizures, or other abnormalities. The rate of free water supplementation should be adjusted as needed to ensure an appropriate drop in plasma sodium concentration, the goal being a drop of no more than 1 mEq/hr and no signs of cerebral edema. Water may be supplemented intravenously (as 5% dextrose in water) or orally on an hourly schedule in animals that are alert, willing to drink, and not vomiting. It is important to note that free water replacement alone will not correct clinical dehydration or hypovolemia, because free water replacement does not provide the sodium required to correct these problems (see Total Body Sodium Content Versus Plasma Sodium Concentration). Free water replacement in the hypernatremic patient is relatively safe, even in animals with cardiac or renal disease, because two thirds of the volume administered will enter the cells.

54.3.5 Complications of Therapy for Hypernatremia

Cerebral edema is the primary complication of therapy for hypernatremia. Clinical signs of cerebral edema include obtundation, head pressing, coma, seizures, and other disorders of behavior or movement. If these signs develop during the treatment of hypernatremia, immediately stop the administration of any fluid that has a lower sodium concentration than the patient and disallow drinking. The patient's plasma sodium concentration should be measured to confirm that it is lower than it was when treatment was instituted. This is an important step, because signs of worsening hypernatremia may be similar to those seen with cerebral edema. If the plasma sodium concentration has decreased, even if it has dropped at less than 1 mEq/L/hr, cerebral edema should be considered.

Cerebral edema is treated with a slow, single bolus dose of mannitol at 0.5 to 1 g/kg IV over 20 to 30 minutes. Mannitol should be administered via a central vein if possible, but it may be diluted 1:1 in sterile water and given through a peripheral vein in an emergency situation. If mannitol is not available, or if a single dose does not improve signs, consider a dose of 7.2% Na^+ sodium chloride at 3 to 5 ml/kg over 20 minutes. The administration method is similar to that used for mannitol. Do not administer hypertonic saline as a rapid bolus, because it can cause vasodilation.

54.4 HYPONATREMIA

Hyponatremia is defined as plasma or serum sodium concentration below the reference interval. Clinically relevant hyponatremia is uncommon in critically ill dogs and cats.

54.4.1 Etiology

Dogs and cats with hyponatremia almost always have free water retention in excess of total body sodium. Generation of hyponatremia usually requires water intake in addition to impaired water excretion.

54.4.1.1 Decreased Effective Circulating Volume

A common cause of hyponatremia in dogs and cats is decreased effective circulating volume, which causes ADH release and water intake in defense of intravascular volume, and thus decreases plasma sodium concentration. Possible causes include congestive heart failure,[3] excessive gastrointestinal losses,[20,21] excessive urinary losses, body cavity effusions,[22,23] and edematous states. Note that in the case of congestive heart failure, the patient has increased total body sodium (is “overhydrated”) because of activation of the renin-angiotensin-aldosterone system, yet is hyponatremic due to increased water retention in excess of sodium retention. In the case of excessive salt and water losses from the GI or urinary tract, the patient is total body sodium depleted (is “dehydrated”) and is hyponatremic due to compensatory water drinking and retention to maintain effective circulating volume.

54.4.1.2 Hypoadrenocorticism

Hypoadrenocorticism leads to hyponatremia through decreased sodium retention (due to hypoaldosteronism) combined with increased water drinking and retention in defense of inadequate circulating volume. Animals with atypical hypoadrenocorticism, whose aldosterone production and release are normal, may also develop hyponatremia, because low circulating cortisol concentration leads to increased ADH release and resultant water retention regardless of intravascular volume status.[24]

54.4.1.3 Diuretics

Thiazide or loop diuretic administration can lead to hyponatremia by induction of hypovolemia, hypokalemia that causes an intracellular shift of sodium in exchange for potassium, and the inability to dilute urine.[24] Renal failure can cause hyponatremia by similar mechanisms.

54.4.1.4 Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate ADH secretion (SIADH) causes hyponatremia through water retention in response to improperly high circulating concentrations of ADH. The syndrome has been reported in dogs[25,26] and has many known causes in humans[24] (see Chapter 71, Syndrome of Inappropriate Antidiuretic Hormone).

54.4.1.5 Other Causes of Hyponatremia

Hyponatremia has been reported in animals with GI parasitism,[21] other infectious diseases,[27,28] psychogenic polydipsia, and pregnant dogs.[29] A syndrome of cerebral salt wasting has been described in humans with CNS disease but has not been reported clinically in dogs or cats. Cerebral salt wasting is differentiated from SIADH by evaluation of hydration status: patients with cerebral salt wasting are clinically dehydrated because of a decrease in total body sodium content, and those with SIADH are usually adequately hydrated with excessive free water retention.[30]

54.4.2 Clinical Signs

Mild to moderate hyponatremia usually causes no specific clinical signs. If hyponatremia is severe (usually <120 mEq/L) or occurs rapidly, it may be associated with CNS signs such as obtundation, head pressing, seizures, coma, and death. All cells that have Na^+/K^+-ATPase pumps swell as a result of hyponatremia as water moves into the relatively hyperosmolar cell from the hypoosmolar extracellular space, but those of the CNS are clinically the least tolerant of this change in cell volume.

An experimental study found increased myocardial contractility during injection of hyponatremic or hypoosmolar solutions in dogs.[18] Hyponatremia decreases renal concentrating ability in dogs.[31] There is one report of artifactual hemogram changes in canine blood secondary to hyponatremia using a specific hematology analyzer.[19]

54.4.3 Physiologic Adaptation to Hyponatremia

Hyponatremia causes free water to move into the relatively hyperosmolar cell from the hypoosmolar extracellular space, leading to increased cell volume. Interstitial and intracellular CNS edema increases intracranial tissue hydrostatic pressure. This pressure enhances fluid movement into the cerebrospinal fluid, which flows out of the cranium, through the subarachnoid space and central canal of the spinal cord, and back into venous circulation. Swollen neurons also expel solutes such as sodium, potassium, and organic osmolytes to decrease intracellular osmolality and encourage water loss to the ECF, returning cell volume toward normal. Ion expulsion occurs rapidly, but loss of organic osmolytes requires hours to days. Therefore clinical signs associated with hyponatremia, and potential complications of management, are associated with both the magnitude and rate of sodium concentration change.

54.4.4 Treatment of the Normovolemic, Hyponatremic Patient

The general goal in the treatment of hyponatremia is to raise plasma sodium concentration slowly toward the lower end of the reference interval, at a rate no greater than 0.5 to 1 mEq/L per hour. The exception is in cases of symptomatic or severe hyponatremia ($[Na^+]_p$ <120 mEq/L), when a rapid increase of plasma sodium to 120 mEq/L is desirable.

Hyponatremia due to decreased effective circulating volume is most often mild ($[Na^+]_p \geq 130$ mEq/L) and usually self-corrects with appropriate treatment of the underlying disease. Fluids with a sodium concentration less than that of the patient should be avoided. The plasma sodium concentration and the patient's CNS status should be monitored regularly, but complications of hyponatremia or its treatment are unlikely to occur in these situations. Patients with hyponatremia due to congestive heart failure will likely remain hyponatremic as a result of diuretic administration, the resultant polydipsia, and ingestion of a low-sodium diet.

Patients with moderate to severe hyponatremia ($[Na^+]_p$ <130 mEq/L), or with CNS signs due to hyponatremia, 227

228 should be managed carefully. Asymptomatic patients that are edematous may be treated with water restriction alone, and those that are asymptomatic and normally hydrated or dehydrated may be treated with administration of fluids containing a higher sodium concentration than that of the patient.

In the emergency situation of symptomatic hyponatremia, when plasma sodium concentration is less than 120 mEq/L, or in cases in which conservative treatment is ineffective, therapy is more aggressive. The most reliable method for ensuring excretion of free water is administration of mannitol (0.5 to 1 g/kg IV over 20 to 30 minutes) along with furosemide (0.5 to 1 mg/kg IV) to ensure that electrolyte-free water is excreted along with the mannitol. Fluid loss should be replaced with standard replacement intravenous fluids, unless the patient is overhydrated and the fluid loss desired. Further explanation of this technique is available for review elsewhere.[32] The goal is to raise the plasma sodium concentration by no more than 10 mEq/L during the first 24 hours, and by no more than 18 mEq/L during the first 48 hours of treatment, never to exceed the low end of the reference interval. The limit of 10 mEq/L during the first day of treatment is more important than the rate over a specific period within that day.[24] It seems reasonable to be even more cautious in asymptomatic patients to minimize the likelihood of complications.

54.4.5 Complications of Therapy for Hyponatremia

The major complication of treatment for hyponatremia is myelinolysis. Myelinolysis is a result of neuronal shrinking away from the myelin sheath as water moves out of the neuron during correction of hyponatremia. Clinical signs of myelinolysis usually manifest many days after intervention, so the clinician cannot assume that a rapid change in plasma sodium concentration has been well tolerated simply because no CNS signs are present during initial treatment. Overzealous correction of severe hyponatremia has led to paresis, ataxia, dysphagia, obtundation, and other neurologic signs in dogs.[33-36] All of these dogs had initial plasma sodium concentrations of less than 110 mEq/L, and all had sodium concentration corrections that exceeded the above- recommended rate. Myelinolysis lesions in dogs are commonly seen in the thalamus, rather than the pons as in humans. Patients with myelinolysis may recover with intensive supportive treatment, although some do not.

Because the signs of myelinolysis are delayed, it is rare for a patient to develop abnormal CNS signs during initial treatment of hyponatremia. However, if new neurologic signs develop during treatment, administration of any fluid that is hyperosmolar to the patient (mannitol, hypertonic or isotonic fluids) should be stopped. The patient's plasma sodium concentration is checked to confirm that it has increased. This is an important step, because signs of worsening hyponatremia may be similar to those seen with treatment. If the plasma sodium concentration is higher than it was at the initiation of treatment, even if the concentration has increased slowly, CNS damage should be considered. Treatment of CNS signs due to overly rapid correction of hyponatremia requires administration of free water to drop the plasma sodium concentration by 1 mEq/L. Decreasing sodium concentration in an already hyponatremic animal can be difficult unless the patient is treated with a loop diuretic such as furosemide to clamp urine osmolality, and water is replaced simultaneously.

54.5 PSEUDOHYPONATREMIA

Pseudohyponatremia is the term used to describe hyponatremia in a patient with normal or elevated plasma osmolality. The most common cause of pseudohyponatremia in dogs and cats is hyperglycemia. Glucose is an effective osmole, so when hyperglycemia is present, the excess glucose molecules cause an increase in ECF water, diluting sodium to a lower concentration. For each 100 mg/dl increase in blood glucose, sodium concentration drops by approximately 1.6 mEq/L.[24] This effect is nonlinear, however; mild hyperglycemia leads to smaller changes in plasma sodium concentration than more severe hyperglycemia (see Chapter 68, Hyperglycemic Hyperosmolar Syndrome, for more information about this condition in diabetes mellitus). Pseudohyponatremia does not require specific treatment, and the sodium concentration will increase as the hyperglycemia resolves and water moves back into the cells. The other common cause of pseudohyponatremia in dogs and cats is mannitol infusion with retention (rather than renal excretion) of mannitol molecules.

54.6 VOLUME EXPANSION IN THE HYPOVOLEMIC, HYPONATREMIC, OR HYPERNATREMIC PATIENT

Patients with moderate to severe abnormalities in sodium concentration ($[Na^+]_p$ <130 or >170) that require intravascular volume expansion should be resuscitated with a fluid that has a sodium concentration that matches that of the patient (± 6 mEq/L). Hyponatremic animals may be resuscitated with a balanced electrolyte solution containing 130 mEq/L sodium if appropriate, or with a maintenance solution that has sodium chloride added to bring the sodium concentration of the solution up to that of the patient. Hypernatremic animals should be resuscitated with a balanced electrolyte solution with NaCl added in a quantity sufficient to bring the solution's sodium concentration up to that of the animal. The simplest way to add sodium to a bag of commercially available fluid is to add 23.4% NaCl to the bag. This product contains 4 mEq NaCl per ml of solution, so it adds a significant quantity of sodium in a small volume.

55 Chapter 55 Potassium Disorders

Laura L. Riordan, DVM

Michael Schaer, DVM, DACVIM, DACVECC

55.1 KEY POINTS

- Normal serum potassium concentration is essential for normal neuromuscular function.
- Common predisposing conditions for potassium abnormalities include diabetes mellitus, chronic renal disease (especially in cats), and metabolic alkalosis.
- The main clinical manifestation in the dog and cat is hypokalemic myopathy.
- Rate of potassium infusion rather than total amount infused is of major therapeutic importance.
- Mild to moderate hypokalemia (serum potassium 2.5 to 3.5 mEq/L) can be corrected at a rate up to 0.5 mEq/kg per hour.
- Decreased renal excretion is the most common cause of hyperkalemia in small animal patients.
- Before determination of serum potassium level in any hyperkalemic patient or in any animal with urinary tract obstruction, an electrocardiogram (ECG) should be evaluated to detect bradycardia, atrial standstill, or ventricular arrhythmias.
- Renal failure, hypoadrenocorticism, and gastrointestinal disease are the most common causes of sodium-to-potassium ratios less than 27:1.
- When serum potassium exceeds 8 mEq/L or severe ECG changes are present, immediate therapy directed toward reducing and antagonizing serum potassium is warranted (i.e., 10% calcium gluconate, sodium bicarbonate, dextrose with or without insulin).

55.2 INTRODUCTION

Few of the disturbances in fluid and electrolyte metabolism are as frequently encountered or as immediately life threatening as disturbances in potassium balance. Many clinicians are already sensitized to the detrimental effects of potassium disorders, especially hyperkalemia, but sometimes the adverse effects of hypokalemia are nearly as harmful. This chapter will discuss the clinical essentials of hypokalemia and hyperkalemia in the dog and cat and show why both are important to patient care.

55.2.1 Normal Distribution of Potassium in the Body

Potassium is the most abundant intracellular cation, with 98% to 99% located in the intracellular compartment. Most intracellular potassium lies in the skeletal muscle cells. The average potassium concentration in the intracellular space of dogs and cats is 140 mEq/L, and that in the plasma space averages 4 mEq/L.[1,2] Serum potassium levels therefore do not reflect tissue concentrations.

55.3 HYPOKALEMIA

55.3.1 Definition and Causes

Hypokalemia occurs when the serum potassium concentration is less than 3.5 mEq/L (normal range 3.5 to 5.5 mEq/L). The general causes of hypokalemia are: (1) disorders of internal balance and (2) disorders of external balance. The clinical conditions most commonly associated with each of these are provided in Box 55-1.

55.3.2 Consequences

Abnormalities resulting from hypokalemia are divided into four categories: metabolic, neuromuscular, renal, and cardiovascular. Glucose intolerance is the most notable adverse metabolic effect of hypokalemia. Experiments have shown that release of insulin from the pancreatic β-cells is impaired when total body potassium levels are decreased.[10]

Potassium is necessary for maintenance of normal resting membrane potential. Subsequently, the most significant neuromuscular abnormality induced by hypokalemia in dogs and cats is skeletal muscle weakness from hyperpolarized (less excitable) myocyte plasma membranes that may progress to hypopolarized membranes.[9-12] Ventroflexion of the head and neck, a stiff, stilted gait, and a plantigrade stance may also be evident. In cats, hypokalemic myopathy typically is associated with chronic renal disease and poorly regulated diabetes mellitus.[2,13] It can also result from a potassium-deficient diet.[13] Frank paralysis and death due to diaphragmatic failure and respiratory muscle failure can occur in severe cases. Hypokalemia can also cause rhabdomyolysis, which may have a toxic effect on the renal tubules.[9,11] Smooth muscle impairment can also occur, leaving the patient with paralytic ileus and gastric atony.[7] These neuromuscular signs are seldom present until serum potassium levels fall below 2.5 mEq/L. Cats with chronic renal disease can become markedly potassium depleted, and the resulting hypokalemia can impair renal tubular function.[2,13,14]

In the myocardial cell, a high intracellular-to-extracellular potassium concentration ratio induces a state of electrical hyperpolarization leading to prolongation of the action potential. This may predispose the patient to atrial and ventricular tachyarrhythmias, atrioventricular dissociation, and ventricular fibrillation. Abnormal ECG findings in animals with hypokalemia are less reliable than in those with hyperkalemia.[15] Canine ECG abnormalities include depression of the ST segment and prolongation of the QT interval (Figure 55-1).[16] Increased P wave amplitude, prolongation of the PR interval, and widening of the QRS complex may also occur. In addition, hypokalemia predisposes to digitalis-induced cardiac arrhythmias and causes the myocardium to become refractory to the effects of class I antiarrhythmic agents (lidocaine, quinidine, and procainamide).

55.3.3 Treatment of Hypokalemia

The main treatment objectives include replacing the potassium deficits and correcting the primary underlying disease process. Potassium gluconate powder is a convenient form of dietary supplementation for dogs and cats that is given orally in food twice daily at a recommended dosage of ¼ teaspoonful (2 mEq) per 4.5 kg body weight. The maintenance dosage should be titrated to effect. Its use is limited to animals that can be fed by mouth or by gastroenteral routes.

55.3.3.1

Box 55-1 Causes of Hypokalemia[3-8]

55.3.3.1.1

Disorders of Internal Balance (Redistribution)

Metabolic alkalosis

Insulin administration

Increased levels of catecholamines

β-Adrenergic agonist therapy or intoxication

Refeeding syndrome

55.3.3.1.2

Disorders of External Balance (Depletion)

Renal potassium wasting

Prolonged inadequate intake

Diuretic drugs

Osmotic or postobstructive diuresis

Chronic liver disease

Inadequate parenteral fluid supplementation

Aldosterone-secreting tumor

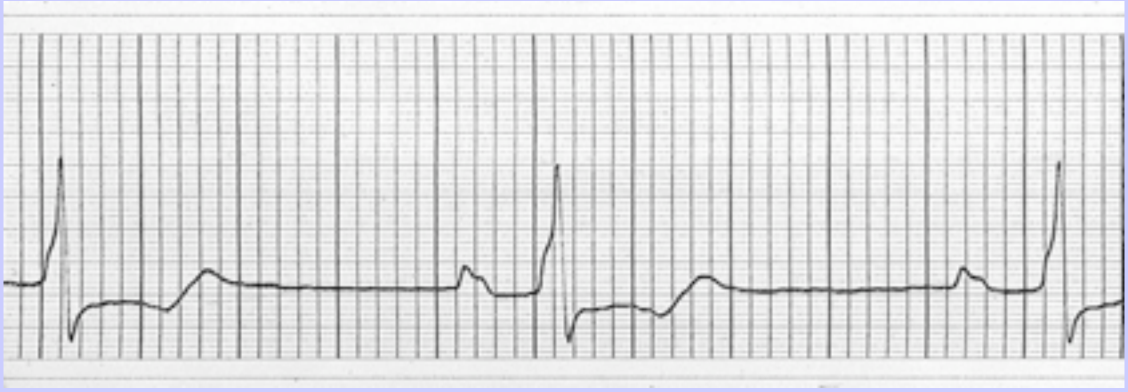
Prolonged vomiting associated with pyloric outflow obstruction

Diabetic ketoacidosis

Renal tubular acidosis

Severe diarrhea

Figure 55-1 Lead II electrocardiogram taken from a dog with a serum potassium measuring 2.1 mEq/L. Note the increased P wave amplitude, the depressed ST segment, and the depressed T waves.



Treatment of moderate (2.5 to 3 mEq/L) to severe (<2.5 mEq/L) hypokalemia in the anorectic or vomiting patient requires parenteral administration of potassium chloride solution (or potassium phosphate in hypophosphatemic patients; Table 55-1). The rate of potassium infusion should seldom exceed 0.5 mEq/kg/hr for mild to moderate hypokalemia.[17] In profoundly hypokalemic patients with normal or increased urine output (serum potassium <2 mEq/L), the rate can be increased cautiously to 1 to 1.5 mEq/kg/hr along with close ECG monitoring.[17] Conditions that may predispose an animal to adverse effects of a potassium infusion include oliguria and anuria, hypoaldosteronism (Addison's disease), and coadministration of potassium-sparing drugs. In a patient with metabolic acidosis, potassium chloride can be added to the buffer-containing intravenous fluids, whereas potassium chloride is added preferentially to normal saline solution for the patient with metabolic alkalosis.

It is important to remember that these values are only ranges that must be adjusted to each patient's pathophysiologic needs. This is exemplified by the severely oliguric or anuric animal requiring minimal 230 maintenance amounts of parenteral potassium chloride, in contrast with the polyuric ketoacidotic diabetic patient 231 receiving regular crystalline insulin, that will require much higher amounts. Animals with distributive shock should be resuscitated with an isotonic crystalloid solution before adding potassium chloride to the crystalloid fluid infusion. In the severely hypokalemic patient (serum potassium <2 mEq), it is prudent to begin potassium treatment during the rehydration period, either as a separate infusion or at a lower fluid rate in order to stay within acceptable guidelines for potassium infusion (0.5 to 1.5 mEq/kg/hr). Administration of sodium bicarbonate or insulin to hypokalemic diabetic patients should be postponed for the first 4 to 8 hours to correct the serum potassium level to greater than 3.5 mEq/L. Failure to do so can lead to marked hypokalemia.

Table 55-1 Guidelines for Routine Intravenous Supplementation of Potassium in Dogs and Cats

Serum Potassium Concentration (mEq/L)	mEq KCl to Add to 250 ml Fluid*	mEq KCl to Add to 1 L Fluid	Maximal Fluid Infusion Rate† (ml/kg/hr)
<2	20	80	6
2.1 to 2.5	15	60	8
2.6 to 3	10	40	12
3.1 to 3.5	7	28	18
3.6 to 5	5	20	25

From Greene RW, and Scott RC: Lower urinary tract disease. In Ettinger SJ, editor: *Textbook of veterinary internal medicine,* Philadelphia, 1975, Saunders.

* It is essential to shut off the flow valve to the patient and that the fluid container contents are thoroughly mixed during and after adding potassium to the parenteral fluids.

† So as not to exceed 0.5 mEq/kg/hr.

55.3.4 Anticipated Complications

Hyperkalemia can occur from excessive potassium supplementation. This is covered in the next section. Hypokalemic neuromuscular dysfunction is worsened and refractoriness to therapy may be evident when hypomagnesemia and hypocalcemia coexist. It is important to correct all serum electrolyte deficiencies to attain normal neuromuscular function (see Chapters 57 and 58, Magnesium Disorders and Phosphate Disorders, respectively).

55.4 HYPERKALEMIA

55.4.1 Definition and Causes

Hyperkalemia occurs when the serum potassium concentration exceeds 5.5 mEq/L and is considered life threatening at serum concentrations greater than 7.5 mEq/L. Hyperkalemia can result from four basic disturbances: increased intake or administration, translocation from the intracellular to the extracellular fluid space, decreased renal excretion, and an artifactual or pseudohyperkalemia (Box 55-2).

Excessive potassium supplementation (potassium chloride or potassium phosphate) in intravenous fluids or overly rapid rates of administration can lead to hyperkalemia. To avoid cardiotoxicity, under most circumstances the intravenous rate should not exceed 0.5 mEq/kg/hr. Hyperkalemia can also occur from the administration of packed red blood cells that are past the expiration date or angiotensin-converting enzymes, potassium-sparing diuretics, or nonselective β-blocking drugs combined with potassium supplementation.

An increased movement of potassium out of cells can lead to hyperkalemia, as seen with a mineral acidosis (uremic, respiratory, or induced by ammonium chloride, hydrogen chloride, or calcium chloride infusions) causing potassium to move out of the intracellular space in exchange for hydrogen ions. This extracellular translocation of potassium can also occur with snakebites, heat stroke, crushing injuries, or tumor lysis syndrome associated with chemotherapy and radiation in dogs with lymphosarcoma.[19,20] Hyperkalemia has also been reported in cats treated with thrombolytic agents for aortic thromboembolism as a result of reperfusion of the affected limb(s).[21]

Although osmotic diuresis decreases the total body potassium concentration in diabetic ketoacidosis, hyperkalemia may occur as a result of decreased cellular uptake of potassium secondary to insulin deficiency, extracellular translocation of potassium with water due to serum hyperosmolality (“solute drag”), increased protein catabolism, prerenal azotemia, and any coexisting renal impairment. Insulin therapy normalizes the serum potassium concentration by correcting the insulin deficiency and hyperosmolality while decreasing the need for protein catabolism.

Decreased urinary excretion secondary to renal or postrenal disease is the most common cause of hyperkalemia in small animal patients. In animals with complete urinary obstruction or uroabdomen, an ECG should be evaluated for evidence of hyperkalemia while the serum potassium concentration is determined. Intravenous, potassium-free fluids such as 0.9% saline should be administered, as indicated, and further steps to reduce serum potassium or reduce the cardiotoxic effects of hyperkalemia should be taken if cardiac arrhythmias are present (see Treatment of Hyperkalemia section).

Oliguria and anuria are most commonly associated with acute tubular damage, however oliguria can also occur with end-stage chronic renal failure. The distal tubule is dependent on both adequate glomerular filtration rate and urine flow to excrete potassium effectively. The severe reduction in both of these determinants with acute renal failure significantly impairs the ability of the distal tubule to excrete sufficient potassium. Attempts to restore a normal effective circulating volume are essential to improving urine output and urinary potassium excretion. If no urine is produced after fluid therapy, additional measures should be taken (e.g., furosemide or mannitol), in attempts to convert the oliguric or anuric patient to a nonoliguric state (see Chapters 135 and 180, Acute Renal Failure and Diuretics, respectively).

Patients with classic, severe hypoadrenocorticism typically have hyperkalemia and hyponatremia and a sodium-to-potassium ratio less than 27:1. An adrenocorticotropic hormone stimulation test is essential to differentiate this disease from acute renal failure, because these patients might also be azotemic. Natriuresis in the absence of 231
aldosterone leads to a reduced effective circulating volume, which further impairs distal tubule potassium 232
excretion. This volume depletion also leads to reduced renal perfusion, prerenal azotemia, and further potassium retention. Initial therapy should include restoration of the effective circulating volume with potassium-free or potassium-deficient fluids (see Chapter 76, Hypoadrenocorticism).

55.4.1.1 Box 55-2 Causes of Hyperkalemia

55.4.1.1.1 Increased Intake or Supplementation

Intravenous potassium-containing fluids

Expired RBC transfusion

Translocation from ICF to ECF

Mineral acidosis (NH_4Cl, HCl)

Diabetes mellitus with ketoacidosis or hyperosmolality

Acute tumor lysis syndrome

Extremity reperfusion following therapy for thromboembolism

55.4.1.1.2 Decreased Urinary Excretion

Anuric or oliguric renal failure

Urethral obstruction

Ruptured urinary bladder

Hypoadrenocorticism

Gastrointestinal disease (trichuriasis, salmonellosis, perforated duodenum)

Chylothorax with mechanical drainage

Drugs (ACE inhibitors, potassium-sparing diuretics, nonspecific β-blockers)

Pseudohyperkalemia

Thrombocytosis or leukocytosis

Akita dog and other dogs of Japanese origin

ACE, Angiotensin-converting enzyme; *ECF,* extracellular fluid; *HCl,* hydrogen chloride; *ICF,* intracellular fluid; *NH_4Cl,* ammonium chloride; *RBC,* red blood cell.

Gastrointestinal disease, especially that associated with trichuriasis, salmonellosis, or duodenal perforation, can be associated with hyperkalemia and a reduced sodium-to-potassium ratio (<27:1).[22,23] Chronic chylothorax managed by intermittent or continual drainage can result in hyperkalemia and hyponatremia.[24] In addition, these abnormalities were reported in a dog with a lung lobe torsion, another with a neoplastic pleural effusion, and three at-term pregnant Greyhounds.[25-27] Although the mechanism of hyperkalemia in such patients is unclear, a reduction in effective circulating volume and subsequent reduced distal renal tubular flow could lead to deficient urinary potassium excretion.

55.4.2 Consequences

Muscle weakness can occur when serum potassium concentrations exceed 7.5 mEq/L. Hyperkalemia may cause bradycardia or atrial standstill due to prolonged depolarization and repolarization of the myocardial conduction system. ECG findings do not correlate precisely with serum potassium concentrations; however, generalizations can be made as to the progression of waveform and conduction changes (Table 55-2).[18]

55.4.3 Pseudohyperkalemia

Potassium can be released from increased numbers of circulating blood cells, especially platelets and white blood cells, causing an artifactual increase in potassium termed *pseudohyperkalemia*. This is seen primarily in animals with severe thrombocytosis or leukocytosis. Pseudohyperkalemia can also be seen in Akita dogs (or other dogs of Japanese origin) secondary to in vitro hemolysis, because their erythrocytes have a functional sodium-potassium adenosine triphosphatase and, as such, have high intracellular potassium concentrations. This potassium is released and causes an artifactual hyperkalemia if hemolysis occurs in the serum blood tube. Confirmation of pseudohyperkalemia can be made by determining the plasma potassium concentration (blood collected in a heparinized tube) as this should not be affected by changes in platelet or white blood cell numbers.

55.4.4 Treatment of Hyperkalemia

An ECG should be performed in any patient with suspected or confirmed hyperkalemia. In asymptomatic animals with normal urine output, serum potassium concentrations between 5.5 and 6.5 mEq/L rarely warrant immediate therapy; however, the cause of the hyperkalemia should be investigated. In all hyperkalemic patients, exogenous potassium administration should be discontinued. Intravenous potassium-free or potassium-deficient isotonic crystalloids can be administered to promote diuresis, and this alone may be sufficient to correct mild hyperkalemia (≤6 mEq/L). Loop (furosemide 1 to 4 mg/kg) or thiazide (chlorothiazide 10 to 40 mg/kg, hydrochlorothiazide 2 to 4 mg/kg) diuretics can increase urinary potassium excretion; however, their use must follow rehydration. Drugs that promote hyperkalemia, such as angiotensin-converting enzyme inhibitors, β-adrenergic antagonists, and potassium-sparing diuretics, should be discontinued. Immediate therapy is directed toward reducing and antagonizing serum potassium in patients with severe ECG changes or when the serum potassium concentration exceeds 8 mEq/L. Ten percent calcium gluconate or calcium chloride can be administered to antagonize the cardiotoxic effects of hyperkalemia, but this has no effect on serum potassium concentrations. β-Adrenergic agonists, sodium bicarbonate, and dextrose with or without insulin can be administered to reduce serum potassium concentrations as described in Table 55-3. Peritoneal dialysis and hemodialysis will effectively treat hyperkalemia that is not responsive to the above-mentioned interventions.

Table 55-2 Electrocardiographic Changes With Hyperkalemia[18]

Serum Potassium Concentration	Electrocardiographic Change
>5.5 mEq/L	Peaked, narrow T wave
>6.5 mEq/L	Prolonged QRS complex and PR interval
	Depressed R wave amplitude
	Depressed ST segment
>7 mEq/L	Depressed P wave amplitude
>8.5 mEq/L	Atrial standstill
	Sinoventricular rhythm
>10 mEq/L	Biphasic QRS complex
	Ventricular flutter
	Ventricular fibrillation
	Ventricular asystole

Table 55-3 Treatment of Life-Threatening Hyperkalemia

Drug	Dosage	Mechanism of Action	Onset of Action
10% Calcium gluconate	0.5 to 1.5 ml/kg IV slowly over 5 to 10 minutes with ECG monitoring	Allows for decreased cardiacmuscle membrane potential but will not lower serum potassium	3 to 5 minutes
Sodium bicarbonate	1 to 2 mEq/kg IV slowly over 15 minutes	Causes metabolic alkalosis allowing for potassium to move intracellularly	15 minutes
25% Dextrose	0.7 to 1 g/kg IV over 3 to 5 minutes	Allows for translocation of potassium into the intracellular space	<1 hour
25% Dextrose with insulin	Regular insulin at *0.5 U/kg IV with IV dextrose at 2 g/U of insulin administered	As above	30 minutes
Terbutaline	0.01 mg/kg IV slowly	Stimulates Na^+/K^+-ATPase to cause translocation into the cell	20 to 40 minutes

ECG, Electrocardiographic; *IV*, intravenous; *Na^+/K^+-ATPase*, sodium-potassium adenosine triphosphatase.

* With hypoadrenocorticism the insulin dosage should be reduced to 0.25 U/kg IV because of the patient's predisposition to hypoglycemia.

56 Chapter 56 Calcium Disorders

Todd Green, DVM

Dennis Chew, DVM, DACVIM

56.1 KEY POINTS

- Severe hypercalcemia or hypocalcemia can be lethal in dogs and cats, especially if extremes of serum calcium concentration develop rapidly.
- Disorders of hypocalcemia are encountered more commonly than are disorders of hypercalcemia.
- Hypocalcemia based on total serum calcium is often mild and less frequently requires calcium-specific management than does hypercalcemia.
- Toxicity of hypercalcemia is greatly magnified if the serum phosphorus concentration is also increased.
- No calcium-specific management is indicated when the total serum calcium is increased but the ionized calcium level is normal.
- No calcium-specific management is indicated when the total serum calcium is decreased, but the ionized calcium level is normal.
- Hypercalcemic crisis is most likely to be encountered when there is toxicity from excess vitamin D metabolites circulating in the body.
- Acute management of moderate to severe ionized hypercalcemia involves intravenous saline, furosemide, calcitonin, and glucocorticoids.
- Severe hypercalcemia may benefit from intermittent intravenous doses of bisphosphonates to decrease osteoclast function. Pamidronate is the first-choice bisphosphonate in veterinary medicine, but zoledronate is more potent and is achieving greater popularity among oncologists.
- In many instances, management of severe and symptomatic hypocalcemia involves the administration of immediate intravenous boluses of calcium salts followed by a continuous rate infusion to maintain normal serum ionized calcium levels.
- Ionized hypocalcemia occurs more frequently than predicted when only the total serum calcium is measured, especially in the critical care setting.

56.2 CALCIUM HOMEOSTASIS

Calcium is an important electrolyte that is crucial for numerous intracellular functions, extracellular functions, and skeletal bone support. Calcium is necessary for muscle contraction; ionized calcium mediates acetylcholine release during neuromuscular transmission. Calcium also stabilizes nerve cell membranes by decreasing membrane permeability to sodium. Because of the complexity of its functions, normal homeostatic control mechanisms attempt to keep serum calcium within a narrow range. When these homeostatic mechanisms are disrupted or overwhelmed, conditions of hypocalcemia and hypercalcemia can occur. Three primary forms of calcium exist in serum and plasma: ionized (free), protein bound, and complexed (calcium bound to phosphate, bicarbonate, lactate, citrate, oxalate).[1] The ionized form of calcium is the biologically active form in the body and is considered the most important indicator of functional calcium levels.

Calcium regulation is a complex process involving primarily parathyroid hormone (PTH), vitamin D metabolites, and calcitonin. These calcium regulatory hormones exert most of their effects on the intestine, kidney, and bone. PTH is synthesized and secreted by the chief cells of the parathyroid gland in response to hypocalcemia or low calcitriol levels (also known as $1,25(OH)_2D_3$, the principal active vitamin D metabolite). PTH is synthesized and secreted constantly at low rates to maintain serum ionized calcium levels within a narrow range in healthy animals. PTH secretion normally is inhibited by increased serum ionized calcium levels, as well as by increased concentration of circulating calcitriol. The principal action of PTH is to increase blood calcium levels through increased tubular reabsorption of calcium, increased osteoclastic bone resorption, and increased production of $1,25(OH)_2D_3$.

Vitamin D and its metabolites also play a central role in calcium homeostasis. Dogs and cats, unlike humans, photosynthesize vitamin D inefficiently in their skin and therefore depend on vitamin D in their diet.[2] After ingestion and uptake, vitamin D is first hydroxylated in the liver to $25(OH)D_3$ (calcidiol), and then it is further hydroxylated to calcitriol by the proximal tubular cells of the kidney. This final hydroxylation by the 1α-hydroxylase enzyme system to form active calcitriol is under tight regulation, and is influenced primarily by serum PTH, calcitriol, phosphorus, and calcium concentrations. Decreased levels of phosphorus, calcitriol, and calcium promote calcitriol synthesis, and increased levels of these substances all cause a decrease in calcitriol synthesis.

In terms of calcium homeostasis, calcitriol primarily acts on the intestine, bone, kidney, and parathyroid gland. In the intestine, calcitriol enhances the absorption of calcium and phosphate at the level of the enterocyte. In the bone, calcitriol promotes bone formation and mineralization by regulation of proteins produced by osteoblasts. In addition, calcitriol is also necessary for normal bone resorption because of its effect on osteoclast differentiation. In the kidney, calcitriol acts to inhibit the 1α-hydroxylase enzyme system, as well as to promote calcium and phosphorus reabsorption from the glomerular filtrate. In the parathyroid gland, calcitriol acts to inhibit the synthesis of PTH.

Although minor when compared with the effects of PTH and the vitamin D metabolites, calcitonin also plays a role in calcium homeostasis. It is produced in the thyroid gland in response to increased concentration of calcium following a calcium-rich meal and also during hypercalcemia. Calcitonin acts on the bone to inhibit osteoclastic bone resorption activity.

56.3 CALCIUM MEASUREMENT

56.3.1 Sample Handling Techniques

When sampling patients for calcium measurements, the patient should fast before collection if possible. Both serum and heparinized plasma samples can be used. When plasma samples are used, certain anticoagulants such as oxalate, citrate, and ethylenediaminetetraacetic acid should not be used, because they can dramatically lower calcium levels when measured in the laboratory. When measuring ionized calcium, serum is preferred over whole or heparinized blood. In addition, anaerobic samples are preferred for ionized calcium measurement, because pH can alter the concentration. In aerobic conditions, carbon dioxide can be lost, thus raising the pH in the sample. An alkalotic pH may increase the binding of calcium to protein and therefore artificially decrease the amount of ionized calcium in the sample. Aerobic samples can be used with reasonable diagnostic accuracy for ionized calcium measurement when sent to a referral laboratory, but species-specific correction formulas are needed that correct the sample pH to 7.40. Hand-held point-of-care analyzers consistently report ionized calcium values that are less than those from bench machines; this error increases with the magnitude of the calcium being measured.[3]

56.3.2 Ionized Versus Total Calcium

The calcium status of most animals usually is obtained first via measurement of total calcium. However, this parameter frequently does not reflect the ionized calcium concentration of the diseased patient,[4] especially in critically ill animals. Therefore, for accurate assessment of patient calcium status, measurement of ionized calcium is recommended. So-called correction formulas that are used to predict ionized calcium status from total serum calcium are quite inaccurate.[4]

56.4 HYPERCALCEMIA

Hypercalcemia can be caused by numerous disease processes (Box 56-1) and may exert toxic systemic effects in multiple organs when ionized hypercalcemia is present.

56.4.1 Clinical Signs and Diagnosis

Clinical signs associated with hypercalcemia loosely parallel the severity of calcium elevation. Common signs include polyuria and polydipsia (dogs, not cats), anorexia, constipation, lethargy, and weakness. Severely affected animals may display ataxia, obtundation, listlessness, muscle twitching, seizures, or coma. Bradycardia may be detected on physical examination, and electrocardiographic (ECG) monitoring may reveal a prolonged PR interval, widened QRS complex, shortened QT interval, shortened or absent ST segment, and a widened T wave. Bradyarrhythmias may progress to complete heart block, asystole, and cardiac arrest in severely affected animals. Other abnormalities may also be secondary to the underlying disease process causing the hypercalcemia.

Usually hypercalcemia is documented initially during measurement of serum total calcium as part of the animal's diagnostic workup for the clinical signs. Normal calcium values for dogs and cats can have a wide range and can differ from laboratory to laboratory, so reference values should be used from the laboratory to which the sample was submitted. In general, normal total calcium values are approximately 10 mg/dl for dogs and 9 mg/dl for cats. These values are for mature animals, because growing animals (dogs especially) can have higher total calcium values, likely secondary to normal bone growth. Once a diagnosis of hypercalcemia is suspected based on the total calcium value (>12 mg/dl in the dog and <11 mg/dl in the cat), an ionized calcium measurement should be performed to confirm the diagnosis.

A diagnosis of hypercalcemia is confirmed with an ionized calcium measurement greater than 6 mg/dl or 1.5 mmol/L in the dog or greater than 5.7 mg/dl or 1.4 mmol/L in the cat. The increase in ionized calcium typically parallels the increase in total serum calcium except in animals with renal failure, in which the increase in total calcium is caused by calcium binding with citrate, phosphate, or bicarbonate.

Once the hypercalcemia is confirmed, a thorough physical examination should be repeated. The clinician should palpate the anal sacs (dogs) and peripheral lymph nodes for any enlargement, perform a fundic examination, and do a thorough evaluation for any masses that may have been missed on initial examination (e.g., mammary tumors). Further diagnostic maneuvers should be tailored to the individual patient based on clinical signs, physical examination findings, initial laboratory testing, and suspected etiology, but may include a complete blood cell count, chemistry panel, urinalysis, imaging (thoracic radiographs, abdominal radiographs, abdominal ultrasonography, parathyroid ultrasonography), fine-needle aspiration with cytologic evaluation of any masses found, PTH measurement, PTH-related protein measurement, calcidiol measurement, calcitriol measurement, bone biopsy, and bone marrow aspiration.

56.4.1.1 Box 56-1 Differential Diagnoses for Hypercalcemia

56.4.1.1.1 Nonpathologic

Postprandial

Juvenile, growing animal

Laboratory error

Lipemia

56.4.1.1.2 Transient or Inconsequential

Hemoconcentration

Hyperproteinemia

Hypoadrenocorticism

56.4.1.1.3 Pathologic or Persistent/Consequential

56.4.1.1.3.1 Parathyroid Dependent

Primary hyperparathyroidism

- Adenoma
- Adenocarcinoma
- Hyperplasia
- Overdose recombinant PTH

56.4.1.1.3.2

Parathyroid Independent

Malignancy

Humoral hypercalcemia of malignancy

- Lymphosarcoma
- Anal sac apocrine gland adenocarcinoma
- Carcinoma (thyroid, prostate, mammary, etc.)
- Thymoma

Hematologic malignancies (bone marrow osteolysis, local osteolytic disease)

- Lymphosarcoma
- Multiple myeloma
- Leukemia
- Myeloproliferative disorders

Bone neoplasia (primary or metastatic)

Idiopathic hypercalcemia (cats)

Chronic renal failure

Calcinosis cutis—during recovery, especially after DMSO

Hypervitaminosis D

- Iatrogenic
- Plants (calcitriol glycosides)
- Rodenticide (cholecalciferol)
- Antipsoriasis creams (calcipotriene or calcipotriol)

Granulomatous disease (calcitriol synthesis)

  - Fungal
  - Injection site reaction

Acute renal failure

Skeletal lesions

  - Osteomyelitis
  - Hypertrophic osteodystrophy
  - Disuse osteoporosis
  - Bone infarction

Excessive oral calcium

  - Calcium-containing intestinal phosphate binders
  - Calcium supplementation (calcium carbonate)

Hypervitaminosis A

Raisin/grape toxicity

56.4.2 Differential Diagnoses

A list of differential diagnoses for hypercalcemia is presented in Box 56-1, with neoplasia-associated hypercalcemia being the most common cause in dogs. In cats, neoplasia is thought to be the third most common cause of hypercalcemia behind idiopathic hypercalcemia and renal failure. Serum phosphorus levels tend to be normal or low in animals with primary hyperparathyroidism or malignancies with an elevated PTH-related protein. A thorough discussion of the pathophysiology of hypercalcemia in various disease processes is beyond the scope of this chapter; however, a thorough understanding of these principles is important because they serve as a guide for diagnosis and treatment.[1]

56.4.3 Treatment of Hypercalcemia

The consequences of hypercalcemia can be severe and can affect multiple body systems including the central nervous system (CNS), gastrointestinal tract, heart, and kidneys. Therefore a timely diagnosis and rapid intervention are vital. However, there is no absolute calcium value that should serve as a guide for initiating aggressive treatment. Rather, intervention should be guided by multiple factors, including the magnitude of hypercalcemia, rate of development, stable or progressive disease, clinical signs associated with hypercalcemia, organ dysfunction (renal, cardiac, CNS), clinical condition of the patient, and the suspected etiology of the hypercalcemia (Figure 56-1). In addition, evaluation of phosphorus concentrations may help in guiding therapy, because a calcium-phosphorus product of greater than 60 represents increased risk for soft tissue mineralization.

Definitive treatment for hypercalcemia is removing the underlying cause. However, in many cases the cause is not readily apparent, and sometimes palliative therapy must be instituted before treating the primary disease (Table 56-1).

Acute therapy often involves the use of one or more of the following: intravenous fluids, diuretics (furosemide), glucocorticoids, and calcitonin (Figure 56-2). The fluid of choice for hypercalcemia therapy is 0.9% sodium chloride, because the additional sodium ions present competition for calcium and result in reduced renal tubular calcium reabsorption. In addition, 0.9% sodium chloride is calcium free, thus not adding to the calcium load on the body. Intravenous fluid therapy should be used to correct dehydration over 4 to 6 hours and then given at rates of at least 1.5 to 2 times maintenance (see Chapter 64, Daily Intravenous Fluid Therapy). Potassium supplementation often is needed with this fluid protocol (potassium 5 to 40 mEq/L) depending on serum potassium concentrations (see Chapter 55, Potassium Disorders). Judicious fluid therapy should be used in patients with cardiac disease or hypertension, because volume overload and pulmonary congestion may easily occur. Furosemide enhances urinary calcium loss but should not be used in volume-depleted animals. Suggested dosages of furosemide are 1 to 2 mg/kg IV, SC, PO q12h. A constant rate infusion (CRI) of 0.2 to 1 mg/kg/hr may occasionally be needed for several hours during a hypercalcemic crisis. Meticulous attention to fluid therapy needs is essential when this method is used to avoid serious volume contraction. It may prove beneficial to place a urinary catheter in order to match the amount of fluid administered with the amount of urinary losses to ensure adequate volume replacement.

Figure 56-1 Definition of hypercalcemic crisis.

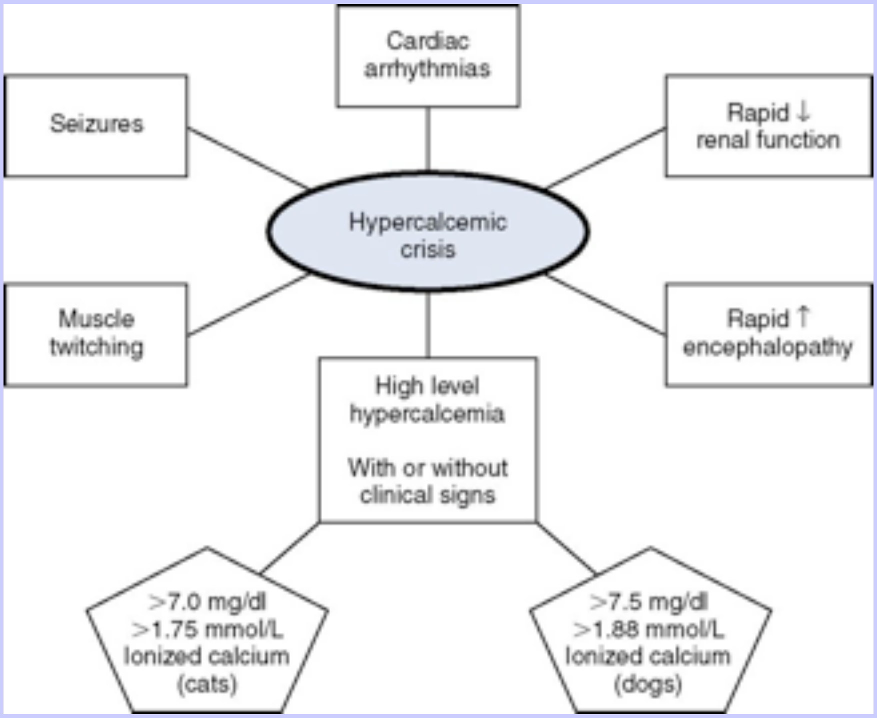

Table 56-1 Treatment of Hypercalcemia

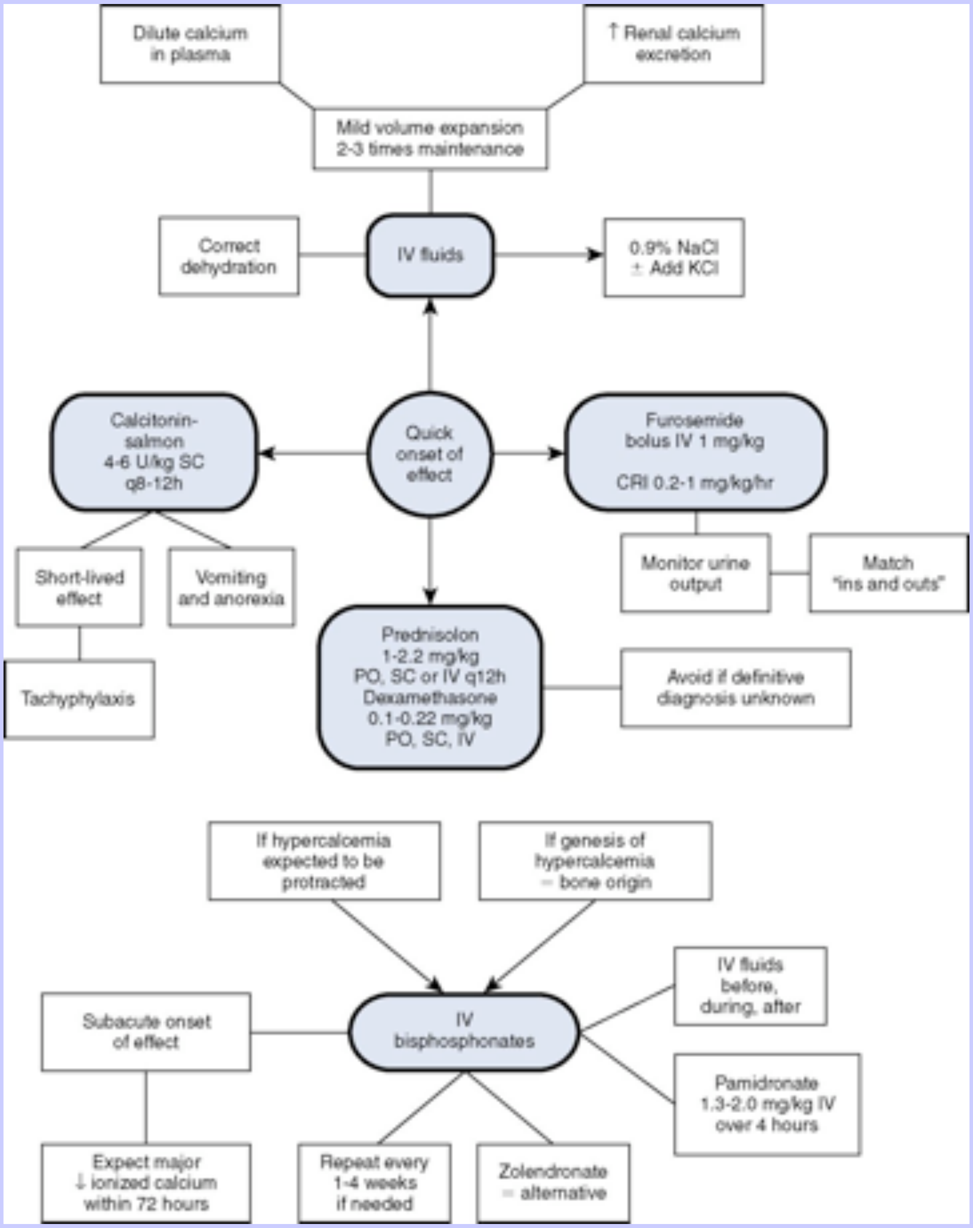
Treatment	Dosage	Indications	Comments
0.9% NaCl	90 to 120 ml/kg IV q24h	Moderate to severe hypercalcemia	Contraindicated in congestive heart failure and hypertension
Furosemide	1 to 2 mg/kg IV, SC, PO q12h CRI 0.2 to 1 mg/kg/hr	Moderate to severe hypercalcemia	Volume expansion necessary before administration Rapid onset
	CRI 0.2 to 1 mg/kg/hr		Rapid onset
Dexamethasone	0.1 to 0.22 mg/kg SC, IV q12h	Moderate to severe hypercalcemia	Use before identification of etiology may make definitive diagnosis difficult or impossible
Prednisone	1 to 2.2 mg/kg PO, SC, IV q12h	Moderate to severe hypercalcemia	Use prior to identification of etiology may make definitive diagnosis difficult or impossible
Calcitonin-salmon	4 to 6 IU/kg SC q8-12h	Hypervitaminosis D	Response may be short lived Vomiting may occur after multiple doses Rapid onset
Sodium bicarbonate	1 mEq/kg slow IV bolus (may give up to 4 mEq/kg total dosage)	Severe, life-threatening hypercalcemia	Requires close monitoring Rapid onset
Pamidronate	1.3 to 2.0 mg/kg in 150 ml 0.9% NaCl IV over 2 to 4 hr	Moderate to severe hypercalcemia	Expensive Delayed onset
Cinacalcet	No veterinary dosing published	Tertiary hyperparathyroidism Malignant primary hyperparathyroidism	May have future uses in veterinary medicine

Modified from DiBartola SP: *Fluid, electrolyte, and acid-base disorders in small animal practice*, ed 3, St Louis, 2006, Saunders.*CRI,* Constant rate infusion; *IV,* intravenous; *NaCl,* sodium chloride; *PO,* per os; *SC,* subcutaneous.

Glucocorticoids can cause a reduction in serum calcium concentration in many animals with hypercalcemia. Glucocorticoids lead to reduced bone resorption, decreased intestinal calcium absorption, and increased renal calcium excretion. The magnitude of decline with therapy depends on the cause of the hypercalcemia. Dexamethasone often is given at dosages of 0.1 to 0.22 mg/kg SC, IV q12h, or prednisone at dosages of 1 to 2.2 mg/kg PO, SC, IV q12h. However, in patients that have no definitive diagnosis for the hypercalcemia, calcitonin therapy should be considered instead of glucocorticoids, because the latter may interfere with obtaining an accurate cytologic or histopathologic diagnosis.

Calcitonin acts to decrease serum calcium concentrations by reducing the activity and formation of osteoclasts. Calcitonin-salmon can be used at a dosage of 4 to 6 IU/kg SC q8-12h. Vomiting may occur after several days of administration. Sodium bicarbonate can also be considered for crisis therapy because it decreases the ionized and total calcium; effects on the bound fractions of calcium have not been examined in this situation.[5] Sodium bicarbonate is given at a dosage of 1 mEq/kg IV as a slow bolus (up to 4 mEq/kg total dose) when patients are at risk for death (see Table 56-1). Acid-base status should be monitored closely to avoid inducing alkalemia or 236 other complications of bicarbonate therapy (i.e., paradoxical cerebral acidosis, hypernatremia). Peritoneal or 237 hemodialysis using calcium-free dialysate can be considered in cases refractory to traditional therapy. Fluid therapy should always be considered as the first treatment option, and other modalities added based on response to therapy and the status of the patient.

Figure 56-2 Treatment of critically ill patients with ionized hypercalcemia. *CRI,* Constant rate infusion; *IV,* intravenous; *PO,* per os; *SC,* subcutaneous.



Dilute calcium in plasma
↑ Renal calcium excretion
Mild volume expansion 2-3 times maintenance
Correct dehydration
IV fluids
0.9% NaCl ± Add KCl
Calcitonin-salmon 4-6 U/kg SC q8-12h
Quick onset of effect
Furosemide bolus IV 1 mg/kg
CRI 0.2-1 mg/kg/hr
Short-lived effect
Vomiting and anorexia
Monitor urine output
Match "ins and outs"
Tachyphylaxis
Prednisolon 1-2.2 mg/kg PO, SC or IV q12h Dexamethasone 0.1-0.22 mg/kg PO, SC, IV
Avoid if definitive diagnosis unknown
If hypercalcemia expected to be protracted
If genesis of hypercalcemia = bone origin
IV fluids before, during, after
Subacute onset of effect
IV bisphosphonates
Pamidronate 1.3-2.0 mg/kg IV over 4 hours
Expect major ↓ ionized calcium within 72 hours
Repeat every 1-4 weeks if needed
Zolendronate = alternative

Subacute or long-term treatment to decrease calcium levels may be needed in some cases rather than acute rescue therapy. Glucocorticoids and furosemide can be given for long-term therapy and are usually administered orally. In addition, subcutaneous fluids (0.9% sodium chloride) can be given at dosages of 75 to 100 ml/kg q24h as needed.

Bisphosphonates are a class of drugs that have been used in veterinary medicine for management of hypercalcemia.[4] These drugs decrease osteoclastic activity, thus decreasing bone resorption. Bisphosphonates often take 1 to 2 days to inhibit bone resorption, so they are not considered drugs of choice for acute or crisis therapy.[6] Pamidronate has been the most commonly used bisphosphonate in veterinary medicine for management of hypercalcemia; zoledronate is more potent than pamidronate and can be considered for use in selected patients. Pamidronate can be given intravenously at dosages of 1.3 to 2 mg/kg in 150 ml 0.9% saline as a 2-hour to 4-hour infusion.[7] This dose can be repeated in 1 week, if needed, but the salutary effect may last for 1 month in some instances. Oral alendronate at 1 to 3 mg/kg/week may be prescribed for the chronic treatment of idiopathic hypercalcemia in cats, but it is not as effective as intravenous bisphosphonate therapy in the acute setting. Oral bisphosphonates can cause esophageal irritation and have been reported to cause abdominal discomfort, nausea, and vomiting in humans.[8]

Calcimimetics belong to a new class of drugs that will likely have future use in veterinary medicine to treat some cases of hypercalcemia in which the underlying cause cannot be treated adequately by other means (tertiary hyperparathyroidism, primary hyperparathyroidism due to carcinoma). These drugs activate the calcium sensing receptor and thus decrease PTH secretion. Cinacalcet has been marketed for use in humans to treat renal secondary hyperparathyroidism and nonsurgical primary hyperparathyroidism.

56.5 HYPOCALCEMIA

Decreased total serum calcium is a relatively common electrolyte disturbance in critically ill dogs and cats. In one study the prevalence of ionized hypocalcemia in sick dogs was 31%.[4]

56.5.1 Clinical Signs and Diagnosis

A list of clinical signs that occur with hypocalcemia is presented in Box 56-2. Signs of hypocalcemia are often not seen until serum total calcium concentrations are less than 6.5 mg/dl (<4 mg/dl or <1 mmol/L ionized calcium), and many animals show few signs even with lower calcium levels. Most animals with rapid development of hypocalcemia show clinical signs. Severely affected animals may have decreased inotropy and chronotropy (bradycardia), and ECG abnormalities may include a prolonged QT interval (due to prolonged ST segment), deep, wide T waves, or atrioventricular block.

56.5.1.1 Box 56-2 Clinical Signs Associated With Hypocalcemia

56.5.1.1.1 Common

None

Muscle tremors or fasciculations

Facial rubbing

Muscle cramping

Stiff gait

Behavioral change

- Restlessness or excitation
- Aggression
- Hypersensitivity to stimuli
- Disorientation

56.5.1.1.2 Occasional

Seizures

Panting

Pyrexia

Lethargy

Anorexia

Prolapse of third eyelid (cats)

Posterior lenticular cataracts

Tachycardia or ECG alterations (i.e., prolonged QT interval)

56.5.1.1.3 Uncommon

Polyuria or polydipsia

Hypotension

Respiratory arrest or death

Modified from DiBartola SP: *Fluid, electrolyte, and acid-base disorders in small animal practice,* ed 3, St Louis, 2006, Saunders. *ECG,* Electrocardiographic.

Hypocalcemia usually is discovered fortuitously after routine measurement of serum total calcium concentration. Hypocalcemia is defined as a total calcium concentration less than 8 mg/dl in dogs, and less than 7 mg/dl in cats. When hypocalcemia is diagnosed via total calcium concentrations, it should always be confirmed with an ionized calcium measurement. Using ionized calcium concentrations, hypocalcemia is defined as less than 5 mg/dl (1.25 mmol/L) in dogs, and less than 4.5 mg/dl (1.1 mmol/L) in cats.

After a diagnosis of hypocalcemia is confirmed, other diagnostic strategies such as complete blood cell count, chemistry panel, urinalysis, PTH measurement, and vitamin D metabolite measurements should all be considered.

56.5.2 Differential Diagnoses

A list of differential diagnoses for hypocalcemia is presented in Box 56-3. The most common cause of a total serum hypocalcemia is hypoalbuminemia. However, the hypocalcemia is usually mild and usually no signs are seen that are attributable to the hypocalcemia with this condition. Correction formulas have been advocated in the past to correct calcium levels for a low albumin, but these formulas do not accurately predict ionized calcium concentrations and are therefore not recommended.[4]

56.5.2.1 Box 56-3 Differential Diagnoses for Hypocalcemia

- Hypoalbuminemia
- Chronic renal failure
- Eclampsia
- Acute renal failure
- Pancreatitis
- Soft tissue trauma or rhabdomyolysis
- Hypoparathryoidism
    - Primary hypoparathryoidism
        - Idiopathic
        - Iatrogenic (postoperative bilateral thryoidectomy)
    - After sudden reversal of chronic hypercalcemia
    - Secondary to magnesium depletion, retention

- Ethylene glycol
- Phosphate enema
- Bicarbonate administration
- Improper sample anticoagulant (EDTA)
- Infarction of parathyroid gland adenoma
- Rapid IV infusion of phosphates
- Acute calcium-free IV infusion
- Intestinal malabsorption, PLE, starvation
- Hypovitaminosis D
- Blood transfusion (citrated anticoagulant)
- Hypomagnesemia (PTH secretion and receptor effects)
- Nutritional secondary hyperparathyroidism
- Acute tumor lysis syndrome
- Chelating agents
    - CaEDTA, dimercaprol (British anti-Lewisite), D-penicillamine, and meso-2,3-dimercaptosuccinic acid (succimer, IV radiocontrast)
- Excessive bisphosphonate treatments

Modified from DiBartola SP: *Fluid, electrolyte, and acid-base disorders in small animal practice,* ed 3, St Louis, 2006, Saunders. *EDTA*, Ethylenediamine tetraacetic acid; *PLE*, protein-losing enteropathy; *PTH*, parathyroid hormone.

Renal failure appears to be the second most common cause of hypocalcemia in dogs. Primary hypoparathyroidism is the one condition that will require long-term calcium-specific treatment. If the serum phosphorus level is high, the most likely diagnoses to rule out include renal failure, pancreatitis with or without prerenal azotemia, excessive intake of phosphorus, and primary hypoparathyroidism.

56.5.3 Treatment

The consequences of untreated severe ionized hypocalcemia can be life threatening because of myocardial failure and respiratory arrest. The decision to treat hypocalcemia should be based on multiple factors, including severity of clinical signs, speed of development of hypocalcemia, and the etiology of the primary disease. Hypermagnesemia and hypomagnesemia can impair the secretion of PTH, and PTH actions on its receptor, so measurement of serum magnesium (preferably ionized magnesium) is important, especially in animals with refractory hypocalcemia.

Patients with decreased total calcium concentrations but normal ionized calcium concentrations require no treatment. If a decreased ionized calcium concentration is found, the clinician must decide if therapy is warranted. If the patient is stable, no clinical signs referable to hypocalcemia are documented, and the ionized calcium is not progressively decreasing, then it is reasonable to consider not treating these patients. Patients with a severe decrease in ionized calcium concentration warrant calcium-specific treatment regardless of clinical signs.[9,10] Therapy may also be initiated in an asymptomatic patient with moderate ionized hypocalcemia that is decreasing progressively to prevent the development of signs. Patients with clinical signs attributed to hypocalcemia clearly should receive calcium-specific rescue therapy.

Treatment of hypocalcemia can be divided into acute and subacute to long term. As with all cases of hypocalcemia, attempts should always be made to treat the primary disease causing the disorder. Most cases of hypocalcemia do not require long-term therapy, with hypoparathyroidism being the exception. Many cases will require acute treatment, especially those with tetany, seizures, or muscle fasciculations. Therapy typically involves the administration of calcium salts, as well as vitamin D metabolites.

For acute therapy, calcium should be administered intravenously to effect over a 10- to 20-minute period. Calcium gluconate and calcium chloride are both available for treatment, but calcium gluconate is preferred because it is not irritating if injected perivascularly (unlike calcium chloride). Calcium salts should never be given subcutaneously, because they can cause severe skin necrosis and abscess formation. Calcium gluconate (10% solution, calcium 9.3 mg/ml) can be given at dosages of 0.5 to 1.5 ml/kg IV to effect. Heart rate and ECG should be monitored closely during administration to look for bradycardia, a prolonged PR interval, widened QRS complex, shortened QT interval, elevated, shortened, or absent ST segment, and a widened T wave, all of which may indicate cardiac toxicity. It is important to note that it may take up to 30 to 60 minutes for all clinical signs to resolve after correction of hypocalcemia, and some behavioral changes and panting may persist during this time.

For subacute management, the initial bolus of calcium salts often needs to be followed with a CRI of calcium, especially if the hypocalcemia is expected to persist. A CRI of elemental calcium can be delivered at a rate of 1 to 3 mg/kg/hr IV based on the severity of hypocalcemia to maintain normal calcium levels until oral calcium administration and or vitamin D metabolites can be used to control serum calcium concentrations. Vitamin D metabolites should also be started early if the hypocalcemia is expected to persist, because it may take several days for intestinal calcium transport to be maximized. Calcitriol is the preferred active vitamin D metabolite because it has a quick onset of action, short plasma half-life, and relatively short biologic effect half-life (important if overshoot hypercalcemia occurs). Calcitriol is dosed at 20 to 30 ng/kg q24h for 3 to 4 days for induction, then 5 to 15 ng/kg q24h for maintenance therapy, titrated to the desired level of serum calcium concentration.

For long-term therapy (e.g., primary hypoparathyroidism), oral calcium usually is needed to control serum calcium levels. It should be noted, however, that the goal of therapy with hypoparathyroidism is not to return calcium levels completely to normal, because this can have deleterious effects (hypercalciuria despite normocalcemia in the absence of basal effects that PTH normally has on renal tubules). One should aim to control signs and correct calcium levels to just below normal. Many forms of oral calcium are available (calcium carbonate, calcium lactate, calcium chloride, calcium gluconate) and all are dosed at 25 to 50 mg/kg q24h. Calcium carbonate is the most common form of calcium used and is generally well tolerated. Calcitriol can also be used at the previously mentioned dosages.

57 Chapter 57 Magnesium Disorders

Linda G. Martin, DVM, MS, DACVECC

57.1 KEY POINTS

- Hypomagnesemia is a common electrolyte disorder in critically ill veterinary patients.
- Given that less than 1% of total body magnesium is located in the serum, serum magnesium concentrations do not always reflect total body magnesium stores. Consequently, a normal serum magnesium concentration can occur when there is a total body magnesium deficiency.
- Magnesium homeostasis is primarily a function of intestinal absorption and urinary excretion; therefore hypomagnesemia is almost always caused by disturbances in one or both of these organ systems.
- Most cases of hypermagnesemia involve a component of renal insufficiency.
- Severe hypomagnesemia and hypermagnesemia cause clinical signs associated with the cardiovascular and neuromuscular systems.

57.2 INTRODUCTION

For more than a decade, there has been a growing interest in the clinical effects and therapeutic role of magnesium in veterinary medicine. Magnesium disorders are common in both feline and canine critically ill patients. Increased morbidity, mortality, and prevalence of concurrent electrolyte disorders occur in critically ill animals with altered total serum magnesium concentrations when compared with normomagnesemic critically ill animals.[1-3]

Magnesium is the second most abundant intracellular cation, exceeded only by potassium. The vast majority of magnesium is found in bone and muscle. Sixty percent of the total body magnesium content is present in bone, incorporated into the crystal mineral lattice or in the surface-limited exchangeable pool. This pool consists of magnesium that is in equilibrium with the magnesium ions in the extracellular fluid and serves as a reservoir for maintenance of the extracellular magnesium concentration. Twenty percent is located in skeletal muscle and the remainder is located in other tissues, primarily the heart and liver. Less than 1% of total body magnesium is present in the serum.[4,5] In the serum, magnesium exists in three distinct forms: an ionized fraction, an anion-complexed fraction, and a protein-bound fraction. The ionized fraction is thought to be the physiologically active component and accounts for approximately 66% and 63% of the total serum magnesium concentration in cats and dogs, respectively. Approximately 4% and 6% are complexed to compounds such as phosphate, bicarbonate, sulfate, citrate, and lactate in cats and dogs, respectively. The remaining 30% and 31% of total serum magnesium are bound to protein (primarily albumin) in cats and dogs, respectively.[6,7]

Magnesium is required for many metabolic functions, most notably those involved in the production and use of adenosine triphosphate (ATP). This electrolyte is a coenzyme for the membrane-bound sodium-potassium ATPase pump and functions to maintain the sodium-potassium gradient across all membranes. Calcium ATPase and proton pumps also require magnesium. Magnesium is also essential for protein and nucleic acid synthesis, regulation of vascular smooth muscle tone, cellular second messenger systems, and signal transduction. In addition, data suggest that magnesium exerts an important influence on lymphocyte activation, cytokine production, and systemic inflammation.[8-10]

Magnesium homeostasis is achieved through intestinal absorption and renal excretion. Absorption occurs primarily in the small intestine (jejunum and ileum) with little or none occurring in the large intestine. The loop of Henle is the main site of magnesium absorption in the kidney. The kidney appears to be the main regulator of serum magnesium concentration and total body magnesium content.[8] This is achieved by both glomerular filtration and tubular reabsorption.[5] Renal magnesium excretion will increase in proportion to the load presented to the kidney; conversely, the kidney conserves magnesium in response to a deficiency.[8]

Lactation appears to play a role in gut and renal handling of magnesium. Increased levels of parathyroid hormone, in addition to calcium concentration, most likely participate in magnesium conservation during lactation to supply the mammary glands with a sufficient amount.[11] No primary regulatory hormone has been identified for magnesium homeostasis, although the parathyroid, thyroid, and adrenal glands are likely involved.[12]

57.3 HYPOMAGNESEMIA

Most magnesium-related disorders are caused by conditions that lead to the depletion of total body stores. Hypomagnesemia is a common electrolyte abnormality in both canine and feline intensive care unit patients.[1-3] However, this electrolyte disorder appears to be less common in the general canine hospital population.[13] Ionized hypomagnesemia has been documented in perioperative feline renal transplant recipients, as well as cats with diabetes mellitus and diabetic ketoacidosis.[14,15] Other evidence suggests that animals on peritoneal dialysis, dogs with congestive heart failure being treated with furosemide, dogs with protein-losing enteropathy, and lactating dogs are also at risk for hypomagnesemia.[16-19]

57.3.1 Causes

Causes of magnesium deficiency are both numerous and complex. Three general categories are involved: 240
decreased intake, increased losses, and alterations in distribution. Potential causes are listed in Box 57-1. 241
Decreased dietary intake, if sustained for several weeks, can lead to significant magnesium depletion. In addition, catabolic illness and prolonged intravenous fluid therapy or parenteral nutrition without sufficient magnesium supplementation can contribute to depletion.[4,8,16]

57.3.1.1 Box 57-1 Causes of Hypomagnesemia

I **Decreased Intake**
    A Inadequate nutritional intake
    B Prolonged intravenous fluid therapy or parenteral nutrition without magnesium replacement
II **Increased Losses**
    A Gastrointestinal
        1 Malabsorption syndromes

        2 Extensive small bowel resection
        3 Chronic diarrhea
        4 Inflammatory bowel disease
        5 Cholestatic liver disease
    B Renal
        1 Intrinsic tubular disorders
            a Glomerulonephritis
            b Acute tubular necrosis
            c Postobstructive diuresis
            d Drug-induced tubular injury
                (1) Aminoglycosides
                (2) Amphotericin B
                (3) Cisplatin
                (4) Cyclosporine
        2 Extrarenal factors influencing renal magnesium handling
            a Diuretic-induced states
                (1) Furosemide
                (2) Thiazides
                (3) Mannitol
            b Digitalis administration
            c Diabetic ketoacidosis
            d Hyperthyroidism
            e Primary hyperparathyroidism
    C Lactation

III **Alterations in Distribution**

    A Extracellular to intracellular shifts
        1 Glucose, insulin, or amino acid administration

- B Chelation
    - 1 Elevation in circulating catecholamines
        - a Sepsis or shock
        - b Trauma
        - c Hypothermia
    - 2 Massive blood transfusion
- C Sequestration
    - 1 Pancreatitis

Magnesium losses can occur through the gastrointestinal(GI) tract, kidneys, or both. Because magnesium balance is primarily a function of intestinal absorption and urinary excretion, depletion is almost always caused by disturbances in one or both organ systems. Increased GI losses can result from inflammatory bowel disease, malabsorptive syndromes, cholestatic liver disease, or other diseases that cause prolonged diarrhea. Fluid from the intestinal tract contains a high concentration of magnesium. For this reason, patients with protracted episodes of large-volume diarrhea are prone to significant magnesium depletion.[4,9]

Because the kidney is the primary pathway of magnesium excretion, it often serves as a focal point for the development of hypomagnesemia through urinary loss. Acute renal dysfunction as a consequence of glomerulonephritis or the nonoliguric phase of acute tubular necrosis is often associated with a rise in the fractional excretion of magnesium. A number of endocrinopathies are also associated with an increase in the fractional excretion of magnesium, including diabetic ketoacidosis and hyperthyroidism.[9,15]

Numerous drugs administered to emergency and critically ill patients can increase renal magnesium loss. Most of the commonly administered diuretic agents (furosemide, thiazides, mannitol) and cardiac glycosides induce hypomagnesemia by increasing urinary excretion. Other drugs such as aminoglycosides, amphotericin B, cisplatin, and cyclosporine predispose to renal tubular injury and excessive magnesium loss.[4,8]

Disease states or therapeutic modalities can cause the redistribution of circulating magnesium by producing extracellular to intracellular shifts, chelation, or sequestration. Administration of glucose, insulin, or amino acids cause magnesium to shift intracellularly. Also, catecholamine elevations in animals with sepsis, trauma, or hypothermia may cause ionized hypomagnesemia. It appears that β-adrenergic stimulation of lipolysis generates free fatty acids that chelate magnesium, thereby producing insoluble salts. In addition, citrated blood products can avidly chelate magnesium ions when administered in large quantities. In acute pancreatitis, magnesium can form insoluble soaps, and magnesium sequestration may occur in areas of fat necrosis surrounding the pancreas.[4,8]

57.3.2 Clinical Signs

Clinical signs of magnesium depletion are often related to its effects on the cell membrane that result in changes in resting membrane potential, signal transduction, and smooth muscle tone. The effects of magnesium on the myocardium are linked to its role as a regulator of other electrolytes, primarily calcium and potassium. For this reason, one of the most dramatic clinical signs associated with hypomagnesemia is cardiac arrhythmias, including atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, and ventricular fibrillation. Hypomagnesemia also predisposes patients to digoxin-induced arrhythmias. Magnesium depletion not only enhances digoxin uptake by the myocardium, but also inhibits the myocardial sodium-potassium ATPase pump, as does digoxin. Before overt arrhythmia development, subtle electrocardiographic (ECG) changes may be seen. These include prolongation of the PR interval, widening of the QRS complex, depression of the ST segment, and peaking of the T wave. In addition to these changes, hypomagnesemia can cause hypertension, coronary artery vasospasm, and platelet aggregation.[9,20]

Hypomagnesemia can cause various nonspecific neuromuscular signs. Concurrent hypocalcemia and hypokalemia may also contribute. Magnesium deficiency increases acetylcholine release from nerve terminals and enhances the excitability of nerve and muscle membranes. It also increases the intracellular calcium content in skeletal muscle. Clinical manifestations of magnesium deficiency can include generalized muscle weakness, muscle fasciculations, ataxia, and seizures. Esophageal or respiratory muscle weakness can be manifested as dysphagia or dyspnea, respectively.[4,9]

Because magnesium is necessary for the movement of sodium, potassium, and calcium into and out of cells, other manifestations of hypomagnesemia include metabolic abnormalities such as concurrent hypokalemia, hyponatremia, and hypocalcemia. Concurrent hypokalemia that is refractory to aggressive potassium supplementation may be due to magnesium deficiency causing excessive potassium losses through the kidneys. When hypokalemia is refractory to potassium supplementation, assessment of magnesium status and subsequent magnesium supplementation are recommended. Hypocalcemia is another manifestation of magnesium deficiency. Because hypomagnesemia impairs parathyroid hormone release and enhances calcium movement from extracellular fluid to bone, hypocalcemia frequently accompanies magnesium depletion. Therefore clinical signs of hypocalcemia are often observed in patients with magnesium deficiency.[4,9]

57.3.3 Diagnosis

Magnesium deficiency should be suspected in patients predisposed to its development (disease processes or therapeutic modalities that can lead to hypomagnesemia) and exhibiting clinical signs and laboratory features consistent with magnesium depletion. Determination of total serum magnesium concentration is usually the most readily available technique for estimation of magnesium status. However, the precise clinical diagnosis of hypomagnesemia can be difficult. Because more than 99% of total body magnesium is located in the intracellular compartment, total serum concentrations do not always reflect total body stores. Therefore a normal total serum magnesium concentration can occur in an animal with a total body magnesium deficiency.[4,5] However, a low total serum concentration in a patient at risk for deficiency is usually significant. The reported reference range for total serum magnesium is 1.89 to 2.51 mg/dl in dogs, and 1.75 to 2.99 mg/dl in cats.[3,15]

The ionized magnesium concentration is thought to provide a more accurate reflection of intracellular ionized magnesium status and represents the “active” component. Ionized magnesium appears to equilibrate rapidly across the cell membrane; thus extracellular ionized magnesium values may be more reflective of intracellular stores. The canine reference range for ionized magnesium is 0.43 to 0.6 mmol/L, and the feline reference range is 0.43 to 0.7 mmol/L.[7]

57.3.4 Therapy

The amount and route of magnesium replacement depends on both the degree of hypomagnesemia and on the patient's clinical condition. Mild hypomagnesemia may resolve with management of the underlying disorder and modification of intravenous fluid therapy. Animals receiving long-term diuretic and digoxin therapy may benefit from oral magnesium supplementation. Supplementation should be considered if total serum magnesium concentrations are lower than 1.5 mg/dl and at any level if clinical signs (cardiac arrhythmias, muscle tremors, refractory hypokalemia) are present. Renal function and cardiac conduction must be assessed before magnesium administration. Because magnesium is excreted primarily by the kidneys, the dosage should be reduced by 50% in azotemic patients and serum concentrations should be monitored frequently to prevent hypermagnesemia. Magnesium prolongs conduction through the AV node. Therefore any patient with cardiac conduction disturbances should have judicious supplementation and continuous ECG monitoring.

Both sulfate and chloride salts are available for parenteral supplementation. The intravenous route is preferred for rapid repletion of magnesium concentrations. (The intramuscular route is generally painful.) An initial dosage of 0.5 to 1 mEq/kg q24h can be administered by continuous rate infusion in 0.9% sodium chloride or 5% dextrose in water. A lower dosage of 0.3 to 0.5 mEq/kg q24h can be used for an additional 3 to 5 days. For management of life-threatening ventricular arrhythmias, a dose of 0.15 to 0.3 mEq/kg of magnesium diluted in normal saline or 5% dextrose in water can be administered slowly over 5 to 15 minutes.[21] Parenteral administration of magnesium sulfate may result in hypocalcemia due to chelation of calcium with sulfate. Therefore magnesium chloride should be given if hypocalcemia is also present. Other side effects of magnesium therapy include hypotension, atrioventricular block, and bundle branch blocks. Adverse effects usually are associated with intravenous boluses rather than continuous rate infusions.

Chloride, gluconate, oxide, and hydroxide salts are available for oral administration. The suggested dosage is 1 to 2 mEq/kg q24h. The main side effect of this route is diarrhea.[21]

57.4 HYPERMAGNESEMIA

Hypermagnesemia appears to be a less common and simpler clinical entity than hypomagnesemia. Because large quantities of magnesium can be eliminated easily by the kidneys, it is unusual to encounter hypermagnesemia in the absence of azotemia. Unlike magnesium depletion, normal serum concentrations cannot hide increased body stores.

57.4.1 Causes

Conditions in which hypermagnesemia has been noted include renal failure, endocrinopathies, and iatrogenic overdose, especially in patients with impaired renal function. It appears that absolute magnesium excretion falls as glomerular filtration rate declines, so it is not surprising that most patients with hypermagnesemia have some degree of renal insufficiency. In general, the degree of hypermagnesemia parallels the degree of renal failure. Acute renal failure is more likely to be associated with clinically significant hypermagnesemia than chronic renal failure, but it may occur in the latter.[5]

Several endocrinopathies may be associated with hypermagnesemia. These diseases include hypoadrenocorticism, hyperparathyroidism, and hypothyroidism. In comparison with renal failure, these diseases cause hypermagnesemia less frequently and to a milder degree. The mechanisms that lead to hypermagnesemia are not well understood in these endocrine disorders. The prerenal azotemic state present in most patients with hypoadrenocorticism may contribute to hypermagnesemia.[22]

Improper dosing of magnesium replacement therapy or lack of consideration of the underlying renal function generally plays a role in iatrogenic hypermagnesemia. Many cathartics, laxatives, and antacids contain magnesium, so care should be exercised if multiple doses are given to a patient with underlying renal disease. Sorbitol-containing cathartics are advised when patients require multiple doses to detoxify the GI tract or have renal disease.[5,20]

57.4.2 Clinical Signs

Nonspecific clinical signs of hypermagnesemia include lethargy, depression, and weakness. Other clinical signs reflect the electrolyte's action on the nervous and cardiovascular systems. Hypermagnesemia usually results in varying degrees of neuromuscular blockade. One of the earliest clinical signs of magnesium toxicity is hyporeflexia. Profound magnesium toxicity has been associated with respiratory depression secondary to respiratory muscle paralysis. Severe respiratory depression can result in hypoventilation and subsequent hypoxemia. An absent menace and palpebral reflex have been reported in one dog and one cat that developed acute hypermagnesemia secondary to iatrogenic overdose.[23] In addition to this, hypermagnesemia can lead to blockade of the autonomic nervous system and vascular collapse.[20,22]

Cardiovascular effects of hypermagnesemia result in ECG changes including prolongation of the PR interval and widening of the QRS complex. This is due to delayed atrioventricular and interventricular conduction. Bradycardia can occur in hypermagnesemic patients. At severely high serum magnesium concentrations, complete heart block and asystole can occur. Ectopy does not appear to be enhanced by elevated serum magnesium concentrations. Hypermagnesemia has also been reported to produce hypotension secondary to relaxation of vascular resistance vessels. Myocardial contractility is probably not affected by hypermagnesemia. Additionally, hypermagnesemia may impair platelet function and coagulation.[22]

57.4.3 Diagnosis

Unlike magnesium deficiency, normal serum concentrations cannot hide increased magnesium stores. Total serum magnesium concentrations greater than 2.99 mg/dl in cats and 2.51 mg/dl in dogs are considered indicative of hypermagnesemia.[3,15] Ionized magnesium concentrations above 0.7 mmol/L in cats and 0.6 mmol/L in dogs are considered to be ionized hypermagnesemia.[7]

57.4.4 Therapy

Therapy consists first and foremost of stopping all exogenous magnesium administration. Further treatment is based on the degree of hypermagnesemia, clinical signs, and renal function. A patient with mild clinical signs such as depression and hyporeflexia can be treated with supportive care and observation, provided that renal function is normal. More severe cases that involve unresponsiveness, respiratory depression, and any degree of hemodynamic instability should be treated with intravenous calcium. Calcium is a direct antagonist of magnesium at the neuromuscular junction and may be beneficial in reversing the cardiovascular effects of hypermagnesemia. Calcium gluconate can be given at 0.5 to 1.5 ml/kg as a slow intravenous bolus over 10 minutes. Saline diuresis and furosemide can also be used to accelerate renal magnesium excretion. Furosemide should not be given to a dehydrated or hypovolemic patient. In patients with severely impaired renal function, peritoneal dialysis or hemodialysis may be required if treatment is necessary.

In patients with severe clinical signs, anticholinesterases may be administered to offset the neurotoxic effects of hypermagnesemia. Physostigmine can be given at 0.02 mg/kg IV q12h until clinical signs subside. In severe cases complicated by cardiopulmonary arrest, intubation and mechanical ventilation are recommended. Hypermagnesemic shock may be refractory to epinephrine, norepinephrine, and other vasopressors, making resuscitation efforts extremely difficult.[5,22]

58 Chapter 58 Phosphate Disorders

Janet Aldrich, DVM, DACVECC

58.1 KEY POINTS

- Energy-rich phosphates provide power for cell membrane pumps and ion channels to maintain electrochemical gradients and electrical currents that operate most biologic systems.
- Severe hypophosphatemia can cause hemolysis, rhabdomyolysis, impaired renal function and acid-base regulation, and impaired glucose metabolism.
- Hyperphosphatemia can cause hypocalcemia, renal secondary hyperparathyroidism, and metastatic calcification.

58.2 INTRODUCTION

Phosphorus is essential for many important biologic processes including those requiring energy from adenosine triphosphate (ATP), one of the most important substances in nature. Hyperphosphatemia and hypophosphatemia are diagnostically important as indicators of underlying disease and therapeutically important because phosphorus-directed therapy may improve patient care and outcome.

58.3 CHEMISTRY

Plasma phosphorus consists of organic (phospholipids, phosphate esters) and inorganic forms (orthophosphate, pyrophosphate). Clinical laboratories report inorganic phosphorus levels, which may be taken to be the orthophosphate fractions because the pyrophosphate amount is small. The orthophosphates are in three forms: free (55%), protein bound (10%), and complexed to magnesium or calcium (35%). The free fractions are mainly present as divalent HPO_4^{2-} or monovalent $H_2PO_4^-$ species; these ionic species are the active forms and their levels are regulated. At a pH of 7.4 they exist in a 4:1 divalent-to-monovalent ratio (i.e., 4 mmol HPO_4^{2-} to 1 mmol $H_2PO_4^-$).

Clinical laboratories report the elemental phosphorus bound in phosphate molecules in the sample as phosphorus (inorganic) in mg/dl. But it is the phosphate molecule that participates in biologic processes, usually expressed in mEq/L or mmol/L. Unit conversion reveals that 3.1 mg/dl of phosphorus = 1 mmol/L phosphate = 1.8 mEq/L phosphate.[1]

58.4 TERMS

Confusion can arise because the terms *phosphorus* (the element) and *phosphate* (the molecule) are often used interchangeably. For simplicity in this chapter, the term *phosphate* is used to mean either phosphorus or phosphate.

58.5 DISTRIBUTION AND FUNCTION

Total body phosphate is distributed as follows: 85% hydroxyapatite in bone (a complex of calcium, phosphate, and hydroxyl ions), 15% in soft tissue, and less than 1% in the extracellular compartment. Phosphate has an important structural and functional role, essential to many biologic processes. For example, phosphate-dependent energy systems are responsible for the maintenance of electrochemical gradients across cell membranes, for the generation of electrical currents, and for driving muscle contractions. Phosphate is also involved in protein function regulation; it is a component of deoxyribonucleic acid and ribonucleic acid, and it is essential to the structure of bone and teeth in addition to having acid-base effects.

58.6 HOMEOSTASIS

Phosphate homeostasis is maintained by intestinal absorption of phosphate balanced by renal regulation of serum phosphate concentration, [P]. Phosphate is conserved by renal reabsorption, decreases in fecal excretion, and growth cessation. Phosphate exchange between extracellular and soft tissue or bone compartments plays a role in metabolism but is not primarily involved in homeostasis. Phosphate homeostasis is affected by parathyroid hormone (PTH), vitamin D, and calcitonin, but can occur without hormonal influence.[1]

58.6.1 Intestinal

Dietary phosphate is absorbed in the small intestine passively and by vitamin D–dependent transport. Passive transport is by diffusional flux through the paracellular pathway and is the most important means of absorption. Factors promoting intestinal absorption are sodium stimulation of a 1,25-(OH)2vitD (calcitriol)–sensitive apical sodium-phosphate cotransporter, decreasing pH, and growth hormone. If luminal phosphate is in short supply, because of either low dietary phosphate or the presence of phosphate-binding drugs, vitamin D–dependent active transport becomes important. Hyperphosphatemia regulates vitamin D metabolism by stimulating production of an inactive form of vitamin D, thus decreasing active vitamin D and therefore decreasing intestinal phosphate absorption.

58.6.2 Renal

Phosphate is reabsorbed in the proximal tubule by a transcellular sodium-phosphate symporter on the apical side 244 and a phosphate anion antiporter on the basolateral side of the renal epithelial cells. When maximal tubular 245 reabsorption of phosphate (TmP) is reached, the rest is excreted in the urine. This is the set point for serum [P]. The normal filtered load of phosphate is just a little higher than the TmP so that a small amount spills in to the urine. Tubular reabsorption is decreased by diuresis. Growth hormone increases TmP so that reabsorption is increased. This is the likely mechanism of increased serum [P] in young animals.

The three most important hormones affecting renal handling of phosphate are PTH, calcitriol, and calcitonin, although regulation of phosphate can be maintained without them. The effect of PTH is to decrease renal reabsorption of phosphate by inhibiting the sodium-phosphate symporter while increasing reabsorption of calcium. Calcitriol plays a small role in phospate reabsorption, mostly by its primary effect of decreasing PTH. Calcitonin has a hypophosphatemic effect (see Bone, next).

58.6.3 Bone

Acutely, PTH promotes transfer of calcium, but not phosphate, from the soluble part of bone where ions cross the membrane barrier created by osteoblasts and osteocytes. In stable bone, PTH stimulates increased osteoclastic and decreased osteoblastic activity, resulting in release of calcium and phosphate. In spite of the increased release of phosphate from bone to the extracellular fluid, the phosphaturic effect of PTH prevents hyperphosphatemia if renal function is normal.

Calcitonin's hypophosphatemic effect is attributable to inhibition of bone resorption (by inhibiting osteoclasts) and promoting movement of phosphate from extracellular fluid into bone.

58.7 SERUM PHOSPHATE CONCENTRATION

Normal values for [P] are approximately 3 to 6 mg/dl in adult dogs and cats.[2] In young dogs and cats [P] is significantly higher than in adults. Values for [P] as high as 11 mg/dl are normal in growing puppies.[3] In kittens from birth to 8 weeks, a reference interval of 7 to 11 mg/dl was determined.[4] Values decrease to adult levels by 12 months of age. Interpretation of [P] should be made with awareness that serum levels may not parallel intracellular stores, because phosphate is mostly intracellular. Diurnal variation in [P] has been observed in dogs with concentrations lowest in morning, highest at midnight.[1]

Autoanalyzers dependent on a color reaction for phosphate analysis may produce falsely increased values because of the turbidity caused by proteins in hyperglobulinemic patients.[5] Hyperlipidemia may cause a false increase, and in vitro hemolysis may cause release of intracellular phosphate. A falsely low value may be found in samples containing mannitol, because it binds the molybdate used in the colorimetric assay in some analyzers. Conjugated bilirubin may increase or decrease the [P] value depending on the assay used.

58.8 HYPOPHOSPHATEMIA

58.8.1 Definition

Hypophosphatemia refers to a decrease in [P] below the normal range. Values of concern are those less than 2 mg/dl. Phosphate-deficient diets or depletion of phosphate body stores are not always reflected in decreases in [P]. In phosphate deprivation there is no net loss from the body. In starvation, which is caloric deprivation, phosphate is lost proportionately to other cellular elements so that the phosphate content of the remaining cells is normal.

58.8.1.1 Box 58-1 Causes of Hypophosphatemia or Phosphate Depletion

58.8.1.1.1 Decreased Intestinal Absorption or Increased Loss

Phosphate-binding drugs

Omission of phosphate from diet

Vomiting, diarrhea

Malabsorption

Vitamin D deficiency

58.8.1.1.2 Redistribution From Extracellular Fluid to Cells and Bone

Intravenous glucose, high insulin levels (exogenous, endogenous)

Diabetes mellitus, diabetic ketoacidosis

Hyperalimentation (refeeding syndrome)

Hepatic lipidosis

Respiratory alkalosis

Metabolic acidosis

Epinephrine

Salicylate poisoning

Resynthesis of bone

58.8.1.1.3 Renal or Dialysis-Associated Loss

Diuresis

Diuretic drugs (furosemide, mannitol, thiazides, acetazolamide)

Diabetes mellitus, diabetic ketoacidosis

Hypomagnesemia

Hyperparathyroidism

Dialysis with phosphate-deficient dialysate

Malignancy

Renal tubular defects (Fanconi syndrome)

58.8.2 Causes

Three mechanisms of hypophosphatemia or phosphate depletion are decreased intestinal absorption, redistribution of phosphate from extracellular to intracellular sites, and renal (or dialysis-associated) loss (Box 58-1).

58.8.2.1 Decreased Intestinal Absorption

Phosphate-binding antacids decrease intestinal absorption of phosphate from dietary and secreted sources. Gastrointestinal disease can interfere with phosphate absorption because of vomiting, diarrhea, or malabsorption. Vitamin D–dependent phosphate absorption is important in states of low dietary phosphate or in the presence of phosphate-binding drugs, and its deficiency may cause hypophosphatemia.

58.8.2.2 Redistribution

Shift of phosphate from the extracellular compartment into cells and bone may result in decreased [P] with or without decrease in body stores.

58.8.2.2.1 Insulin and Glucose

Intravenous administration of glucose-containing solutions or high insulin levels (exogenous or endogenous) promotes movement of phosphate and glucose into cells where phosphate is trapped as glucose-6-phosphate.

58.8.2.2.2 Refeeding

Hyperalimentation promotes cell growth and repletion of cellular phosphate stores. If feeding solutions are insufficiently supplemented with phosphate, significant hypophosphatemia can result.[6,7] In cats with hepatic lipidosis, hypophosphatemia most commonly occurs with refeeding.

58.8.2.2.3 Acid-Base

Alkaline intracellular pH stimulates phosphofructokinase and therefore glycolysis, which draws phosphate into the cells to form phosphate-containing intermediate molecules, an effect that has been shown in hyperventilated dogs. Low phosphate can occur as a result.

Acidic intracellular pH promotes degradation of phosphate-containing intracellular compounds, causing release of phosphate. This would be expected to cause hyperphosphatemia, but subsequent phosphaturia is promoted because acidosis impairs the sodium-phosphate transporter on the renal tubular epithelial cell. The net result may be hypophosphatemia.

58.8.2.2.4 Epinephrine

Epinephrine mediates redistribution of phosphate out of the extracellular compartment. This response occurs at about the same epinephrine levels as do the chronotropic and pressor responses. Conditions promoting a rise in epinephrine, such as sepsis, burn injury, strenuous exercise, or administration of exogenous epinephrine, may cause acute hypophosphatemia.

58.8.2.3 Renal or Dialysis-Associated Loss

Diuresis (saline, drug-induced, osmotic) augments phosphaturia. Hypomagnesemia augments phosphaturia, but it rarely causes hypophosphatemia alone. Hyperparathyroidism promotes hypophosphatemia by increasing PTH which has a phosphaturic effect.[8] Hyperparathyroidism may be primary or secondary to renal disease or an all-meat (low calcium) diet in carnivores. Renal tubular defects such as Fanconi syndrome may promote phosphaturia. They have a variable effect on [P]. Some malignancies promote phosphaturia, because they produce substances that decrease renal phosphate absorption and renal hydroxylation of vitamin D. Hypercalcemia of malignancy often is associated with hypophosphatemia.

58.8.2.4 Mixed Causes

Uncontrolled diabetes mellitus, diabetic ketoacidosis, and hyperglycemic hyperosmolar nonketotic syndrome cause phosphaturia and, combined with inadequate dietary intake, result in loss of body stores of phosphate.[9] Mechanisms include osmotic diuresis, metabolic acidosis, and insulin therapy.

Salicylate poisoning may cause respiratory alkalosis and may also directly stimulate glycolysis, either of which draws phosphate into the cells.

Eclampsia is due to a failure to mobilize calcium and phosphate from bone to match losses in milk.

Hypercalcemia of malignancy often is associated with hypophosphatemia.

58.8.3 Effects

If hypophosphatemia is severe enough to cause a significant decrease in phosphate-containing metabolites, it can cause abnormal function of many organs and systems.

58.8.3.1 Cell Function

Phosphate-depleted red blood cells have impaired release of oxygen because of decreases in 2,3-diphosphoglycerate, abnormal shape and deformability, and are at risk for hemolysis caused by ATP depletion.[10,11] Hemolysis can occur at [P] values less than 1 mg/dl in dogs and has been reported at less than

2.5 mg/dl in cats.[7] Phosphate depletion impairs white blood cell chemotaxis, phagocytosis, and bactericidal activity. Impaired clot retraction and shortened platelet life span with a tendency toward hemorrhage occurs in dogs.[6]

58.8.3.2 Muscle

The myopathy of phosphate depletion is caused by a decreased capacity to form ATP. Clinical signs include weakness, myocardial insufficiency, and respiratory insufficiency. Rhabdomyolysis may result, especially in dogs with earlier subclinical phosphate depletion.[12]

58.8.3.3 Metabolic

Impaired glucose metabolism, phospholipid synthesis, and bone mineralization, as well as increased release of magnesium from bone and decreased reabsorption in the kidney, and liver dysfunction may result from severe hypophosphatemia.[13]

58.8.3.4 Acid-Base

Phosphate depletion can cause renal proximal tubular bicarbonate wasting, impair distal acidification, and decrease ammoniagenesis, resulting in metabolic acidosis.

58.8.4 Therapy

It is difficult to identify a specific benefit from treatment of hypophosphatemia, because simultaneous treatment of acid-base, electrolyte, and nutritional abnormalities impairs evaluation of the effect of phosphate repletion alone. When phosphate levels are less than 1 mg/dl, complications such as hemolysis, respiratory failure, muscle weakness, and impaired oxygen delivery may occur.[10] Phosphate levels less than 2 mg/dl have been associated with muscle weakness, anorexia, or tremor in human patients.[13] Phosphate levels less than 1.5 mg/dl should be treated in diabetic cats.[10] Because diabetic ketoacidosis is a common cause of hypophosphatemia, and because of the deleterious effects of hypophosphatemia, some authors recommend the routine administration of phosphate to these patients unless they are hyperphosphatemic.[13]

58.8.4.1 Prevention

Phosphate-binding drugs, intravenous glucose, and diuretics should be stopped, if possible. Feeding solutions, especially in debilitated patients, should be supplemented with phosphate.

58.8.4.2 Treatment

Because [P] may not parallel total body stores, therapy must be monitored closely to avoid hyperphosphatemia and other adverse effects (see next section). Phosphate preparations are available for delivery by oral and intravenous routes. For mild hypophosphatemia, oral is the route of choice. Skim milk has 1 g of calcium and phosphate per quart and may be enough in mild hypophosphatemia.[14] Phosphate preparations for oral use are available. Enteral phosphate can cause diarrhea. 246 247

58.8.4.2.1

Box 58-2 Precautions Required for Intravenous Phosphate Supplementation

- Check phosphate level q6-12h. Discontinue IV supplementation when [P] is >2 mg/dl.
- If using potassium phosphate, be sure that the rate does not exceed the maximum potassium infusion rate.
- If the patient is hypercalcemic or hypocalcemic, administer phosphate at a slower rate and monitor calcium levels.
- If the patient is hypomagnesemic, concurrent magnesium supplementation is suggested.
- Phosphate solutions for intravenous use are hyperosmolar and should be diluted before administration.
- Hypotension, hypomagnesemia, and hyperosmolality may result from intravenous administration of phosphate, especially if administered too rapidly.
- Do not add calcium to phosphate preparations. Precipitation can result.

In moderate to severe hypophosphatemia, intravenous supplementation is indicated. Preparations for intravenous use include potassium phosphate (93 mg/ml phosphate + 4 mEq/ml potassium) and sodium phosphate (93 mg/ml phosphate + 4 mEq/ml sodium). Suggested dosages are 0.011 to 0.033 mmol/kg/hr of phosphate. When [P] is greater than 2 mg/dl the infusion should be discontinued. For patients with severe diabetes mellitus, a 50:50 mixture of potassium chloride and potassium phosphate at a rate not to exceed the maximum for potassium infusion (0.5 mEq/kg/hr) is useful.[15] Cats with hepatic lipidosis can become hypophosphatemic, especially when refeeding is started, and supplementation as for the diabetic may be needed. Several important precautions should be taken with all intravenous phosphate supplementation; these are listed in Box 58-2.

58.9

HYPERPHOSPHATEMIA

58.9.1

Causes

Hyperphosphatemia occurs by three mechanisms: increased phosphate load (exogenous or endogenous), decreased glomerular filtration rate, and increased renal tubular absorption. The most common cause is renal failure (Box 58-3).

58.9.1.1

Increased Phosphate Load

Rapid introduction of large amounts of phosphate orally or intravenously, when the kidney is set to reabsorb nearly all filtered phosphate, can result in hyperphosphatemia.[16] Although the large intestine usually absorbs little phosphate, enemas containing phosphate can cause hyperphosphatemia,[17] especially if there are mucosal defects. Vitamin D intoxication causes increased intestinal absorption and increased bone resorption. Hyperphosphatemia was reported with intoxication by calcipotriene, an antipsoriasis drug causing hypercalcemia, and with liposome-encapsulated amphotericin B.[18,19]

58.9.1.2

Redistribution

Phosphate may be released from intracellular stores in bone resorption, or processes causing cell damage such as necrosis, tumor lysis syndrome,[20] rhabdomyolysis, or hemolysis. Metabolic or respiratory acidosis, strenuous exercise, and malignant hyperthermia cause a decrease in intracellular pH, which inhibits glycolysis, thus decreasing incorporation of inorganic phosphate into organic compounds. This increases the intracellular free phosphate, which then distributes to the extracellular compartment.[21]

58.9.1.2.1

Box 58-3 Causes of Hyperphosphatemia

58.9.1.2.1.1

Increased Phosphate Load

58.9.1.2.1.1.1

Exogenous

Large amount of oral phosphate or IV phosphate introduced rapidly

Phosphate-containing enemas

Vitamin D intoxication, cholecalciferol rodenticide toxicity

Drugs (calcipotriene, liposomal amphotericin B)

58.9.1.2.1.1.2

Endogenous (Redistribution)

Bone

Necrosis

Metabolic acidosis, especially organic acidosis

Acute respiratory acidosis

Tumor lysis syndrome

Acute hemolysis

Rhabdomyolysis

Strenuous exercise

Malignant hyperthermia

58.9.1.2.1.2 Decreased Renal Excretion

Renal failure (prerenal, renal, post)

Urinary tract rupture

58.9.1.2.1.3 Increased Renal Reabsorption

Hypoparathyroidism

Acromegaly

Hyperthyroidism

Glucocorticoid withdrawal

Bisphosphonates

58.9.1.3 Decreased Glomerular Filtration Rate

The most common cause of hyperphosphatemia is renal failure. In acute failure, phosphate often rises before creatinine and blood urea nitrogen. In chronic failure, phosphate rises after adaptive mechanisms such as increased PTH, decreased calcitriol, and intrinsic tubular adaption have failed.

58.9.1.4 Increased Renal Absorption

Various endocrine abnormalities promote hyperphosphatemia. In hypoparathyroidism, the phosphaturic action of PTH is diminished.[22] Growth hormone excess in acromegaly or hyperthyroidism increases the TmP and glomerular filtration rate. Hyperthyroidism also causes increased bone resorption and PTH suppression.[16] Glucocorticoids inhibit sodium-dependent phosphate uptake in the kidney, and their withdrawal can cause hyperphosphatemia.

Bisphosphonates, used to treat hypercalcemia, can decrease phosphate excretion and cause hyperphosphatemia.

58.9.2 Effects

58.9.2.1 Hypocalcemia

Hyperphosphatemia, especially if it develops rapidly (within a few days), may cause a clinically significant ionized hypocalcemia, possibly severe enough to cause tetany. The mechanism is calcium precipitation, inhibition of bone resorption, and suppression of renal hydroxylation of vitamin D.[13] In renal failure, the hyperphosphatemia-induced decrease in serum calcium stimulates PTH and plays a role in renal secondary hyperparathyroidism.

58.9.2.2 Renal

Hyperphosphatemia from any cause can promote renal intratubular precipitation of calcium and phosphate, which has the potential to interfere with tubular function and worsen the hyperphosphatemia.

58.9.2.3 Metastatic Calcification

Deposition of calcium phosphate salts in undamaged soft tissue caused by elevated calcium-phosphate product (Ca × P) is one form of metastatic calcification. The level of Ca × P at which this is likely to occur, previously reported at 70 mg^2/dl^2 has been reevaluated and a therapeutic goal in human patients with renal failure of 55 mg^2/dl^2 suggested.[21] The mineral deposits incite a periarticular, articular, and conjunctival inflammatory response in humans. Calcium-phosphate deposits also occur in the heart and lungs, but their deposition is not as clearly related to an increased Ca × P.[22] Calciphylaxis, a medium and small artery vasculopathy with mural calcification, is associated with an increased Ca × P. The syndrome results in ischemia and necrosis of skin, fat, organs, and skeletal muscle.[23] In dogs and cats with chronic renal failure, metastatic calcification is identified but does not usually cause clinical signs. Control of hyperphosphatemia is important in the management of renal secondary hyperparathyroidism.[24]

58.9.2.4 Acid-Base

Phosphate is a weak acid at physiologic pH; hence, increases in [P] will cause a metabolic acidosis.[25]

58.9.3 Therapy

58.9.3.1 Prevention

Exogenous sources of phosphate and intestinal absorption of phosphate should be reduced in patients with renal impairment. Endogenous sources of phosphate from cell breakdown, as in tumor lysis syndrome, should be managed with renal support and avoidance of nephrotoxic agents.

58.9.3.2 Treatment

Volume expansion and diuresis promote renal phosphate excretion. Phosphate is removed during dialysis at a rate determined by the volume and composition of the dialysate and the body fluids, and by the type of dialysis membrane used.

Aluminum-containing phosphate-binding drugs (aluminum hydroxide, aluminum carbonate, and aluminum oxide) bind intestinal phosphate so that dietary and secreted phosphate are not absorbed. They also decrease absorption of endogenous phosphate excreted from parotid glands and the pancreas.[25] Use of aluminum-containing phosphate binders in human patients has declined because of toxicity, but there is little evidence of toxicity in dogs and cats. Calcium carbonate and calcium acetate are available and are widely prescribed in human patients, but they may promote hypercalcemia.[26] Non–calcium-containing phosphate binders, such as sevelamer hydrochloride, are in use in humans and animals.[25,27]

59 Chapter 59 Acid-Base Disturbances

Jan P. Kovacic, DVM, DACVECC

59.1 KEY POINTS

- The Henderson-Hasselbalch and strong ion approaches to acid-base analysis group parameters that the clinician would prefer to separate to isolate cause and effect and to guide treatment.
- Respiratory changes in acid-base are caused by changes in the plasma carbon (CO_2) dioxide concentration. This is a measure of ventilation and its ability to match cellular production of CO_2.
- Metabolic changes can be divided into changes related to sodium, chloride, protein, phosphate, and lactate, as well as the many strong anions that are not routinely quantified for acid-base effect but can play a major role in acidemia in disease states.
- A base excess algorithm that estimates the contribution of each of the metabolic contributors to an acid-base disturbance is a practical method to identify the contribution of each mediator and to make more accurate decisions for therapy.

59.2 INTRODUCTION

Changes in hydrogen ion concentration in the body are associated with molecular changes that can have significant physiologic effects. Consequently, homeostasis aims to maintain a normal hydrogen ion concentration. Hydrogen ion concentration is measured as pH, the negative base-10 logarithm of the hydrogen ion concentration, $[H^+]$. The normal extracellular pH is generally in the range of 7.4. Elevated blood hydrogen ion levels (pH <7.4) are described as an *acidemia,* and reduced hydrogen ion levels (pH >7.4) are described as an *alkalemia.* [1]

There is a widely held misunderstanding that the body regulates hydrogen ion concentration within very narrow limits. This is a result of the observation that normal pH is approximately 7.41 in dogs and 7.39 in cats and that changes in pH become life threatening if pH falls below 7.1 or rises above 7.7. The misconception that this represents exquisite control of $[H^+]$ is a result of the logarithmic nature of the pH scale. In reality, the life-threatening alarm values for pH represent a $[H^+]$ that ranges from 80 nanoEq/L at a pH of 7.1 to 20 nanoEq/L at a pH of 7.7. This is a four-fold difference in $[H^+]$ between the low and high alarm values. This is equivalent to the statement that sodium concentration is well regulated because its concentration must fall below 75 mEq/L or rise above 300 mEq/L before we become alarmed. Clearly sodium is regulated much more closely, and as clinicians we are alarmed well before the concentration reaches these extremes.

Several approaches to acid-base analysis have been developed. They include the Henderson-Hasselbalch, or conventional, approach that uses pH, partial pressure of carbon dioxide (PCO_2), bicarbonate (HCO_3^- , base excess (BE), and anion gap, and the Stewart approach, which uses pH, PCO_2, strong ion difference (SID), and the quantity of weak acids (A_{TOT}). As clinicians, we find ourselves naming acid-base disturbances while gaining little understanding of the etiology of the patient's acid-base problems and little insight into effective therapy. The primary problem is that within each of these traditional approaches multiple etiologic factors are grouped together.

The clinician needs a way to isolate cause and effect to assess the mechanisms behind the disturbance and to focus treatment.

59.2.1 Box 59-1 Henderson-Hasselbalch Equation

$$pH = 6.1 + \log\left(\left[HCO_3^-\right] \div \left[0.03 \times PCO_2\right]\right)$$

where 6.1 is the pKa in body fluids; $[HCO_3^-]$ is the concentration of HCO_3^- measured in mmol/L; 0.03 is the solubility coefficient for carbon dioxide in plasma; and PCO_2 is the partial pressure of carbon dioxide in mm Hg.

Both approaches to acid-base analysis start with a measurement of pH, a parameter that represents the chemical summation of all acid-base disturbances. An abnormal pH is interpreted as acidemia or alkalemia. This is the net change in $[H^+]$ that results from all acidifying events (acidosis) and all alkalinizing events (alkalosis). Rarely is an acidemia or alkalemia so severe that the clinician's objective is to treat the disturbance without regard to etiology. The real value in acid-base analysis is to discover the multiple compensating and counterbalancing causes that are common in critical care patients.

Acid-base disturbances are broadly categorized as respiratory or metabolic in nature. Conventional acid-base analysis is based on the Henderson-Hasselbalch equation (Box 59-1), which uses bicarbonate concentration, $[HCO_3^-]$, as the sole measure of the metabolic contribution to acid-base balance and the PCO_2 as the single causative agent for respiratory acid-base disturbances. Using this conventional approach the primary abnormality (metabolic or respiratory) is the system that is responsible for the initial change in pH. For example, an acidemia with a low HCO_3^- and low PCO_2 would be considered a primary metabolic acidosis, because the acidemia must be a result of the low HCO_3^-.[1,2] The conventional approach identifies four acid-base abnormalities; these are described in Table 59-1.

The PCO_2 is universally considered the sole causative agent for respiratory acid-base disturbances. However, the parameter(s) used to assess metabolic disturbances varies with the analytic approach chosen. For clinical application, acid-base disturbances should be studied from the perspective of the individual etiologic agents that cause them (Table 59-2).

59.3 RESPIRATORY ACID-BASE DISTURBANCES

Carbon dioxide acts as an acid because of its ability to react with water to produce carbonic acid. In this way, the 249 250 PCO_2 affects the HCO_3^- buffer system and ultimately the hydrogen ion concentration.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Table 59-1 Acid-Base Disturbances Identified With the Conventional Approach

Acid-base Disturbance	**pH**	**PCO_2**	**$[HCO_3^-]$**
Respiratory acidosis	↓	↑	↑
Respiratory alkalosis	↑	↓	↓
Metabolic acidosis	↓	↓	↓
Metabolic alkalosis	↑	↑	↑

$[HCO_3^-]$, Bicarbonate concentration measured in mEq/L;

PCO_2, is partial pressure of carbon dioxide measured in mm Hg; ↑, increased; ↓, decreased.

Table 59-2 Acid-Base Disturbances Based on Etiology

Respiratory Causes of Acid-Base Disturbances	
Increased carbon dioxide	Respiratory acidosis (hypoventilation)
Decreased carbon dioxide	Respiratory alkalosis (hyperventilation)
Metabolic Causes of Acid-Base Disturbances	
Decreased sodium	Hyponatremic metabolic acidosis
Increased sodium	Hypernatremic metabolic alkalosis
Increased chloride	Hyperchloremic metabolic acidosis
Decreased chloride	Hypochloremic metabolic alkalosis
Increased protein	Hyperproteinemic metabolic acidosis
Decreased protein	Hypoproteinemic metabolic alkalosis
Increased phosphate	Hyperphosphatemic metabolic acidosis
Decreased phosphate	Hypophosphatemic metabolic alkalosis
Increased unmeasured anions	Lactic acidosis
	Ketoacidosis
	Toxic acidosis (ethylene glycol, salicylate)
	Acidosis of renal failure

Because carbon dioxide is a gas for which concentration in the blood is controlled by pulmonary ventilation, the lung plays a role in controlling acid-base status. This is a rapid process that can alter blood pH within minutes. Normal arterial PCO_2 in dogs is 37 mm Hg and in cats it is 31 mm Hg. The PCO_2 is maintained by normal pulmonary function, normal function of the diaphragm and respiratory muscles, normal pleural space dynamics, and normal respiratory drive controlled by the brain.

If the PCO_2 is abnormal, there is a respiratory component to the acid-base disturbance, but it is not necessarily pathologic. PCO_2 is determined directly by effective alveolar minute ventilation which, in turn, is controlled by the respiratory center of the brain. CO_2, oxygen, and pH can all alter alveolar minute ventilation via central and peripheral chemoreceptors. Chemoreceptors do not respond to changes in PCO_2 directly; rather they detect associated changes in $[H^+]$. Hence abnormalities in PCO_2 can be subsequent to primary respiratory disorders or can occur in response to metabolic acid-base abnormalities and their associated changes in $[H^+]$. When metabolic processes occur that increase $[H^+]$, the respiratory center will respond with hyperventilation to lower PCO_2. Conversely when $[H^+]$ is low, hypoventilation will occur to increase PCO_2 appropriately. This is the normal respiratory response to a metabolic alteration and serves to minimize the overall change in pH.[1,4]

Table 59-3 Expected Compensatory Changes to Primary Acid-Base Disorders

Primary Disorder	**Expected Compensation**
Metabolic acidosis	↓ PCO_2 of 0.7 mm Hg per 1 mEq/L decrease in $[HCO_3^-]$ ±3
Metabolic alkalosis	↑ PCO_2 of 0.7 mm Hg per 1 mEq/L decrease in $[HCO_3^-]$ ±3
Respiratory acidosis—acute	↑ $[HCO_3^-]$ of 0.15 mEq/L per 1 mm Hg ↑ PCO_2 ±2
Respiratory acidosis—chronic	↑ $[HCO_3^-]$ of 0.35 mEq/L per 1 mm Hg ↑ PCO_2 ±2
Respiratory alkalosis—acute	↓ $[HCO_3^-]$ of 0.25 mEq/L per 1 mm Hg ↓ PCO_2 ±2
Respiratory alkalosis—chronic	↓ $[HCO_3^-]$ of 0.55 mEq/L per 1 mm Hg ↓ PCO_2 ±2

$[HCO_3^-]$, Bicarbonate concentration measured in mEq/L; *PCO_2*, partial pressure of carbon dioxide measured in mm Hg, ↑, increased; ↓, decreased.

Conventional acid-base nomenclature states that a metabolic disturbance that is accompanied by an appropriate compensatory respiratory change is classified as a simple metabolic disturbance and the respiratory component is not named. A compensatory change is considered “appropriate” if it is of a magnitude similar to that predicted by the calculated compensatory response. These calculations are provided in Table 59-3 and are discussed further later in this chapter.[1,3]

In clinical practice it may be beneficial to identify the respiratory component, because this physiologic response may have more serious consequences for the patient than the initial metabolic disturbance. For example, a patient in shock with serious head trauma may present with a metabolic acidosis and appropriate respiratory compensation. Although the respiratory alkalosis in this case is compensatory and not considered an acid-base abnormality, it may be clinically significant because the low PCO_2 causes cerebral vasoconstriction, which may be dangerous in this patient. Further assessment, including clinical monitoring, will identify if the respiratory change is likely to be physiologic or if there are other, pathologic, respiratory disturbances that may amplify or attenuate the physiologic response.

59.3.1 Increased Carbon Dioxide: Respiratory Acidosis

Respiratory acidosis may result from a primary respiratory disorder or it can be a physiologic respiratory compensation for a metabolic alkalosis. An increase in HCO_3^- of 1 mEq/L should result in an increase in PCO_2 of 0.7 mm Hg in both dogs and cats.[1,3]

Pathologic respiratory acidosis results from an imbalance in CO_2 production via metabolism and excretion via the lung. Common causes include large airway obstruction or generalized small airway obstruction such as asthma, respiratory center depression, neuromuscular disease, heat stroke, malignant hyperthermia, pleural space disease, and chest wall disruption.[4] The result is respiratory failure and hypoventilation. Cardiopulmonary arrest is a special case in which CO_2 accumulates in tissues as perfusion and ventilation ceases. Initiation of spontaneous or mechanical breathing may provide minute volumes normally associated with hyperventilation, but the plasma CO_2 levels will remain high until effective circulation is established and excess CO_2 dioxide is eliminated.

Therapy for pathologic respiratory acidosis involves improving ventilation by treating the underlying cause. In severe cases of hypoventilation that persists despite therapy, mechanical ventilation is indicated (see Chapter 213, Basic Mechanical Ventilation). Elevated levels of CO_2 can cause hypoxemia in patients breathing room air, and all animals with significant hypercapnia (>60 mm Hg) should receive oxygen therapy.[4]

59.3.2 Decreased Carbon Dioxide: Respiratory Alkalosis

Respiratory alkalosis may result from pulmonary or nonpulmonary disease processes causing hyperventilation, or it can be a physiologic respiratory compensation for metabolic acidosis. A decrease in HCO_3^- of 1 mEq/L should result in a decrease in PCO_2 of 0.7 mm Hg in dogs.[3] In cats, limited evidence suggests that the PCO_2 does not change, and this calculation for expected compensation is not recommended.

Pathologic respiratory alkaloses usually are caused by hypoxemia that stimulates chemoreceptors, pulmonary disease that stimulates stretch receptors and nociceptors independent of hypoxemia, heart failure and baroreceptor stimulation, pain and anxiety, excessive mechanical ventilation, and multiple factors that stimulate centrally mediated hyperventilation.[4]

Therapy is directed at the underlying cause and at suppressing the hyperventilation if the CO_2 is less than 20 to 25 mm Hg when cerebral vasoconstriction is a concern.

59.4 METABOLIC ACID-BASE DISTURBANCES

Clinically, several measures have been used to evaluate the metabolic contribution to acid-base balance. These include HCO_3^-, BE, total carbon dioxide concentration (TCO_2), and evaluation of SID and A_{TOT}. The HCO_3^- is a calculated value provided by the blood gas machine and is the summation of many metabolic processes that can alter $[H^+]$. The HCO_3^- may hide serious but canceling acidoses and alkaloses such that the clinician has little information for effective treatment. In addition, HCO_3^- will change with changes in PCO_2; consequently, it may not be an accurate reflection of the metabolic component when there are significant respiratory acid-base abnormalities.

The BE is an alternative measure of the metabolic component. The BE provides a measure of the metabolic component that is independent of changes in PCO_2. Standardized BE equals the amount of strong acid or base needed to restore the plasma pH of 1 L of blood to 7.4 at a $PaCO_2$ of 40 mm Hg and a temperature of 37° C; it is also calculated via formulas programmed into the blood gas machine.[1] TCO_2 concentration is a result provided on serum biochemistry analyses and is a measure of the sum of HCO_3^-, carbonic acid, and the dissolved CO_2 in the system. Because HCO_3^- is quantitatively by far the major contributor to TCO_2 concentration, this measure can be used as an index of HCO_3^- levels in the absence of a blood gas result, although this value will always be slightly above the true HCO_3^- concentration. A decrease in HCO_3^-, a negative BE, and a decreased TCO_2 all indicate a metabolic acidosis, and an increase in HCO_3^-, positive BE, and increased TCO_2 are indicative of a metabolic alkalosis.

59.4.1 Box 59-2 Anion Gap Equation

$$\text{Anion gap}^{*} = \left(\left[Na^+\right] + \left[K^+\right]\right) - \left(\left[HCO_3^-\right] + \left[Cl^-\right]\right)$$

*In reality there is no actual anion gap; rather, this is a measure of unmeasured anions and cations in the system. An increase in the anion gap usually reflects an increase in unmeasured anions.

59.4.2 Anion Gap

By calculation of the anion gap, metabolic acidosis can be divided into one of two broad categories—elevated anion gap metabolic acidosis and normal anion gap metabolic acidosis.[1] When acidosis occurs without changing the anion gap, the cause is hyperchloremia (the measured chloride increases along with the acidosis so the gap does not change). Thus a normal anion gap is called *hyperchloremic acidosis* and a high anion gap is called *normochloremic acidosis*. Electroneutrality dictates that the total number of cations in the system must equal the total number of anions, so there is no anion gap in reality.

In the clinical setting, a greater proportion of cations can be measured directly in comparison with anions. The difference between the two, the anion gap, is a measure of the quantity of unmeasured anions in the system. The anion gap is calculated via the formula provided in Box 59-2. Elevations in anion gap are associated with specific disease states and may help narrow the rule-out list for the patient with metabolic acidosis (see Table 59-2). In the normal animal the unmeasured anions represented by the anion gap comprise mainly albumin and a small amount of inorganic phosphate. States of hypoalbuminemia and hyperalbuminemia alter the anion gap significantly such that it is no longer a reliable indicator of the presence of abnormal acids.[5]

59.4.3 Stewart Approach

In recognizing that multiple metabolic processes can contribute to the overall metabolic component, the Stewart approach to acid-base analysis may be more useful to the clinician. Stewart identified three individual determinants of acid-base balance. These were PCO_2, SID, and A_{TOT}.[2,6-8] SID commonly is estimated from the difference in serum sodium and chloride concentrations. According to this approach to acid-base analysis, pH is a product of water dissociation which, in turn, is determined by the balance between strong cations and anions (SID) and the presence of weak acids in the system. The relative concentration of HCO_3^- is not considered to be a determinant of pH. Increases in SID are indicative of an alkalotic effect on the system, and decreases in SID are indicative of an acidotic effect. A_{TOT} is the quantity of weak acids and consists primarily of albumin and phosphate. The interested reader is directed to references 6 through 8 for further discussion of the principles of the Stewart approach to acid-base analysis. There are still inherent problems with this system, because the calculation of SID groups the sodium and chloride effects, and A_{TOT} sums the effect of protein and phosphate.

59.4.4 Quantitative Analysis of Base Excess

Clinically it is beneficial to consider the contribution of each individual process to the overall BE to determine the cause of metabolic acid-base abnormalities, their relative magnitude, and to guide therapy. These processes include changes in sodium concentration, chloride concentration, serum protein, phosphate, lactate, and unmeasured anions. Unfortunately the mechanism by which each of these processes affects acid-base balance remains controversial. Two schools of thought are presented in this discussion; however, by using simple equations the clinician can approximate the relative impact of each of these factors on acid-base balance.[6,9]

59.4.4.1 Hyponatremic Metabolic Acidosis

Sodium is the major extracellular cation. It acts as a strong ion, so it exists in the ionic, charged form at physiologic pH. Because water follows sodium, hyponatremia can also be considered a relative increase in free water. One explanation for the acid-base effect of hyponatremia is that free water is acidic relative to normal body pH, so increases in free water (decreases in sodium) content will have an acidifying effect on the system.[10] The Stewart explanation is that if the sodium level of plasma decreases, the decrease in positive charge is offset by an increase in $[H^+]$ and a decrease in HCO_3^-. This is acidifying.

The contribution of a decrease in plasma sodium concentration is to decrease the BE (making it more negative) by 25% of the change in the patient's sodium for dogs, 22% for cats[6]:

$$\Delta\ \mathrm{BE} = 0.25 \times ([\text{Patient sodium}] - [\text{Normal sodium}]) \text{ for dogs}$$

$$\Delta\ \mathrm{BE} = 0.22 \times ([\text{Patient sodium}] - [\text{Normal sodium}]) \text{ for cats}$$

Hyponatremia is associated with sodium loss from vomiting or diarrhea, third space sodium loss, nephrotic syndrome, hypoadrenocorticism, congestive heart failure, psychogenic polydipsia, diuretic administration, hypotonic fluid use, and the syndrome of inappropriate antidiuretic hormone (SIADH) release.[1]

Treatment is directed at correcting the underlying cause and providing sodium replacement (if indicated) using appropriate replacement fluids and sodium bicarbonate. Care should be taken that fluids do not contain excess chloride, which may create a hyperchloremic metabolic acidosis and exacerbate the problem.

59.4.4.2 Hypernatremic Metabolic Alkalosis

Hypernatremia is a reflection of an alkalinizing effect on the system as described earlier. The contribution of an increase in plasma sodium concentration is to increase the BE by 25% of the change in the patient's sodium for dogs, 22% for cats[6]:

$$\Delta\ \text{BE} = 0.25 \times ([\text{Patient sodium}] - [\text{Normal sodium}]) \text{ for dogs}$$

$$\Delta\ \text{BE} = 0.22 \times ([\text{Patient sodium}] - [\text{Normal sodium}]) \text{ for cats}$$

Hypernatremia can occur with vomiting, renal failure, postobstructive diuresis, diabetes insipidus, water deprivation, sodium bicarbonate administration, use of other medications complexed with sodium, and hypertonic fluid use.

Treatment is directed at correcting the underlying cause and limiting sodium intake if elevations in sodium and osmolality are severe.

59.4.4.3 Hyperchloremic Metabolic Acidosis

Hyperchloremia is associated with an acidifying effect on the system. Chloride concentration may change independently of sodium, but it will also be altered by changes in free water in a manner parallel with sodium concentration. The free water–associated changes and their influence on acid-base status are calculated in the sodium equation. Therefore, to isolate independent changes in chloride, the measured chloride concentration must be corrected for this free water change.[1,6,9]

$$\text{Corrected chloride} = \text{Patient chloride} \times ([\text{Normal sodium}] \div [\text{Patient sodium}])$$

The conventional explanation for the acid-base effect marked by changes in chloride concentration is that it is a reflection of changes in HCO_3^- concentration. Because the two major anions in the body, chloride and HCO_3^-, are handled in a reciprocal manner, changes in HCO_3^- will be reflected by a similar but inverse change in chloride.[11] The Stewart explanation is that chloride is the major extracellular anion and as a strong ion exists in its ionic form. If the chloride level of plasma increases, the increase in negative charge is offset by an increase in $[H^+]$ and a decrease in HCO_3^-. This is acidifying.

The contribution to metabolic acid-base balance marked by an increase in plasma corrected chloride concentration is to directly decrease the BE[6,9]:

$$\Delta\ \text{BE} = ([\text{Normal chloride}] - [\text{Patients corrected chloride}])$$

Hyperchloremia may result from renal failure, diarrhea, total parenteral nutrition, and the administration of drugs or fluids that have a lower sodium-to-chloride ratio than normal. The normal sodium-to-chloride ratio is approximately 3:2.

Iatrogenic hyperchloremic metabolic acidosis is a common finding in intensive care patients receiving fluids and multiple medications. If the clinician does not pay attention to the sodium-to-chloride ratio of intravenous fluids and to the use of potassium chloride supplements and other medications that contain chloride, it is easy for it to accumulate, with serious consequences on acid-base status. Furthermore, hyperchloremic acidosis relies on the kidneys to eliminate the excess chloride, so rapid treatment is difficult and is complicated further in patients with renal tubular disease.

59.4.4.4 Hypochloremic Metabolic Alkalosis

Just as increased chloride concentrations are associated with an acidifying effect on the system, decreased 252
chloride concentrations are associated with alkalinizing effects. The contribution of a decrease in plasma 253
corrected chloride concentration is to directly increase the BE[6,9]:

$$\Delta\ \mathrm{BE} = ([\,\mathrm{Normal\ chloride}\,] - [\,\mathrm{Patient\ corrected\ chloride}\,])$$

Hypochloremia relative to sodium can occur with pyloric outflow obstruction and vomiting, diuretic administration, fluid use, or with sodium bicarbonate therapy. Treatment is directed at the underlying cause and toward restoring a normal sodium-to-chloride ratio.

59.4.4.5 Hyperproteinemic Metabolic Acidosis

Increases in serum protein are associated with an acidifying effect. The conventional explanation for this acid-base effect is that at physiologic pH plasma proteins, primarily albumin, act as weak acids. Consequently, increases in plasma protein will have an acidifying effect.[11] The Stewart explanation is that at physiologic pH proteins exert a net negative charge that in canine plasma totals about 16 mEq/L. If the protein level of plasma increases, the increase in negative charge is offset by an increase in $[H^+]$ and a decrease in HCO_3^- concentration. This is an acidifying event.

An increase in plasma proteins is unusual but may be associated with some inflammatory processes, neoplasia such as multiple myeloma, dehydration, and iatrogenic overadministration of albumin.

The contribution of an increase in total protein is to decrease the BE (more negative) by 3 times the change in the patient's total protein[6,9]:

$$\Delta\ \mathrm{BE} = 3 \times ([\,\mathrm{Normal\ protein}\,] - [\,\mathrm{Patient\ protein}\,]$$

The albumin concentration may also be substituted[6,9]:

$$\Delta\ \mathrm{BE} = 3.7 \times ([\,\mathrm{Normal\ albumin}\,] - [\,\mathrm{Patient\ albumin}\,])$$

Treatment of hyperproteinemic metabolic acidosis involves specific therapy for the underlying disease and, in extreme cases, plasmapheresis.

59.4.4.6 Hypoproteinemic Metabolic Alkalosis

Hypoproteinemia is far more common than hyperproteinemia in critically ill patients. Hypoproteinemia is associated with an alkalinizing effect on the system as discussed earlier. A decrease in plasma proteins may be caused by dilution with an increase in plasma water, loss due to vascular leak states such as protein-losing nephropathy, protein-losing enteropathy, systemic inflammation (systemic inflammatory response syndrome), or decreased synthesis due to hepatic disease or reprioritization. The result of a decrease in plasma protein is to increase the BE by 3 times the change in the patient's protein measured in g/dl[6,9]:

$$\Delta \text{ BE } = 3 \times ([\text{ Normal protein }] - [\text{ Patient protein }])$$

The albumin concentration may also be substituted[6,9]:

$$\Delta \text{ BE } = 3.7 \times ([\text{ Normal albumin }] - [\text{ Patient albumin }])$$

Treatment for hypoproteinemic metabolic alkalosis is directed at the underlying cause of the protein loss.

59.4.4.7 Hyperphosphatemic Metabolic Acidosis

Elevations in serum phosphate are associated with an acidifying effect on the system. The conventional explanation is that phosphate is a weak acid at physiologic pH; hence increases in serum phosphate concentration have an acidotic effect on the system.[11] The Stewart explanation is that the normal phosphate level of 5 mg/dl contributes approximately 2.9 mEq/L of net negative charge to plasma. An increase in negative charge from an increase in phosphate is balanced by an increase in $[H^+]$ and a decrease in HCO_3^-, an acidifying event.

The result of an increase in phosphate is to decrease the BE (more negative) by 60% of the change from normal plasma concentration of inorganic phosphorus reported in mg/dl[6,9]:

$$\Delta \text{ BE } = 0.6 \times ([\text{ Normal phosphate }] - [\text{ Patient phosphate }])$$

Hyperphosphatemia is associated with renal failure, urinary tract obstruction or disruption, cell lysis, or phosphate-containing medications such as intravenous phosphates, phosphate urinary acidifiers, and phosphate enemas. Treatment is directed at the underlying disease or removing the offending therapeutic agent. Hemodialysis and peritoneal dialysis are both effective at reducing serum phosphate concentration.

59.4.4.8 Hypophosphatemic Metabolic Alkalosis

Hypophosphatemia has an alkalinizing effect on the system but because phosphate levels are normally low, a decrease in phosphate will be life threatening before it creates a dramatic change in acid-base balance. Hypophosphatemia may be caused by malnutrition, nutritional disorders, excess renal excretion, or hemodilution. The result of decreases in phosphate is to increase the BE by 60% of the change from normal plasma concentration of inorganic phosphorus reported in mg/dl[6,9]:

$$\Delta \text{ BE } = 0.6 \times ([\text{ Normal phosphate }] - [\text{ Patient phosphate }])$$

Treatment is directed at careful intravenous phosphate replacement and treating the underlying cause.

59.4.4.9 Lactic Acidosis

Endogenous anaerobic metabolism produces lactic acid that dissociates to lactate plus a hydrogen ion. Hence hyperlactatemia is considered a cause of metabolic acidosis.[12] When the lactate anion is associated with a cation other than hydrogen ion, such as sodium as it is in lactated Ringer's solution, its acidifying effect is balanced by the alkalinizing effect of the strong cation it is paired with so that there is no net change in acid-base status.

Serum lactate (measured in mmol/L) will directly decrease the base deficit (more negative) as described by the following equation:

$$\Delta \text{ BE} = -1 \times ([\text{Patient lactate}])$$

If lactate is not measured directly, its effect on BE cannot be calculated and its impact will be accounted for within the unmeasured anion effect.

59.4.4.10 Increased Unmeasured Anions

Acid-base changes can be influenced by substances that are not measured in routine acid-base or chemistry panels. If the foregoing calculations successfully accounted for all the metabolic contributions to acid-base balance, the sum of the calculated effects of sodium, chloride, protein, phosphate, and lactate would equal the BE. In reality there is often a gap between their additive effects and the total BE. If a significant gap exists between the total BE and sum of the calculated effects it is indicative of the presence of unmeasured anions in the system.[6,9]

$$\text{UA}^{-} = \text{BE} - \text{Sum}$$

where Sum = sodium effect + chloride effect + protein effect + phosphate effect + lactate effect (if measured), and UA^{-} = unmeasured anions.

These unmeasured anions may include diabetic ketoacids, toxic acids (ethylene glycol, alcohols, salicylate), and the acids of renal failure other than phosphate.[1] If lactate is not measured and accounted for directly, hyperlactatemia will be reflected in the calculated unmeasured anion effect. When the clinician finds that a significant component of a decline in BE is due to unmeasured anions, a search for the more common causes should be initiated. Treatment for these disorders is directed at the underlying cause.

60 Chapter 60 Lactic Acidosis

Jan P. Kovacic, DVM, DACVECC

60.1 KEY POINTS

- Lactate is synthesized from pyruvate and must be metabolized back to pyruvate to be removed. In anaerobic conditions, pyruvate cannot be used effectively in the Krebs cycle, so lactate levels rise.
- Lactic acid has an acidifying effect on plasma.
- Type A lactic acidosis is the hypoxic form. It occurs when there is inadequate oxygen delivery to the tissues.
- Type B lactic acidosis is the nonhypoxic form. It occurs when there are problems with cellular metabolism in aerobic conditions.
- Lactic acidosis occurs in health and disease. Elevations in lactate are common, but in health the lactate level is restored to normal very quickly after aerobic metabolism is restored.
- Normal lactate levels are less than 2 mmol/L.
- Persistently elevated lactate levels suggest a poor prognosis.

60.2 INTRODUCTION

Lactate is a 3-carbon molecule with a carboxyl group at one end that can accept a hydrogen ion to form lactic acid. The pKa for this hydrogen ion is 3.9. Like many of the organic acids of intermediate metabolism, lactic acid is dissociated completely at physiologic pH, and dissociation of the hydrogen ion leaves a strong anion. Consequently lactic acidosis can be recognized by changes in strong ion balance. According to the Stewart approach to acid-base analysis, strong anions force a change in aqueous solutions to increase hydrogen ion [H^+] and decrease hydroxyl ion [OH^-] concentrations and force a weak acid buffer such as carbonic acid to increase [H^+] and decrease bicarbonate concentration [HCO_3^-].[1-3] In the conventional approach to acid-base analysis, lactic acidosis is considered to be the consequence of the hydrogen ion production that occurs in conjunction with lactate metabolism. When the lactate anion is in association with another cation such as sodium, as it is in lactated Ringers solution, it does not have an acidifying effect.[1,3,4]

Lactate exists in two isomeric forms: d-lactate and l-lactate. d-Lactate is an important metabolic product of bacterial metabolism and has been reported to be clinically significant in man with short bowel syndrome, in cats fed propylene glycol, in cats with diabetes mellitus, and in a cat with exocrine pancreatic insufficiency.[1,4,5] l-Lactate is the isomer produced metabolically in dogs and cats and is the isomer discussed in this chapter. Most hospital analyzers measure only the L-lactate isoform, so d-lactate will be recognized as a metabolic acidosis with an increased anion gap or strong ion gap that is not accounted for by routine lactate measurement. Serum can be submitted to laboratories for specific d-lactate analysis.[4,5]

60.3 LACTATE METABOLISM

Lactate is synthesized from pyruvate and can also be converted back to pyruvate. This reversible reaction is catalyzed by the enzyme lactate dehydrogenase.[6] Lactate dehydrogenase has much greater binding affinity for l-lactate, so when d-lactate is present it is metabolized at a slower rate.

Lactate as an organic acid is unremarkable and behaves as do many other intermediary metabolites. What makes it remarkable is that it exists in a metabolic cul-de-sac with no way in or out except through pyruvate. During anaerobic metabolism when pyruvate is not efficiently metabolized via the Krebs cycle, lactate is formed in high concentration. This can occur with exercise or with disease. Lactate synthesis serves to regenerate nicotinamide adenine dinucleotide, an essential reducing equivalent for ongoing glycolysis. When aerobic conditions are restored, pyruvate is cleared, which opens the pathway for lactate to be metabolized back to normal levels. Lactate may also be transported in the blood and used in the liver under aerobic conditions for energy storage via gluconeogenesis and glycogen synthesis. This pathway involves reconversion of lactate to pyruvate in the liver (Cori cycle) under aerobic conditions to drive the Krebs cycle (Figure 60-1).[4,6]

Lactate is produced primarily in skeletal muscle, gut, brain, skin, and red blood cells. During anaerobic conditions, most lactate is produced in skeletal muscle and the gut. Lactate is metabolized primarily by the liver and kidney.

60.4 LACTIC ACIDOSIS

Lactic acidosis occurs whenever lactate production exceeds its utilization. This can occur with tissue hypoxia or in nonhypoxemic conditions when cellular metabolism is impaired.

Type A lactic acidosis is the hypoxic form. It can occur with true hypoxemia, severe anemia, reduced oxygen delivery from poor perfusion, or from dramatically increased tissue demand from exercise, convulsions, or heat stroke.[1,3,4,7]

Type B lactic acidosis is the nonhypoxic form. It occurs in the face of adequate oxygen delivery when mitochondrial oxidative function is abnormal. This can occur with drugs or toxins, hypoglycemia, diabetes mellitus, liver failure, renal failure, lymphosarcoma, sepsis, and inborn errors of metabolism (Box 60-1).[1,2,4]

60.5 CLINICAL APPLICATION

Lactate levels in plasma reflect the balance between continuous lactate synthesis, lactate breakdown, and the presence of an adequate circulating volume. For dogs the equilibrium state at rest produces a normal plasma lactate concentration of about 2 mmol/L, and for cats about 1.5 mmol/L.[1] Lactate concentrations above these levels should prompt immediate evaluation of the patient.

Lactate levels with exercise or with poor perfusion can increase over 10-fold without serious consequences as long as the increase is short-lived and adequate perfusion and aerobic conditions can be restored. Even with severe lactic acidosis (lactate >20 mmol/L), normal metabolic recovery when perfusion or oxygenation is restored can return the lactate to normal levels within 3 hours. The real problem occurs when increased lactate levels are sustained.

The most common forms of type A lactic acidosis are managed by adjusting the parameters of oxygen delivery:

$$\text{Oxygen delivery} = \text{Arterial oxygen content} \times \text{Cardiac output}$$

$$\text{Arterial oxygen content} = 1.34 \times \text{Hemoglobin (Hb) concentration} \times \%\ \text{Hb saturation} + 0.003 \times \text{Partial pressure of arterial oxygen}$$

$$\text{Cardiac output} = \text{Stroke volume} \times \text{Heart rate}$$

Management is therefore aimed at restoring an effective circulating volume and arterial oxygen content. With most acute-onset lactic acidosis, a rapid response to treatment is expected and lactate levels should decline with no long-term residual effects.

Sustained type A lactic acidosis is a consequence of either inadequate management or ongoing pathology such as aberrations of microcirculation or ischemic tissue. It is a very serious clinical finding that warrants immediate intervention. If cellular injury is extensive as a result of tissue hypoxia, type A lactic acidosis can convert to type B. In this instance oxygenation and circulation may be restored, but cellular injury is too extensive to reestablish normal metabolism and correct the lactic acidosis.

Sustained lactic acidosis can occur with type B, and improvement of perfusion and oxygenation will not resolve the problem. The clinician must identify the underlying cause of the disruption of cellular function and take steps to correct it. Toxins must be bound, metabolized, excreted, or dialyzed. Glucose metabolism must be normalized with adequate glucose supplementation, insulin therapy, or both. Septic patients probably have a combination of type A and type B lactic acidosis because, although oxygen levels may be adequate and perfusion is normal at the organ level, at the tissue level there is often enough disruption of microvascular perfusion such that many tissue beds are operating anaerobically. There may also be a hypermetabolic component that creates pyruvate faster than it can be metabolized in the Krebs cycle. In addition, sepsis can lead to acquired mitochondrial function defects and reduced lactate clearance.[1,2,4,7]

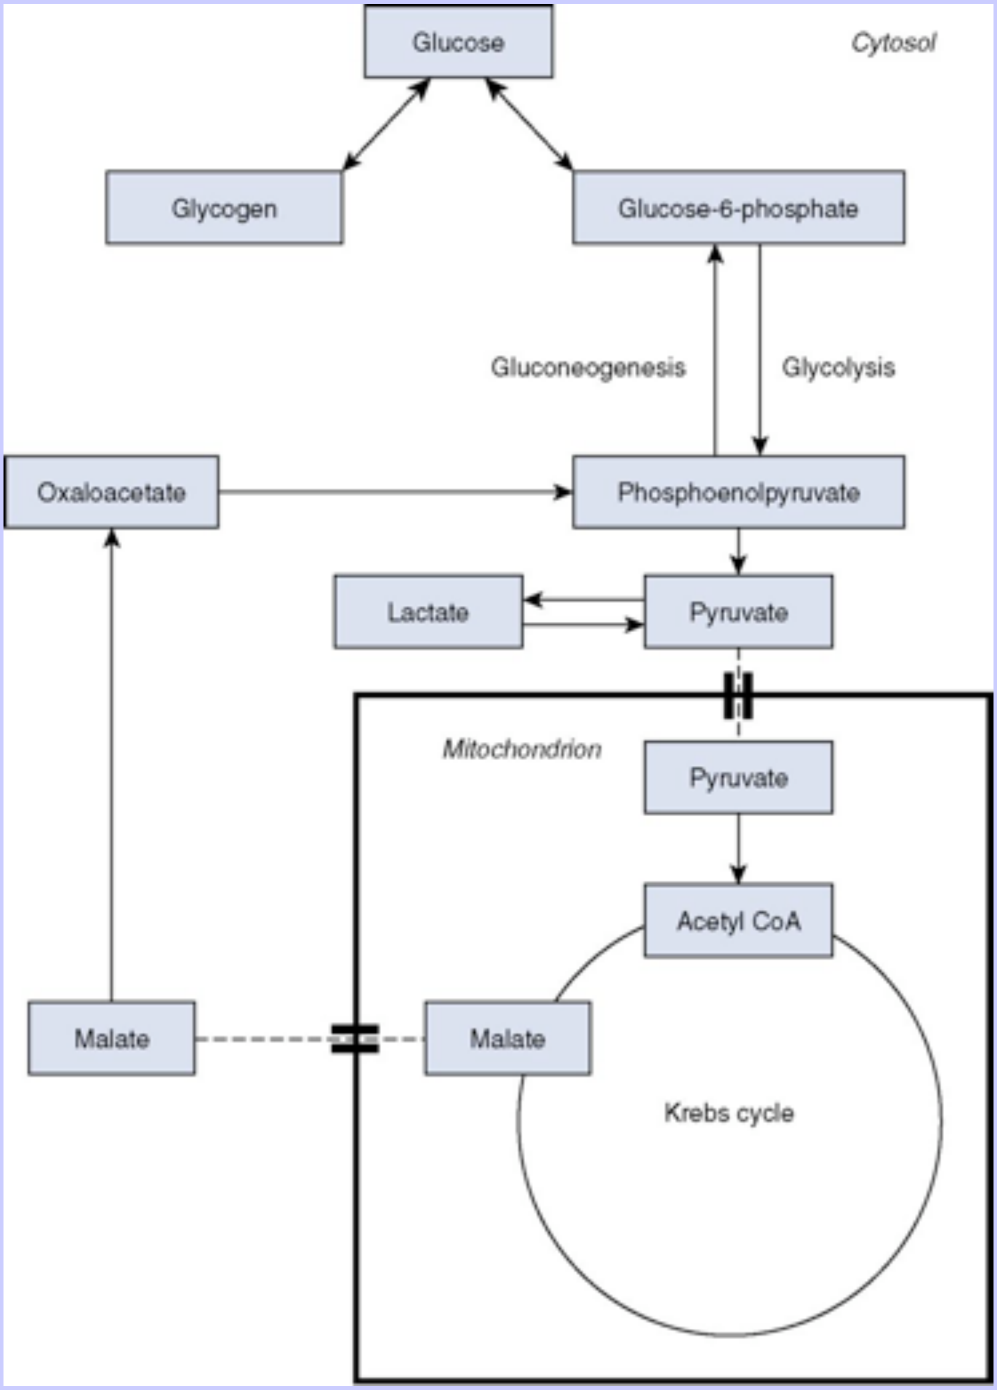
60.6 LACTIC ACIDOSIS WITH CARDIOPULMONARY ARREST

Cardiopulmonary arrest and cardiopulmonary resuscitation (CPR) create a special case of lactic acidosis. During the arrest state, perfusion and oxygen delivery fall to zero and tissue metabolism becomes anaerobic on a global scale. Plasma lactate levels measured in venous blood rise steadily. As CPR is initiated, lactate levels will continue to rise until effective tissue perfusion is achieved. The key to correcting the lactic acidosis of cardiac arrest is the return of spontaneous circulation.[1]

60.7 TREATMENT OF LACTIC ACIDOSIS

Treatment of type A (hypoxic) lactic acidosis is best accomplished by rapidly correcting the underlying cause. The use of sodium bicarbonate or other alkalinizing agents such as Carbicarb (an equimolar mixture of sodium bicarbonate and sodium carbonate), dichloroacetate, or THAM (tris-buffer) should be reserved for type B lactic acidosis that involves failure of cellular function that cannot be reversed, so primary treatment of the acidemia is the only therapeutic option.

Figure 60-1 Schematic of lactate metabolism in the cell. Under aerobic conditions with normal mitochondrial function, pyruvate enters the mitochondria and fuels the Krebs cycle. When pyruvate cannot enterthe mitochondrion it will be metabolized to lactate instead.



60.7.1

Box 60-1 Causes of Type B Lactic Acidosis

- Systemic inflammatory response syndrome
- Diabetes mellitus
- Malignancy—hematologic malignancies in particular
- Thiamine deficiency
- Liver failure
- Hypoglycemia
- Inborn errors of metabolism
- Mitochondrial myopathies
- Toxins
    - Cyanide
    - Ethanol
    - Ethylene glycol
- Drugs
    - Salicylate
    - Lactulose
    - β_2-Agonists
    - Nitroprusside
    - Acetaminophen
    - Propylene glycol
    - Phenformin

When treating type A lactic acidosis, while working to correct the underlying problem, the clinician may feel that the patient's pH is so low that the elevated hydrogen ion concentration has become the patient's most immediate problem. Severe acidosis does impair cardiovascular function and can be a serious barrier to resuscitating a patient in cardiopulmonary arrest. Alkalinizing agents such as sodium bicarbonate and Carbicarb may be used, but it is important to recognize that the lactic acidosis is not corrected with these agents. The acidemia improves, which may be helpful, but if spontaneous circulation is restored and the lactate is cleared quickly, the patient may be left with a hyperosmolar problem and an iatrogenic metabolic alkalosis. For this reason, sodium bicarbonate is rarely indicated for the treating of type A lactic acidosis. [2,4]

61 Chapter 61 Peripheral Venous Catheterization

Harold Davis, BA, RVT, VTS (Emergency/Critical Care and Anesthesia)

61.1 KEY POINTS

- There are four primary catheter types: winged, over-the-needle, through-the-needle, and multilumen.
- Catheter insertion site selection depends on several factors, including vessel availability and the intended purpose of catheterization.
- Proper vessel immobilization facilitates catheter placement.
- There are several catheter-related complications, phlebitis, thrombosis, catheter embolus, subcutaneous fluid infiltration, and infection, that can be minimized by appropriate attention to detail.

61.2 INTRODUCTION

Peripheral venous access is a cornerstone of the treatment of the emergency or critically ill patient. Patients often require temporary venous access for medications, fluid and electrolyte replacement, or transfusion of blood products. Medications and fluids with osmolalities 600 mOsm or less may be administered safely via a peripheral vein.[1] Site selection depends on the available vessels, condition of the vessels and patient, expense, and the urgency of the situation. Vascular access traditionally involves the insertion of a catheter into the cephalic, saphenous, or auricular vein; however, any visible vessel is a potential candidate for catheterization. Various techniques are used to insert catheters, including percutaneous, facilitative relief holes, and venous cutdowns.

61.3 CATHETER TYPES

A variety of catheters are commercially available (Figure 61-1). The length and gauge (diameter) of the catheter to be used are dependent on the species and size of the patient, the veins available and their condition, and the needs of the patient.

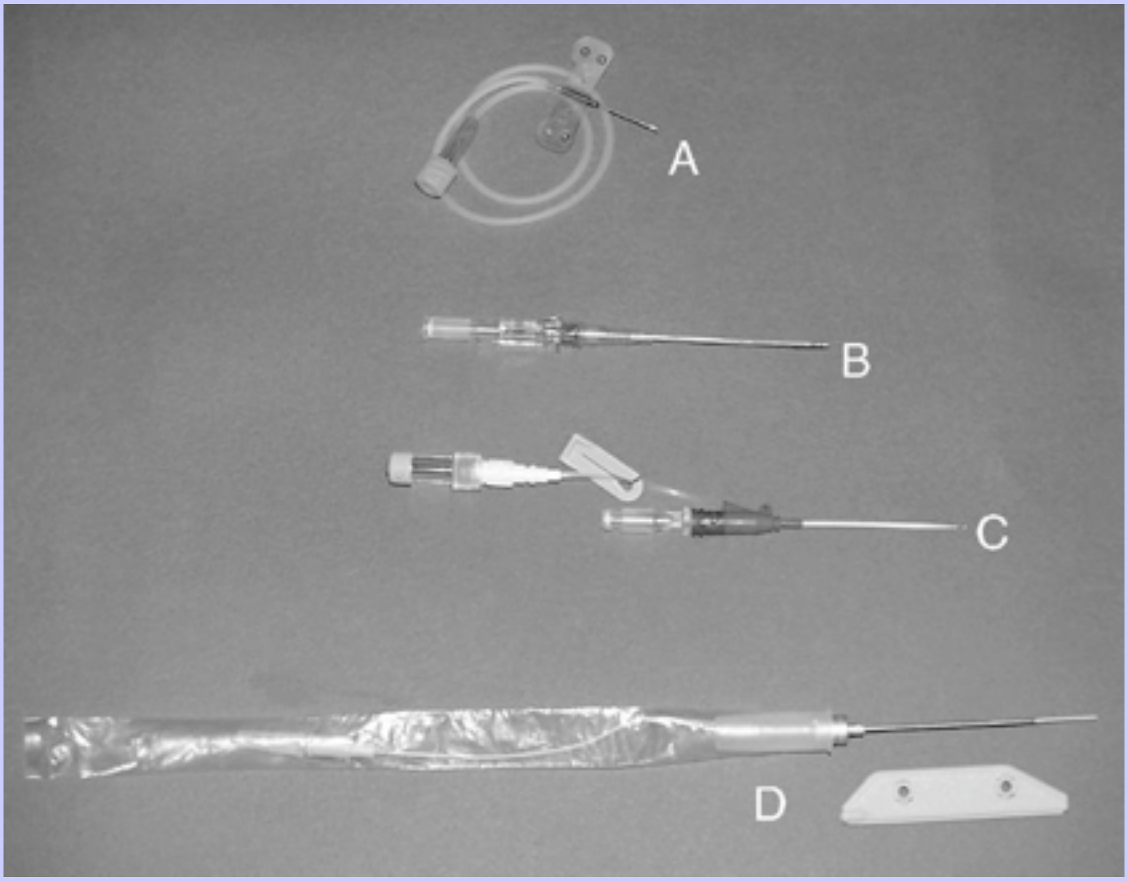
Both the radius and the length of the catheter determine the maximum flow rate. A large-gauge, short catheter is needed if fluids are to be administered rapidly, such as in a severely hypovolemic patient. If a slow infusion is acceptable, then a small-gauge catheter might be appropriate. A smaller catheter-to-vein ratio is considered more “vein friendly.”

There are four general categories of intravenous access devices. They include the winged needle, over-the-needle, through-the-needle, and multilumen catheters.

61.3.1 Winged or Butterfly Needle

The winged needle (butterfly) is for short-term use when the animal is not moving around very much. Applications might include blood collection or administration of nonirritating medications. Common needle size ranges from 25 to 19 gauge. The needles have plastic wings on the shaft to facilitate placement or taping in place. Plastic tubing of various lengths extends from the needle to the syringe connector port. These catheters are easy to place but difficult to maintain because of the ease with which the indwelling sharp needle punctures the vessel wall, allowing for subcutaneous infiltration of fluids or medications.

Figure 61-1 Example of various types of catheters: **A,** Winged needle or butterfly, **B,** over-the-needle catheter, **C,** TwinCath double-lumen catheter, and **D,** through-the-needle catheter with needle guard.



61.3.2 Over-the-Needle

The over-the-needle catheter is the most commonly used type. It is inexpensive and easy to place. The needle point extends a millimeter or so beyond the catheter tip. Over-the-needle catheters are available in a variety of lengths and gauges and are made of various materials (Teflon, polypropylene, polyvinyl chloride, and polyurethane).

61.3.3 Through-the-Needle

Catheters passed through the needle are called *through-the-needle* or *inside-the-needle catheters*. Through-the-needle catheters are usually longer (8 to 12 inches) than over-the-needle catheters and come in a variety of diameters. These catheters are used primarily in the jugular vein but can be used peripherally in the medial or 260 lateral saphenous veins. These catheters can be inserted to the level of the posterior vena cava, allowing for administration of hyperosmotic solutions. They can also be inserted into the cephalic vein but are often difficult to pass beyond the axilla into the larger anterior vena cava. A plastic sleeve prevents catheter contamination during insertion. Once the catheter is placed, the needle is withdrawn from the skin puncture site and covered with a needle guard to prevent the needle from shearing the catheter.

61.3.4 Multilumen

Arrow International (Reading, PA) produces a double-lumen over-the-needle catheter called a TwinCath. The TwinCath is more expensive than regular single-lumen catheters, but it allows simultaneous infusions of otherwise incompatible fluids via one catheter. Catheter placement is identical to that of any single-lumen over-the-needle catheter.

61.4 CATHETER INSERTION SITE

Peripheral insertion sites include the cephalic, lateral and medial saphenous, and the auricular vein.

61.4.1 Cephalic Vein

The cephalic vein is located on the anterior antebrachium. It crosses from the medial aspect of the leg an inch or so proximal to the carpus to join the brachial vein proximal to the elbow, which ultimately joins the external jugular vein. An accessory cephalic vein on the anterior aspect of the metacarpus passes over the carpus and joins the cephalic vein.[2] If possible, it is best to avoid the insertion of the catheter over the carpus, because it will be difficult to secure.

61.4.2 Saphenous Vein

The cranial branch of the lateral saphenous obliquely crosses the lateral aspect of the distal tibia.[2] The lateral saphenous vein is larger than the medial saphenous in the dog, and the medial saphenous is larger than the lateral and is more commonly catheterized in the cat.

61.4.3 Auricular Vein

The auricular veins are prominent in some breeds of dogs (Basset, Dachshund, and Bloodhound) and are fairly easy to catheterize.

61.4.4 Advantages of Peripheral Vein Catheterization

- Peripheral catheters tend to be relatively inexpensive, technically simple to place and well tolerated by most patients.
- Peripheral veins are easily accessible for quick catheterization such as in cardiac arrest or seizures. Two peripheral catheters may be indicated if rapid fluid resuscitation is required.
- Peripheral catheter placement generally requires minimal restraint. Patients suffering respiratory distress do not tolerate the stress of restraint (e.g., as would be required for central vein catheterization).

- Peripheral vein catheterization is generally associated with fewer significant complications such as hemorrhage, infection or thrombosis in comparison with central venous access.

61.5 INSERTION TECHNIQUE

61.5.1 Percutaneous

The area of the insertion site is generously shaved. Surgical preparation is performed with antiseptic scrub and solution. Aseptic technique is important to prevent indwelling catheter–related infection.[3] Proper aseptic technique may be bypassed in emergency situations, but these catheters should be removed once the crisis has passed.

Following skin preparation, the vein is occluded upstream of the insertion site by a tourniquet or an assistant. The distal portion of the leg is grasped in the palm of the hand of the operator and the leg is extended to tense and immobilize the vein. The thumb should not be used to stabilize the vein, because this compresses and collapses the vein. Flexion of the carpus will increase the stretch on the vessel and improve vessel immobilization in achondroplastic breeds. With the bevel up, the catheter is inserted through the skin at approximately a 15-degree angle. The catheter is advanced into the vessel; when blood appears in the flash chamber (hub), the needle and catheter are advanced as a unit for an additional 1 to 4 mm. This will ensure that the end of the catheter is entirely inside the lumen of the vessel. While holding the needle steady and maintaining the longitudinal tension on the leg, the catheter is then advanced off of the needle and into the vessel lumen. The catheter is capped with an injection cap or T-set and flushed with heparinized saline.

The technique for percutaneous catheterization of the auricular vein is similar to that for any peripheral vein. It may be useful to place roll gauze on the underside of the pinna to stabilize the ear.

Not all procedures are associated with spontaneous bleed back into the hub. If the operator thinks that the needle is in the vessel but does not see a flashback, the next step is to attach a syringe filled with heparinized saline and aspirate. Sometimes the flashback occurs, but following catheter insertion blood cannot be aspirated. There are two possibilities: (1) the catheter is in the vein but the vein collapsed around the end of the catheter, or (2) the catheter is not in the vein.

1. Excessive pressure to aspirate may collapse the vein; very gentle aspiration should be attempted.

   - The appearance of any amount of blood in the hub suggests proper placement; the operator should not expect free-flowing blood samples, because it is difficult to aspirate from many peripheral catheters.

   - The catheter tip may be occluded by a kink in the vein such as at the flexed elbow for a cephalic catheter; the leg should be extended.

   - The catheter may be large for the vein, obstructing blood flow past it; the vein should be occluded proximally and the foot squeezed to milk more blood into the vein.

   - If the catheter position still cannot be confirmed, inject a volume of saline into the catheter while watching for a subcutaneous bleb. If a large volume of saline can be injected without forming a subcutaneous bleb, the catheter must be in the vein.

2 The catheter may not be in the vein even though a flashback of blood was observed initially, and this can be attributed to several common technical missteps.

- After the flashback, the tension on the leg and skin was relaxed, allowing the vein to retract off the end of the needle; the tension must be maintained until after the catheter is inserted.

- The flashback was associated with the needle tip being in the vein, but the catheter tip was not wholly within the lumen of the vein; when the catheter was introduced it pushed the vein off the needle.
- The needle-and-catheter unit must be inserted a short distance beyond initial vein entry. Sometimes when the needle-and-catheter unit is advanced, it passes through the deep wall of the vein; the catheter will be pushed through the vein. If this is suspected, the needle-and-catheter unit is carefully withdrawn until backflow is evident ("catch the lumen on the way out"). Then readvancing the catheter into the vessel in the routine manner can be tried.

61.5.2 Facilitative Incision or Relief Hole

Failed catheterization attempts may also be caused by catheter flaring. Flaring of the tip of the catheter may occur when the tip is torn or peeled back during its insertion through the skin. After a failed attempt, inspect the catheter tip for such flaring before reuse. A facilitative incision or relief hole reduces the skin tension and friction against the catheter, minimizing catheter flaring, and is an especially important procedure in severely dehydrated patients or those with tough skin. A facilitative incision may be made with a No. 11 scalpel blade or a 20-gauge needle. A 0.5-mm incision is made directly over the vessel, extending through the dermis and taking care to avoid lacerating the underlying vessel. Local anesthetic blocks are rarely needed; intradermal or subcutaneous lidocaine stings. Following the facilitative procedure, the catheter is inserted as previously discussed.

61.5.3 Venous Cutdown

A venous cutdown is indicated when the veins are small (small patients, or patient that is severely hypovolemic) or when the veins are obscured (obesity, subcutaneous edema, or hematoma). Following aseptic skin preparation awake animals will require local anesthesia of the region, taking care not to inject any agent intravenously. A 1- to 2-cm incision is then made through the skin parallel to the vessel, being careful not to lacerate the vein. The vessel is dissected free of the surrounding tissue. An encircling suture is placed around the vein proximal and distal to the intended venotomy site. The catheter can be inserted directly through the superficial vessel wall or, if a catheter is to be used without a needle, an incision can be made into the vein while applying traction on the preplaced sutures. If an incision is made, once the catheter is inserted, both sutures are tied proximally to prevent bleeding (Color Plate 61-1). The skin is closed and the catheter site is bandaged.

61.5.4 Peripherally Inserted Central Venous Catheters

Central venous catheterization can be achieved by passing a long catheter from a peripheral insertion site to a central vessel. This can allow easy sample aspiration, administration of hypertonic fluids, and long-term catheter maintenance (see Chapter 63, Central Venous Catheterization).

61.6 COMPLICATIONS ASSOCIATED WITH CATHETERIZATION

61.6.1 Phlebitis

Phlebitis is inflammation of the vessel wall occurring as a result of damage to the endothelial lining. Phlebitis is characterized by swelling, tenderness on palpation, and erythema of the skin over the vessel. Phlebitis may be caused by the following:

1. Mechanical damage to the vessel by movement of the catheter, so it should be well stabilized.
2. Administration of hyperosmotic fluids; the osmolality of peripherally administered fluids should not exceed 600 mOsm.
3. Infection; aseptic technique should be maintained at all times if possible.

Some patients seem prone to catheter phlebitis for no apparent reason despite good technique.

61.6.2 Thrombosis

Thrombosis is the formation of a thrombus on the catheter or vessel wall (as a consequence of phlebitis). Thrombosis can result from endothelial trauma or an inflammatory reaction to the catheter material. A vein that "stands up" without being held off and feels thick and cordlike characterizes thrombosis.

61.6.3 Catheter Embolism

Catheter embolism occurs when a fragment of the catheter breaks off and enters the circulation. The fragment may be severed when withdrawing an inside-the-needle catheter. It can also occur if the catheter is cut during bandage change or the patient molests its bandage.

61.6.4 Subcutaneous Fluid Infiltration

Infiltration of fluids into the tissues surrounding the vein may occur if:

1. The catheter was never in the vein in the first place.
2. The catheter is displaced out of the vein by excessive skin movement.
3. Upstream vein occlusion by thrombosis has occurred.

Signs of infiltration are swelling and tenderness around the insertion site.

61.6.5 Infection

An indwelling catheter is an excellent pathway for microorganisms to enter the tissues and the venous system. Infection may be heralded by phlebitis and cellulitis (a purulent discharge from the insertion site). Aseptic technique in catheter placement and maintenance will help to decrease the risk of infection. Fever of unknown origin in a critically ill patient should prompt consideration of replacement of all indwelling catheters.

61.7 CATHETER MAINTENANCE

Intravenous catheter care should be performed every 48 hours or on an as-needed basis if the site gets soiled. The catheter dressing should be removed and the site inspected. Look for clinical signs of phlebitis, infection, and thrombosis and, if present, the catheter should be removed. While flushing the catheter with heparinized saline, the insertion site should be observed for fluid leakage or pain during injection. If either is observed, the catheter should be removed.

If any portion of the catheter is exposed, this should be recorded in the medical record and the catheter should not be reinserted. If the catheter site looks good, the site should be cleaned with an iodophor or chlorhexidine solution. When the catheter site is dry, a sterile 2 × 2 gauze pad is placed over it and the bandage reapplied.

Traditionally it has been recommended not to leave a catheter in place any longer than 72 hours. These recommendations come from human medicine. The likelihood of complications increases the longer a catheter is left in place.[3] It has been our experience that as long as routine catheter care is performed, and the catheter removed when problems are first noticed, one can often exceed the 72-hour rule. A study looking at peripheral and jugular venous catheter contamination in dogs and cats supports our experience.[4]

Intravenous catheters should be observed several times a day. If the catheter bandage is wet, the reason should be identified and the bandage should be changed. Swelling distal to the catheter may be indicative of an excessively tight bandage or tape. Swelling proximal to the catheter may be due to infiltration.

62 Chapter 62 Intraosseous Catheterization

Massimo Giunti, DVM, PhD

Cynthia M. Otto, DVM, PhD, DACVECC

62.1 KEY POINTS

- Intraosseous catheterization is an emergency procedure that allows access to the central circulation comparable to that achieved with a central venous line.
- Intraosseous catheterization is indicated when emergency vascular access is required and intravenous access can not be performed in a timely manner.
- Intraosseous catheterization is an easy, fast, and inexpensive technique that can be performed effectively in various species.
- Intraosseous infusion is contraindicated in recently fractured bones, those in which catheterization has been already attempted, and pneumatic bones of birds.
- The rate of complications for intraosseous infusion is extremely low, and osteomyelitis is the major risk.
- Blood samples obtained from intraosseous catheters can be analyzed for some hematologic, biochemical, and blood gas parameters in steady-state, low-flow conditions, and during the early phase of cardiopulmonary resuscitation.

62.2 INTRODUCTION

Rapid establishment of vascular access is crucial in critically ill patients, particularly those with life-threatening conditions. In animals with hemodynamic failure, peripheral vessels may constrict or collapse and grossly disappear. Finding and cannulating vessels is particularly challenging in small and neonatal patients. Attempts to catheterize a peripheral vein can be frustrating, time consuming, and unsuccessful even for the most skilled personnel. In pediatric prehospital and emergency department settings, peripheral intravenous access could not be obtained in 6% of patients and required over 10 minutes in 24%, with significantly prolonged times in children under 2 years of age.[1]

Compared with percutaneous peripheral vein catheterization, both surgical cutdown and central venous line placement increase the likelihood of successful circulatory access, but they require greater expertise and more time.[1,2] Peripheral venous catheterization within 90 seconds is successful in only 18% of cases. The success rate increases to 37% with subsequent percutaneous femoral vein catheterization.[2]

There are limited alternative routes for drug delivery in cases that require cardiovascular support but lack venous access. The endotracheal route is a last-resort option recommended by the American Heart Association for some resuscitation drugs during cardiac arrest in both adult and pediatric patients.[3,4] This route obviously can not provide for fluid resuscitation, and even for commonly recommended drugs such as epinephrine the clinical effect is less predictable than when intravenous administration is used.[5] Additionally, the dosage of intratracheal epinephrine has to be increased up to 10-fold.[6] Furthermore, lower circulating epinephrine concentration, from endotracheal administration, could result in counterproductive β_2-adrenergic stimulation, which leads to peripheral vasodilation, low diastolic aortic pressure, and decreased myocardial perfusion pressure.[6]

Two proposed but inadvisable routes of drug administration are the sublingual and intracardiac routes.[7] Intracardiac injections are associated with risks (e.g., hemopericardium, coronary artery perforation, myocardial ischemia, arrhythmias) that exceed the benefits. Alternatives to intravenous access are reported,[7] but they are indicated mainly for volume replacement in states of dehydration (subcutaneous or intraperitoneal infusion) and are not effective for hypovolemia.

Curiously, an unusual emergency vascular access, such as corpus cavernosum, was demonstrated to be fast and feasible for fluid resuscitation in dogs with severe hypovolemia, offering new therapeutic perspectives, even if limited to male dogs.[8] In pediatric and adult patients, intraosseous access is now recommended as the first choice if intravenous access is unavailable.[3,4] The intraosseous route is safe, practical, and reliable for fluid resuscitation, drug administration, and even blood sampling for analysis. This chapter focuses on what makes the intraosseous route suitable for fluid infusion and drug administration. The main indications, contraindications, complications, procedures, and future perspectives for intraosseous access in veterinary patients will be presented based on veterinary reports, human studies, and experimental animal models.

62.3

HISTORICAL PERSPECTIVES

The possibility of perfusing the tibia of the dog was demonstrated in 1922 by Drinker and colleagues, who were studying vascular physiology of the bone marrow.[9] Starting from this scientific observation, the potential use of the intraosseous route for parenteral infusion of drugs and fluids was addressed by several studies in Europe and North America during the 1930s and 1940s.[10-12] In rabbits, intraosseous infusions of whole blood and hypertonic glucose solutions rapidly corrected anemia and hypoglycemia, respectively.[10] In dogs, intramedullary injection of citrated blood into the sternum effectively restored blood volume.[11] Moreover, an injection of epinephrine into the marrow of the tibia resulted in a clinical response similar to that achieved by injection into the femoral vein.[11]

Intraosseous infusion was established as a reliable and safe technique for rapid, short-term access into the central circulation in adults and children when veins were inaccessible (e.g., peripheral circulatory failure, burns, and very young patients).[11,12] However, with the introduction of plastic catheters for peripheral venous access during the late 1950s, intraosseous infusions fell into disuse.[1,13] A renewed interest in the intraosseous procedure appeared during the 1980s because of its utility in hypotensive patients and efficacy for the administration of lifesaving drugs.[14] The intraosseous route was recommended as an alternative emergency access in pediatric advanced life support for children under 6 years of age and, more recently, resuscitation guidelines extended its use to children of any age and even to adults.[3,4]

62.4

PHYSIOLOGY

The bone marrow is a semifluid blood-forming tissue enclosed in a nonexpandable bony case. This protective osseous coating prevents bone marrow vessels from collapsing during peripheral circulatory failure. A rich capillary network drives substances injected into the marrow to the large medullary venous channels and quickly through the nutrient and emissary veins to the central circulation.[9-11]

Several types of fluids (blood and blood components, colloids, crystalloids)[11] and several drugs,[15] administered through an intraosseous, a central, or a peripheral intravenous line, are equally effective in reaching the central circulation despite normotensive, hypotensive, or arrest conditions.[14-16] Particularly during hemodynamic failure, intraosseous infusion of resuscitative fluids (e.g., hydroxyethyl starch) and drugs (e.g., sodium bicarbonate) seems to guarantee a higher magnitude of the peak effect and even a prolonged duration of action compared with peripheral venous administration.

Although intraosseously administered drugs reach peak effect more slowly[14,15] because of a reduction in blood flow and an increase in vascular resistance in the bone marrow during systemic hypotension, this effect can be overcome partially by pressurized infusion, especially when using viscous fluids likes colloids, or by a fluid bolus following the injection of a drug into the intraosseous space.[15] Mean intraosseous infusion flow rates of crystalloid solutions delivered under pressure (300 mm Hg) are limited to approximately 29 ml/min in puppies[17] and 47 ml/min in foals. Thus rapid delivery (90 ml/kg within 30 minutes) of fluids during severe hypovolemia may not be possible in dogs that weigh more than 10 kg. However, intraosseous infusion of hyperoncotic, hypertonic, and even crystalloid solutions effectively reversed hypotension in several animal models of hemorrhagic shock (see Chapter 65, Shock Fluids and Fluid Challenge).[18,19,22,23]

62.5 INDICATIONS

There are no studies documenting the incidence or impact of intraosseous catheterization in veterinary medicine. Most of the indications have been extrapolated from human experience and experimental animal models.[7,12,17] The information obtained from pediatric patients, in whom the time required to complete an intraosseous catheterization can be less than 1 minute with over 70% to 80% success, may be particularly relevant to small and neonatal animals.[18,19]

Early implementation of the intraosseous route as an alternative to failed intravenous access is now widely accepted and is included in the guidelines for management of cardiac arrest in pediatric and adult human patients. These recommendations are applicable to veterinary patients as well, particularly for small and neonatal animals whose veins can be difficult to visualize normally and tend to grossly disappear completely during shock. Fluid resuscitation through an intraosseous catheter can restore a vascular volume sufficiently to allow subsequent catheterization of a peripheral vein.

Conditions such as peripheral vascular thrombosis, peripheral edema, status epilepticus, obesity, and burns may be indications for obtaining intraosseous access.[13,18,19] An additional advantage of intraosseous catheterization during 264 emergency situations is the potential for blood sampling. Initial assessment of hematologic, biochemical, and acid- 265 base status and subsequent monitoring of the therapeutic response are essential in critically ill patients. Blood sampling, however, can be challenging during cardiovascular collapse.

The reliability of results obtained from blood collected from intraosseous lines has been investigated in both steady-state and circulatory failure conditions. In normal animals, hemoglobin, hematocrit, some biochemical param-eters (blood urea nitrogen, creatinine, total solids, albumin, bilirubin, sodium, chloride, calcium, phosphorus) and blood gases are sufficiently comparable to those of peripheral or central venous blood to be of clinical value. Values obtained for potassium and glucose, however, need to be interpreted with caution.[20,21] Acid-base values from intraosseous samples in cardiopulmonary resuscitation (CPR) models reflect the mixed venous blood acid-base balance during the first 15 minutes of CPR, and beyond that time values can be influenced by local acidosis.[22,23] In one CPR study, intraosseous and central venous blood biochemical and hemoglobin values remained similar for the first 30 minutes if the intraosseous site was not used for drug infusions.[24]

62.6 CONTRAINDICATIONS

The only absolute contraindication to intraosseous catheterization is a fracture in the bone to be used. In cases of failed intraosseous catheter placement where the cortex has been penetrated, the risk of fluid or drug extravasation increased.[13,19] To minimize risk, a second cannula of larger diameter should be placed through the same entry site or preferably a separate bone should be used. Intraosseous infusions in pneumatic bones of birds are contraindicated. Clearly, intraosseous catheters should not be placed through infected tissues. Sepsis and septic shock have been suggested as contraindications for intraosseous lines; however, reported complication rates in septic children were low.[1]

62.7 METHODS

The increased use of intraosseous catheterization during the last 15 to 20 years[1,19] has been accompanied by the development of new medical equipment. Intraosseous catheters range from traditional manually placed hypodermic needles to the newly dedicated catheters with automated delivery systems.[19,24] The main requirements of any intraosseous delivery system are ease of handling, ability to reload, small expense, and adaptability to most conditions. The supplies necessary for an intraosseous catheterization kit are described in Box 62-1.

Commercial disposable intraosseous infusion needles with a central stylet (Cook Critical Care; Bloomington, IN; Cardinal Health, McGaw Park, IL.) are designed to penetrate the bony cortex, prevent occlusion of the cannula lumen, and establish rapid access to the marrow sinusoids and vascular system.[19] However, an 18- to 30-gauge hypodermic needle is useful in neonates with soft cortical bone, an 18- to 22-gauge spinal needle is excellent in cats, small dogs, and birds, and a bone marrow or intraosseous infusion needle is essential in mature dogs.[18]

A bone injection gun is a spring-loaded, impact-driven intraosseous device developed for use in pediatric and adult humans. It propels the intraosseous cannula at high speed through skin, subcutaneous tissues, and bone cortex to a fixed depth. This automatic device was significantly faster than a standard Jamshidi bone marrow needle in obtaining intraosseous access in the proximal tibia of dogs.[24] The high speed of insertion helps to minimize pain; however, local anesthesia is recommended in conscious patients.[24]

62.7.1 Box 62-1 Supplies Necessary for an Intraosseous Catheter Kit

- Topical antiseptic
- Sterile gloves
- Local anesthetic for the skin and periosteum
- A scalpel blade for making a stab incision through the skin
- Needles
    - Hypodermic (18- to 30-gauge)

  - Spinal (18- to 22-gauge)
  - Bone marrow or intraosseous infusion needles (Figure 62-1, Jamshidi/Illinois, Cardinal Health, or Cook Critical Care)
- Bone injection gun: Optional device for more rapid access to the intraosseous space (Figure 62-2, WaisMed Ltd Houston, TX)
- Syringe for aspiration of bone marrow to confirm correct placement and potentially collect samples for hematologic or biochemical analysis
- Heparinized saline solution
- Fluid with administration set or catheter cap and a pressure bag
- Mechanism to secure the catheter:
  - Tape butterfly and suture material
  - Cyanoacrylates to secure suture directly to hub of needle
  - Commercial intraosseous catheter with flange
  - Bandaging material
- Triple antibiotic ointment or appropriate antiseptic ointment or cream

Figure 62-1 Intraosseous infusion needle. Courtesy Cardinal Health.

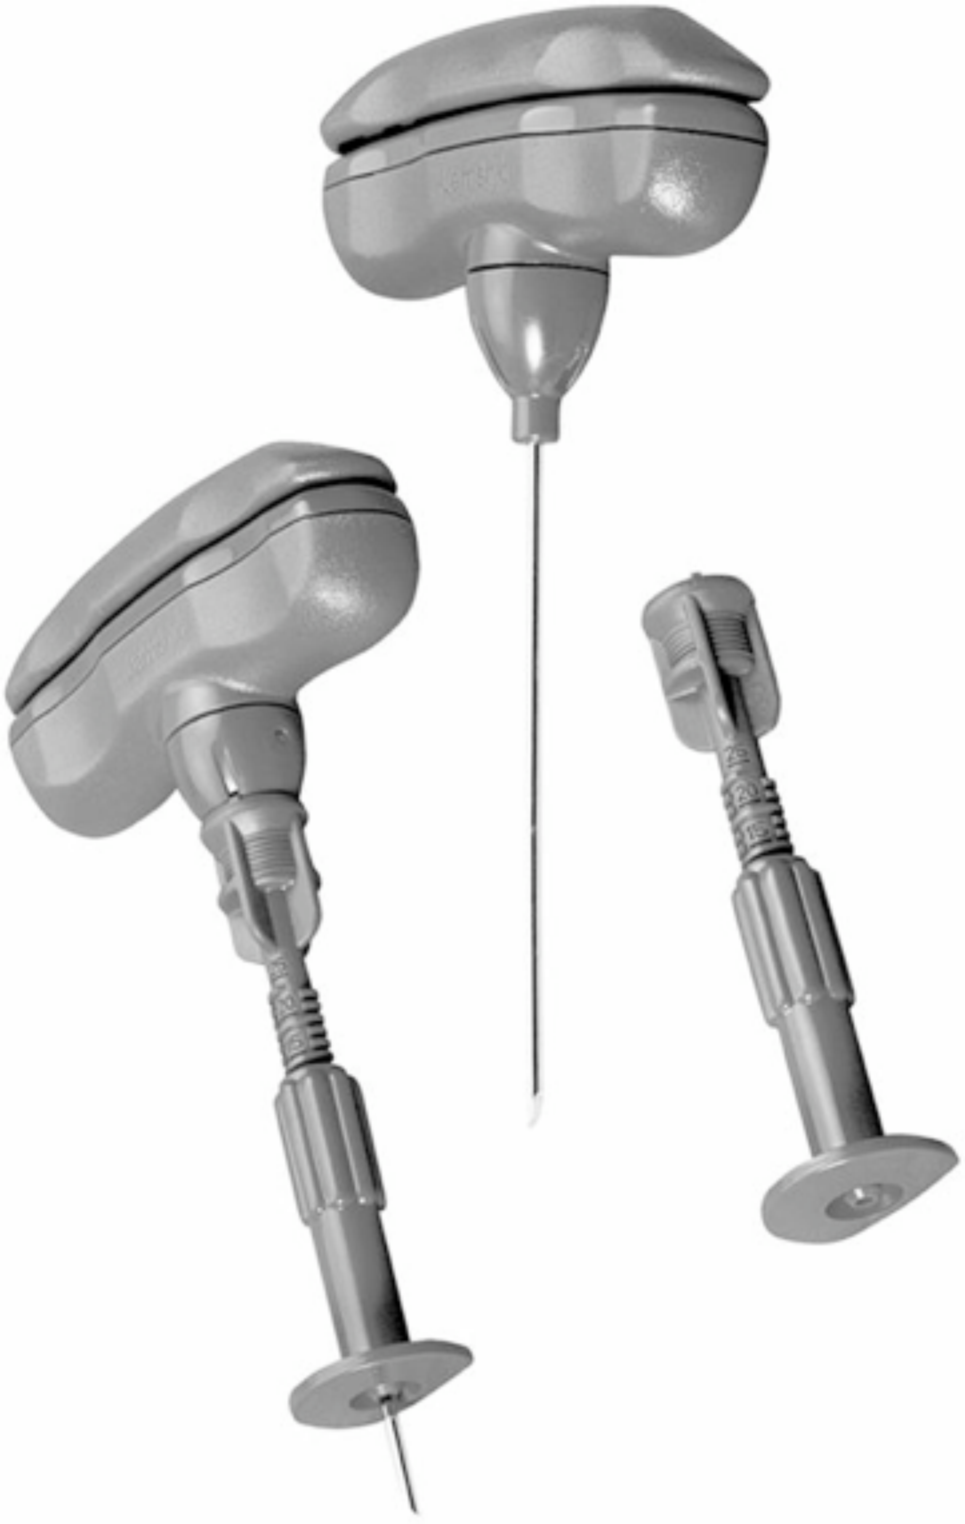

Figure 62-2 Bone injection gun. Courtesy WaisMed Ltd, Houston, TX.

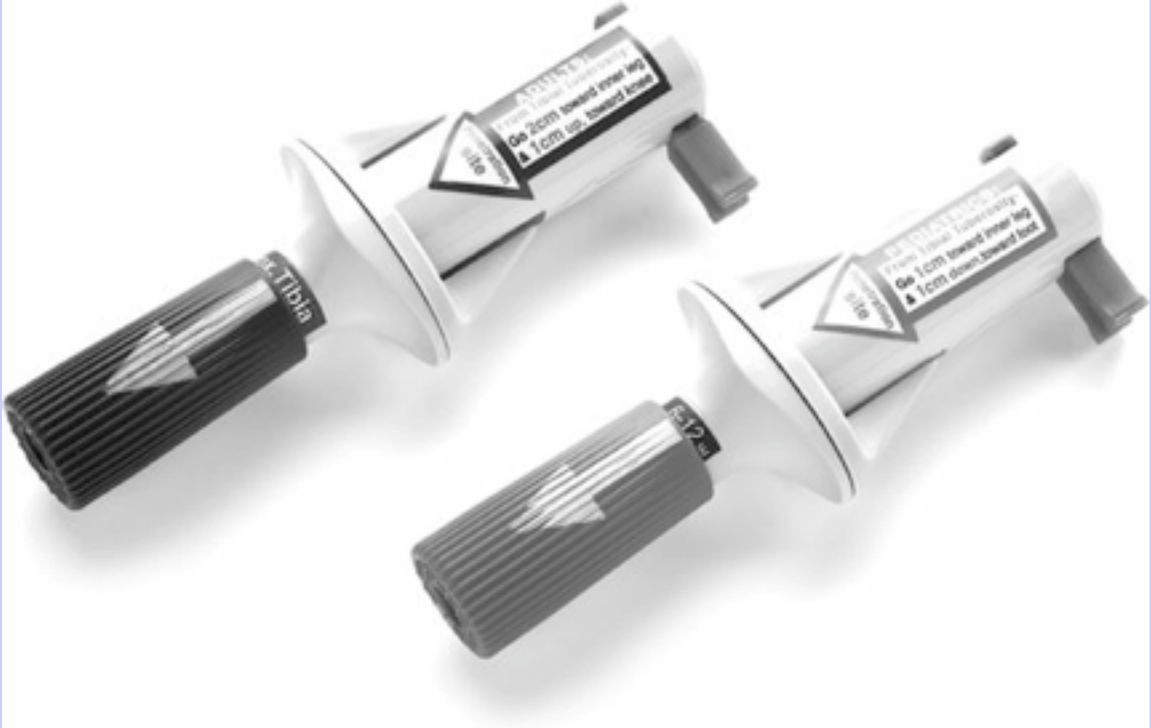

Other devices such as a drill for intraosseous access (EZ-IO, Vida Care, San Antonio, TX) and a sternal intraosseous device (FAST1, Pyng Medical, Richmond, BC, Canada) are now available.[19] Applications in veterinary medicine still need to be verified.

The access site should be easily accessible and should not interfere with ongoing procedures such as CPR. The most commonly used sites include the flat medial surface of the proximal tibia (1 to 2 cm distal to the tibial tuberosity), the tibial tuberosity itself, or the trochanteric fossa of the femur (Color Plate 62-1). Alternative approachable points can be considered such as the wing of the ilium, the ischium, and the greater tubercle of the humerus.[18,25] However, no studies in animal patients suggest any one site to be superior. Finally, the choice of a particular site will depend on the experience and preference of the clinician, the anticipated duration, and the mobility of the patient. The trochanteric fossa of the femur seems to be well tolerated, allows mobility, and is generally easy to place.[18] In obese or very edematous animals or those in status epilepticus, the tibia is probably more accessible.[18]

In humans, alternative sites include sternum, radius, ulna, and calcaneus.[19] Aseptic preparation of the site is required. The periosteum is highly innervated; therefore in stable patients, local infiltration with local anesthetic (e.g., 1% lidocaine) is recommended. A preemptive skin stab incision over the site of penetration of the catheter may prolong the life of the needle.

For placement in the medial tibia, the needle must be directed into the bone slightly distally and away from the proximal growth plate. To prevent sciatic nerve involvement during placement in the femur, the needle should be walked off the medial aspect of the greater trochanter into trochanteric fossa, with the hip joint in a neutral and internally rotated position. Once the desired orientation of the needle is reached, firm pressure should be applied in clockwise, then counterclockwise rotation. This procedure normally generates a small depression that seats the needle in the bone; by increasing the pressure maintaining the same rotation pattern, the needle should proceed through the near cortex. A sudden loss of resistance indicates that the needle has crossed the cortex.

Before administration of fluids or drugs through an intraosseous catheter, verification of correct placement is required. One of the most frequently reported causes of failure of intraosseous catheterization is an error in identifying landmarks. A well-positioned catheter should be firmly seated in the bone and move with the limb without being dislodged. Gentle aspiration should bring bone marrow into the syringe, although in older animals this may not always be possible. A bolus of heparinized saline solution should flow easily, and there should be no accumulation of fluid in the subcutaneous tissue.

If resistance is encountered, the needle can be rotated 90 to 180 degrees to move the beveled edge away from the inner cortex. The subcutaneous tissue must be observed for fluid extravasation. If extravasation is detected, the needle should be removed to prevent further complications and an alternative bone should be chosen for catheter placement. Once correct placement of the needle is verified, administration of fluids or drugs can be started by syringe or by using a standard intravenous administration set. To maintain patency during intermittent usage, a catheter plug can be applied and the catheter flushed with heparinized saline solution.

Initial infusion of fluids under pressure causes pain, lasting approximately 1 to 2 minutes, in conscious human patients. In humans, recommendations to minimize pain include withdrawal of a small volume of bone marrow, and slow injection of 1% lidocaine over 60 seconds before initiating the infusion. To properly secure the needle, a tape butterfly can be wrapped around the hub and sutured to the skin or the periosteum. The suture may also be fixed to the hub of the needle with a cyanoacrylate glue. Some intraosseous needles come with permanent butterflies for suturing.

Coverage of the area with antiseptic or antibiotic cream is suggested and, when possible, a protective bandage can prevent damage to the needle. Intraosseous catheters require the same nursing care as intravenous catheters. In most cases, the intraosseous catheter is considered a temporary access that should be replaced by an intravenous catheter as soon as possible. When prolonged intraosseous infusion is required, guidelines for intravenous catheter care should be followed. Although there are limited data, the risk of complications is thought to be minimal for catheters remaining for up to 72 hours with proper maintenance.[18,25]

62.8 COMPLICATIONS

The documented complication rate associated with intraosseous infusions in humans and animals is low. The types of complications include infection, fat embolism, extravasation of fluids, compartment syndrome, and bone fractures.[13,19] One of the most common concerns when performing intraosseous infusion is osteomyelitis. Proper sterile technique during placement reduces the risk of infection to 0.6% of cases, with potentially lower risk if the catheter is removed as soon as intravenous access is established or within 72 hours.[1]

Several studies have demonstrated that administration of fluids and drugs through an intraosseous route does not impair bone growth.[26] Fat embolism can occur during intraosseous infusion; however, evidence for clinical significance is lacking. Although unlikely with proper technique, extravasation of fluids and compartment syndrome can be associated with major morbidity in humans. Improper catheter placement combined with irritating or hypertonic fluids, high fluid rates, pressure infusion, and large infusion volumes can all predispose to extravasation of fluids and compartment syndrome.[13,19] The latter does not appear to be a major issue in animals; however, if any infiltration is detected the intraosseous infusion should be discontinued immediately. In addition, it is imperative that no additional catheter be placed in the same bone.

Intraosseous infusion of hypertonic solutions is effective and apparently safe from major and long-term complications. Soft tissue and bone marrow necrosis secondary to intraosseous infusion of hypertonic saline has been reported in piglets, in which major clinical signs developed 48 hours postoperatively; therefore caution should be exercised when using hypertonic solutions.[27] Finally, appropriate insertion technique, asepsis, frequent monitoring of the intraosseous access site, and prompt removal of the needle once an intravenous line has been established help to reduce risk factors and complication rates.

63 Chapter 63 Central Venous Catheterization

Harold Davis, BA, RVT, VTS(Emergency/Critical Care and Anesthesia)

63.1 KEY POINTS

- Indications for central venous catheter placement include hemodynamic monitoring, drug administration, and serial blood sampling.
- Saphenous veins can be used as access points to the central venous circulation.
- Medications with osmolalities of greater than 600 mosm/L should be administered via a central vein.
- Multilumen catheters minimize the number of veins that need to be catheterized.
- Patient positioning and immobilization of the vein are key to successful catheterization.

63.2 INTRODUCTION

Central venous catheters terminate in the cranial or caudal vena cava. These catheters may be inserted directly into a large central vein such as the jugular vein or inserted via a peripheral vein: a peripherally inserted central catheter (PICC). Indications for central venous catheter placement include hemodynamic monitoring, drug administration, and serial blood sampling.[1] Central venous catheters often can be left in place for longer periods than peripheral catheters, making them very useful in critically ill patients. The following are situations in which a central catheter may be preferable to a peripheral venous catheter:

- Administration of multiple fluid and drug types that are not compatible with each other, necessitating multiple catheter lumens
- Administration of fluids that have an osmolality greater than 600 mosm/L and constant rate infusions of drugs known to cause phlebitis, such as diazepam, pentobarbital, and mannitol
- Measurement of central venous pressure
- Frequent aspiration of blood samples
- Total parenteral nutrition administration
- Maintenance of venous access for long periods
- When peripheral catheters are at risk of contamination from vomiting, polyuria, diarrhea, or vaginal discharge, because it may be easier to keep a jugular catheter site clean
- To facilitate transvenous pacing

63.3 GENERAL CONCEPTS

Because introduction of foreign material or infectious agents into the central circulation can have far more serious consequences than peripheral vessel contamination, maintenance of aseptic technique when placing and using central venous catheters is of utmost importance (see Chapter 116, Catheter-Related Bloodstream Infection). General recommendations for central venous catheter maintenance is to wipe all injection ports with alcohol before needle puncture, keep insertion sites bandaged, prevent catheter hubs dragging on the ground, and immediately respond to witnessed catheter contamination. This may require cleaning and changing injection ports and fluid lines, or it may necessitate catheter removal. Inadvertent disconnection of fluid lines from a central venous catheter or animal-induced trauma to the catheter can lead to significant hemorrhage. Leaving ports of a central venous catheter open to the atmosphere places the patient at risk of air embolism. For this reason the catheter should be occluded by a catheter lock or manual kinking whenever the catheter hub is open to the atmosphere (e.g., when connecting and disconnecting syringes for blood aspiration).

63.4 CATHETER TYPES

Through-the-needle, long over-the-needle, long single-lumen, multilumen catheters, and catheter introducers can all be used to access central veins (Figure 63-1).[1-3]

63.4.1 Through-the-Needle

Through-the-needle catheters were discussed in Chapter 61, Peripheral Venous Catheterization. They commonly are used to catheterize jugular veins. The Drum-Cartridge is a very long through-the-needle catheter that is an effective PICC for large patients (see Figure 63-1).

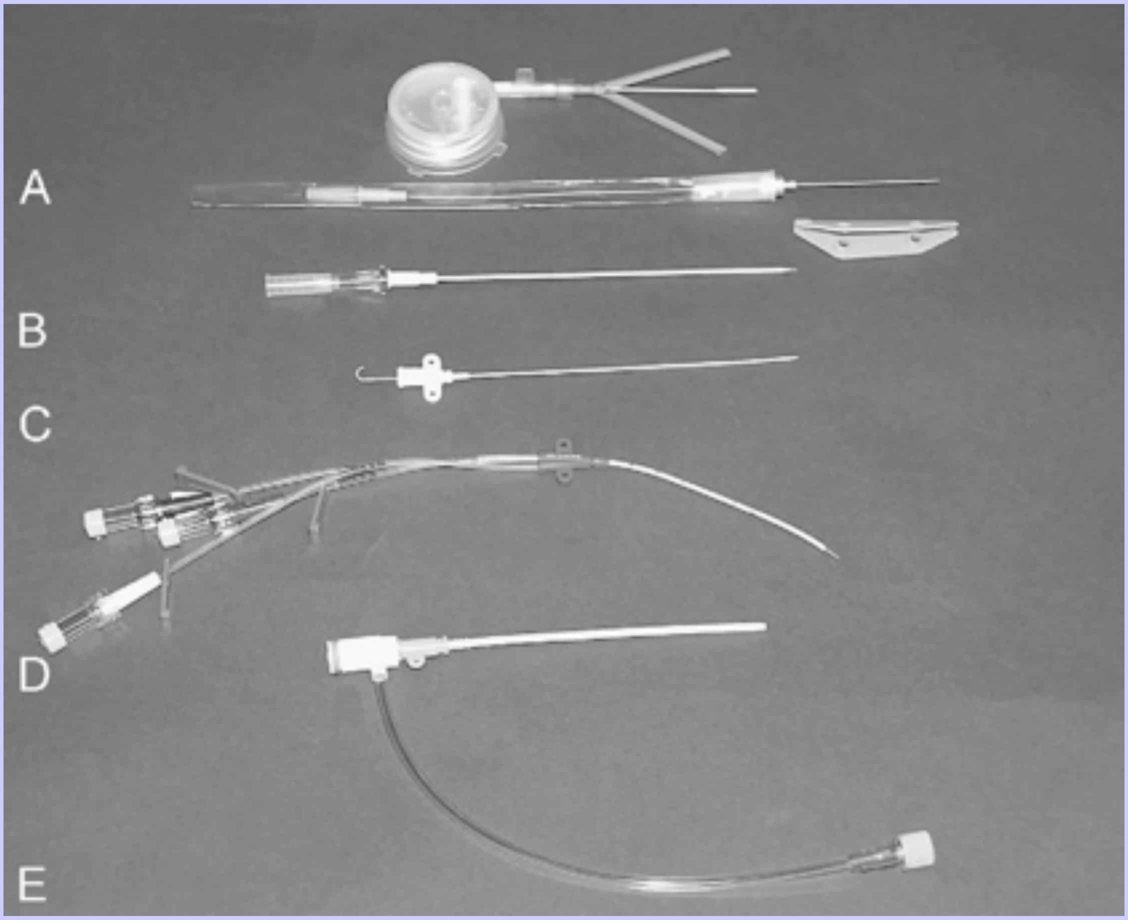
63.4.2 Over-the-Needle

Over-the-needle catheters were discussed in Chapter 61, Peripheral Venous Catheterization. When used for jugular catheterization, they must be of a length appropriate for the patient's size. The subcutaneous tissues in the region of the jugular vein are very loose, resulting in a lot of skin movement. Even though the catheter is well secured to the skin, short catheters can be pulled out of the vein easily.

63.4.3 Long Single-Lumen Catheter

This type of catheter is inserted using the Seldinger guidewire technique or a peel-off sheathed needle technique.[2] These catheters come in a variety of sizes and lengths. Mila International (Florence, KY) and Arrow International (Reading, PA) make central venous catheters that are 14 or 16 gauge by 6 or 8 inches (15 or 20 cm, respectively). Arrow also makes a 20-gauge by 5-inch (12 cm) and a 22-gauge by 4-inch (10 cm) single-lumen catheter. SurgiVet (Waukesha, WI) makes 5, 6, 7, and 8 Fr central venous catheters; the 5 Fr is 6 inches (15 cm) in length and all others are 10 inches (25 cm).

Figure 63-1 Examples of catheters used for central venous catheterization. **A,** Examples of two through-the-needle catheters; the top catheter is a Drum-Cartridge and the other is an Intracath. **B,** A long over-the-needle-catheter. **C,** Central venous catheter. **D,** Triple-lumen catheter. **E,** Catheter sheath introducer.



63.4.4

Multilumen Catheters

Multilumen catheters are placed using the Seldinger guidewire technique or a peel-off sheathed needle technique. Mila and Arrow make multilumen catheters. The catheters may be double, triple, or quadruple lumen. They are available in sizes ranging from 4 to 8.5 Fr and 2 to 24 inches (5 to 60 cm) in length.

Multilumen catheters are extremely useful in the critical care setting; they reduce the number of catheters that need to be placed in the critically ill patient. Fluids and drugs that are incompatible can be administered simultaneously. The catheters can be purchased individually or as a kit that contains all the components necessary for insertion. In addition to the catheter and dilators, the kits include local anesthetic, scalpel, syringe, and so on. Multilumen catheters are more expensive than the commonly used single-lumen catheters.

63.4.5 Percutaneous Sheath Catheter Introducer

Percutaneous sheath introducer systems are large-bore (typically 6 to 8 Fr), relatively short (4 inches) catheters that have a hemostasis valve located in the hub. They also have a short T-extension port for the fluid administration. A central venous catheter, pulmonary artery catheter, or transvenous pacing lead can be passed through the hemostasis valve into the jugular vein. The hemostasis valve acts as a seal to prevent entry of air into the circulation as well as to prevent blood or fluid loss around the catheter. The introducer must be placed with the Seldinger guidewire technique.

63.5 CATHETER INSERTION SITE

Central vein insertion sites include the jugular vein and the lateral and medial saphenous veins (see Chapter 61, Peripheral Venous Catheterization). Long catheters theoretically can be inserted in the cephalic vein and passed up to the level of the cranial vena cava, but they frequently will not pass beyond the elbow. For this reason the cephalic vein rarely is used for PICC lines.

63.5.1 Saphenous Vein

To achieve central vein catheterization via the saphenous vein, long catheters must be used; they are threaded so that they lie in the caudal vena cava. In dogs the lateral saphenous vein is used most commonly, but the medial saphenous vein can also be catheterized. In cats the medial saphenous vein tends to be larger and more easily stabilized for catheterization.

63.5.2 Jugular Vein

The jugular vein is catheterized directly in the cervical region. It lies along a line drawn between the angle of the mandible and the thoracic inlet. Jugular vein catheterization is feasible in both dogs and cats, and the vein may be visible in hemodynamically unstable patients when peripheral venous access is challenging.

The key to jugular catheter insertion is patient positioning and vessel immobilization. If the patient is not positioned properly it can be difficult to visualize and immobilize the vein. Jugular catheters are placed 268 antegrade, with the tip of the catheter always directed toward the heart. Placement of the jugular catheter is best 269 done with the patient in lateral recumbency. The patient's head is extended and its forelimbs positioned caudally by an assistant. Sedation of uncooperative patients is recommended. A bag of fluid, a sandbag, or rolled towels placed under the neck may be helpful (Color Plate 63-1). This flexes the neck and helps to make the vessel more accessible. The assistant should hold off the vein by pressing into the thoracic inlet; this should cause the vein to engorge and “stand up.” The other end of the vein is immobilized by extending the head.

In some cases venous cutdown may be needed to facilitate placement of a central catheter (see Chapter 61, Peripheral Venous Catheterization).

63.6 CATHETER INSERTION

Strict aseptic technique is followed for all central venous catheterization. Sterile gloves should be worn and the insertion site draped if the Seldinger technique is used or if the catheter will be used for total parenteral nutrition.

63.6.1 Through-the-Needle Catheter

The catheter needle should be introduced subcutaneously. The needle tip is positioned over the vein and aligned as close as possible to the longitudinal axis of the vein. The needle tip is inserted into the vein; it maybe necessary to angle the needle somewhat in order to pick up the superficial vein wall. Once it is estimated that the entire needle tip is within the lumen of the vein, the needle is stabilized and the catheter is threaded into the vein. Once the catheter is fully advanced into the vein, apply pressure over the venous puncture site and back the needle out. Once the bleeding has stopped, secure the needle guard around the needle. The catheter is aspirated to confirm proper placement and to clear it of air. It is then flushed with heparinized saline. The catheter should be capped with an injection cap or T-port and flushed again with heparinized saline. The catheter is sutured or stapled close to the insertion site. The insertion site is then covered with a sterile 2 × 2 gauze pad and the catheter site is bandaged.

An alternative insertion of the through-the-needle catheter is to remove the long single-lumen catheter from the insertion needle provided and thread it through a short over-the-needle catheter instead. Appropriate aseptic technique is maintained. This is particularly useful for placing PICC lines in saphenous vessels of small patients. The large needle provided with these catheters is commonly too large for effective venipuncture of a peripheral vessel. Using an over-the-needle catheter as an introducer makes initial venipuncture relatively simple, and the through-the-needle catheter is generally more affordable than a multilumen catheter.

In this situation, a common approach is to first insert a short over-the-needle catheter into the medial or lateral saphenous vein (Color Plate 63-2, *A*). A through-the-needle catheter (with the needle removed) is advanced into the preplaced catheter (Color Plate 63-2, *B*). The two catheter hubs are joined tightly together (Color Plate 63-2, *C*). Butterfly wing tape is used at the catheter hub juncture to prevent accidental dislodgement. The tape is sutured to the catheter (to prevent the tape from slipping) and the tape wings are sutured to the skin proximally to pull the catheter back toward the insertion site (Color Plate 63-2, *D*).

63.6.2 Seldinger Technique

The Seldinger technique uses a smaller introducing catheter or trochar and a guidewire to gain access to vessels or hollow organs. It avoids the requirement of initially puncturing the vessel with a large-bore catheter or trochar.[3] It maybe used to place single-lumen catheters, multilumen catheters, or percutaneous catheter introducer systems. It can also be used to replace an existing catheter in the same location. The Seldinger technique for introduction of a multilumen catheter is described here. The basic concept of this technique will be the same for any type of catheter placement in any vessel.[3]

Before beginning the procedure, the required distance for catheter insertion is premeasured. The aim for a jugular catheter is to have the tip lying within the thoracic cavity, just cranial to the right atrium. This distance commonly is estimated by measuring the distance from the intended insertion site to the caudal edge of the triceps muscle or first rib. For PICC lines the distance from the insertion site to the vena cava is measured. These measurements will then aid in choosing the most appropriate catheter for that patient.

The insertion site is clipped widely and surgically prepared in a routine manner.[1] Infiltration of the intended insertion site with local anesthetic is recommended in conscious animals. The catheter kit, sterile gauze, scalpel blade, suture material, and instruments are opened on a sterile field. The operator wears sterile gloves; in some circumstances a hat, mask, and sterile gown may also be appropriate, and an assistant can be helpful in challenging cases. The distal port of the multilumen catheter is identified. This is the port that terminates at the very tip of the catheter and will be the one through which the guidewire is passed. All ports of the multilumen catheter are flushed with heparinized saline and all ports, with the exception of the distal port, are capped. The insertion site is draped; this is important because the guidewire is long and flimsy, and the risk for contamination is high if draping is not sufficient.

A small relief incision is made through the dermis with a scalpel blade at the site of intended insertion. The introducing needle or short over-the-needle catheter (Color Plate 63-3, *A*) enters the skin through the relief incision and is inserted into the underlying vessel. The guidewire is threaded through the inserting needle or catheter into the vein (Color Plate 64-3, *B*). The distal end of the wire has a flexible J-tip to prevent puncturing the vessel wall. In some instances when it is difficult to pass the J-tip along the vessel, it maybe advantageous to use the straight end of the guidewire instead. It is important to recognize that this will be more traumatic to the vessel and that gentle technique should be maintained at all times. To prevent embolism of the guidewire, the operator should keep hold of it at all times.

Once the guidewire is inserted, approximately two thirds to three fourths of its length is fed into the vessel. It is held in place while the introducing needle or catheter is removed and a vessel dilator is threaded over the wire. The skin entry site may need to be enlarged with a No. 11 scalpel blade to accommodate the dilator. The dilator is grasped near the distal tip and, using a forward twisting motion, is advanced into the vessel (Color Plate 63-3, *C*). To minimize blood loss, pressure is applied over the insertion site with sterile gauze pads as the dilator is removed, leaving the guidewire in place.

In the case of a sheath introducer, the dilator is incorporated in the sheath and is removed once the sheath is in place. The multilumen catheter is threaded over the guidewire until the proximal end of the guidewire protrudes from the hub of the catheter. If the guidewire was advanced too far into the vessel, it will be necessary to back it out of the vessel to achieve this. Finally, while the proximal end of the guidewire is held, the catheter is advanced into the vessel the desired distance as determined by previous measurement (Color Plate 63-3, *D*). The wire is removed.

All ports are then aspirated to remove any air and to ensure that blood is easily drawn through the catheter. If necessary the catheter may be repositioned to allow aspiration of blood. Aseptic technique must be maintained throughout. All ports are flushed with heparinized saline. The catheter is then sutured in place; the insertion site is covered with sterile gauze and bandaged appropriately.

63.6.3 Peel-Off Sheathed Needle Technique

The peel-off sheathed needle (Mila International and SurgiVet) is similar to an over-the-needle catheter. The sheath has two tabs on the proximal end near the hub of the needle; when the tabs are pulled the sheath will split or peel away. The peel-off sheath technique can be used to place long single-lumen and multilumen catheters.

Peel-off sheath placement is similar to over-the-needle catheter technique. Once the needle and sheath placement is confirmed by bleeding, the needle is removed leaving the sheath in the vessel. The catheter is threaded down the sheath. The sheath is then peeled apart by grasping the tabs and pulling outward and upward. Once the sheath is completely separated, the catheter is positioned and secured.

63.7 COMPLICATIONS AND CATHETER MAINTENANCE

The same complications and catheter maintenance as discussed in Chapter 61, Peripheral Venous Catheterization, apply to central venous catheters (see Chapter 116, Catheter-Related Bloodstream Infection).

63.7.1 Heparinized Saline

All unused ports on central venous catheters should be flushed with heparinized saline. The author uses 4 U/ml of heparinized saline (1000 U/250 ml normal saline) q4h. Bags of heparinized saline should be discarded every 12 to 24 hours to minimize the risk of contamination. If a catheter port is not going to be used for a prolonged period, an alternative is to use a heparin lock. The dead space of the catheter is filled with 100 U/ml heparin q12h. The concentrated heparin solution is never flushed into the patient; instead, it is aspirated before administering medications or before replacing the heparin lock. Clear labeling of such ports to avoid inadvertent flushing of the concentrated heparin into the patient is important.

64 Chapter 64 Daily Intravenous Fluid Therapy

Deborah C. Silverstein, DVM, DACVECC

64.1 KEY POINTS

- Daily intravenous fluid therapy is used to correct dehydration, provide maintenance fluid and electrolyte needs, and replace ongoing losses.
- The movement of fluid within the body is determined by hydrostatic pressure, colloid osmotic pressure, vascular endothelial permeability, and osmolality.
- Total body water is distributed in the intracellular and extracellular (plasma and interstitium) fluid compartments. The intracellular space is much larger than the extracellular space.
- The most common types of daily intravenous fluids include isotonic crystalloids, hypotonic crystalloids, free water solutions, and synthetic colloids.
- The fluid type and rate should be tailored to the individual patient's needs.
- Potential complications of fluid therapy include pulmonary edema, subcutaneous edema, organ edema, and electrolyte imbalances.

64.2 INTRODUCTION

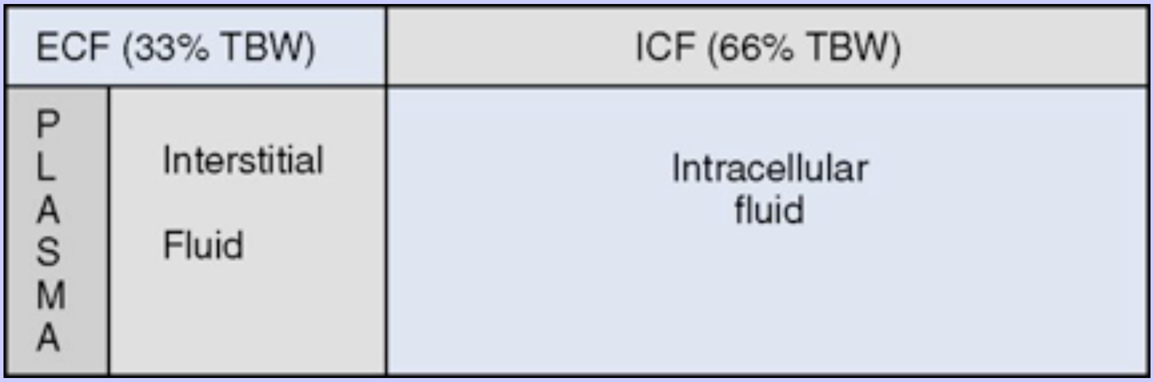
Intravenous fluid therapy is vital for the management of shock, dehydration, and maintenance in animals that require parenteral fluid therapy (see Chapters 61, 62, and 63, Peripheral Venous Catheterization, Intraosseous Catheterization, and Central Venous Catheterization, respectively, and Chapters 65 and 66, Shock Fluids and Fluid Challenge and Transfusion Medicine, respectively). This chapter focuses primarily on the distribution of total body water, patient assessment, and the delivery of synthetic intravenous fluids to maintain normal water, electrolyte, and acid-base status in critically ill dogs and cats that are hemodynamically stable. Because critically ill animals often have fluid and electrolyte balance derangements, overall recovery often depends on recognition and appropriate treatment of these disorders, in addition to diagnosing and treating the primary disease process.

64.3 TOTAL BODY WATER

Living organisms are predominantly composed of water. Total body water content is approximately 60% of body weight in a nonobese adult dog or cat. Total body water is distributed between two main compartments: intracellular fluid (ICF) and extracellular fluid (ECF) (Figure 64-1). Each compartment consists of solutes, primarily electrolytes, dissolved in water. The most important determinant of the size of each body fluid compartment is the quantity of solutes contained in that compartment.[1,2]

The ICF compartment is the larger of the two and comprises 66% of the total body water and 40% of body weight. It is separated from the ECF compartment by the cell membrane, which is very permeable to water but impermeable to most solutes. Cell membranes contain numerous proteins, including ion channels and active solute pumps. The most important active pump is the sodium-potassium ATPase pump, which extrudes three sodium ions out of the cell in exchange for bringing two potassium ions into the cell. This pump is responsible for generation of the electrochemical gradient across cell membranes, typified by a high intracellular potassium concentration, high extracellular sodium concentration, and a negative resting membrane potential.Therefore the most prevalent cation in the ICF is potassium, with much smaller contributions made by magnesium and sodium. The most prevalent anions in the ICF are phosphate and the polyanionic charges of the intracellular proteins.[1,2]

Figure 64-1 The distribution of total body water *(TBW). ECF,* Extracellular fluid; *ICF,* intracellular fluid.



The ECF comprises the remaining 33% of the total body water and 20% of body weight. The ECF is subdivided into the plasma (25% of ECF) and interstitial (75% of ECF) fluid compartments. The interstitial fluid bathes all cells and includes lymph. The primary cation in the ECF is sodium and the most prevalent anions are Cl^- and HCO_3^-. The proteins in plasma and the interstitial space also contribute to the negative charges. The oncotic pressure gradient between the intravascular and interstitial spaces is determined by the ratio of proteins in these two compartments.[1,2]

64.4 MOVEMENT OF FLUIDS WITHIN THE BODY

Water moves freely within most compartments in the body. Small particles such as electrolytes move freely between the intravascular and interstitial compartment, but cannot enter or leave the cellular compartment without a transport system. Larger molecules (>20,000 daltons) do not easily cross the vascular endothelial membrane and may attract small, charged particles, thus creating the colloid osmotic pressure (COP). There are three main natural colloid particles: albumin, globulins, and fibrinogen. An increase in the pressure of fluid within a compartment that pushes against a membrane is known as *hydrostatic pressure*.

In health, fluid balance is determined by the balance between forces that favor reabsorption of fluid into the vascular compartment (increased COP or decreased hydrostatic pressure) and those that favor filtration out of the vascular space (decreased COP or increased hydrostatic pressure).[1] Changes in the osmolality between any of the fluid compartments within the body will cause free water movement across the respective membrane. 271 272

In disease states, both increased fluid losses and decreased intake may lead to dehydration. The nature of the fluid loss (hypotonic, isotonic, or hypertonic) will determine the subsequent changes in osmolality. This will in turn dictate the relative impact on the ICF and ECF compartments.

64.4.1 Isotonic Fluid Loss

Isotonic fluid losses, as seen in animals with polyuric renal failure or bleeding, will lead to depletion of the ECF compartment and dehydration. If severe ECF losses are not replaced, hypovolemia may become clinically apparent. Because isotonic losses will not alter ECF osmolality, there will be no movement of water across the cell membrane and ICF volume will remain unchanged. In order to replace the ECF deficit, isotonic crystalloids should be administered (see Fluid Deficit).

64.4.2 Hypotonic Fluid Loss

Hypotonic fluid losses, as seen with diabetes insipidus or excessive panting, will cause hypernatremia and an increase in ECF osmolality. This will lead to movement of water out of the ICF space. Consequently, there is a depletion of both the ICF and ECF compartments. Isotonic fluid therapy may be sufficient if the hypernatremia is not severe, but in animals with significant hypotonic fluid losses, free water administration is indicated. Care must be taken to lower serum sodium slowly to avoid causing potentially life-threatening cerebral edema (see Chapter 54, Sodium Disorders).

64.4.3 Hypertonic Fluid Loss

Loss of hypertonic fluid, such as with heat exhaustion or highly concentrated urine, may cause hyponatremia and hypoosmolality. This maybe a direct result of the loss of high solute–containing fluid or may be exacerbated by a combination of isotonic or hypertonic fluid loss with hypotonic fluid replacement (i.e., oral water intake). Hypoosmolality will lead to water movement into the ICF compartment, resulting in dehydration and intracellular edema. Significant hyponatremia or hypoosmolality will require careful fluid therapy to avoid rapid (>0.5 mEq/L increase per hour) changes in sodium concentration and subsequent central pontine myelinolysis.

64.4.4 Increased Vascular Permeability

Disease processes that cause an increase in vascular permeability may lead to high-protein fluid extravasation from the intravascular space. This can lead to a decrease in intravascular volume, possibly associated with interstitial edema. Because this will not alter the osmolality of the ECF compartment, increased vascular permeability alone is not expected to alter the ICF volume.

Patient history, physical examination, and laboratory data can provide useful information concerning the route of fluid losses, timeline of these losses, food and water consumption, and current clinical status. This will guide formulation of an appropriate fluid therapy plan.

64.5 FLUID THERAPY PLAN

The fluid type and rate of administration chosen depend primarily on the clinical status of the animal based on the physical examination and laboratory parameters. For animals with evidence of chronic dehydration on physical examination, but stable cardiovascular parameters, fluid deficits should be replaced over 4 to 24 hours. Isotonic replacement fluids are administered according to the patient's estimated dehydration, maintenance needs, and anticipated ongoing losses.

To determine the quantity of fluid necessary for the stable patient with evidence of dehydration, the following formula is used:

$$\begin{aligned}&\text{Body weight (g)} \times \text{percentage dehydration (} = \text{deficit)}\\&\qquad + \text{estimated ongoing losses (ml)}\\&\qquad + \text{maintenance (ml)}\\&= \text{amount to be given (ml) over next } 4 \text{ to } 24 \text{ hours}\end{aligned}$$

64.5.1 Fluid Deficit

Volume deficiencies in each of the body fluid compartments exhibit different clinical signs or laboratory abnormalities. ICF deficits lead to cerebral obtundation, hypernatremia, and hyperosmolality. ICF deficits alone will not cause clinical evidence of dehydration. In contrast, interstitial volume deficits typically are associated with a decrease in skin turgor (increased skin tenting) and dry mucous membranes. Skin turgor provides only a rough estimate of dehydration, and severe emaciation or obesity can make this assessment difficult. Intravascular volume deficits commonly are associated with compensatory vasoconstriction, pale mucous membranes, poor pulse quality, tachycardia, prolonged capillary refill time, and cold extremities. These symptoms are suggestive of poor tissue perfusion and require rapid intervention. Physical examination findings in animals with evidence of dehydration are listed in Table 64-1.

64.5.2 Maintenance

Daily maintenance fluid needs have not been well studied in the dog and cat, so it is especially important that 272
animals receiving intravenous fluids be assessed several times per day. The formula most commonly used is 273
$(BW_{kg} \times 30) + 70$ (ml per day). For animals that weigh less than 2 or more than 50 kg, an alternative formula should be used: $(BW_{kg}{}^{0.75})70$. These calculations take into account the sensible and insensible ongoing fluid losses (feces, urine, panting, sweating). Because there is less water in fat than in muscle, these calculations will overestimate the maintenance needs of overweight patients.[3,4]

Table 64-1 Physical Examination Findings in Dehydrated Patients

Percentage of Dehydration	**Clinical Signs**
<5	No detectable abnormalities
5 to 8	Decreased skin turgor, dry mucous membranes
8 to 10	Decreased skin turgor, dry mucous membranes, eyes may be sunken in orbits, slight prolongation of CRT
10 to 12	Severe skin tenting, prolonged CRT, dry mucous membranes, eyes sunken in orbits, possibly signs of shock
12	All of the above plus signs of shock, often life threatening

CRT, Capillary refill time.

64.5.3 Ongoing Losses

Ongoing fluid losses are estimated from an understanding of the underlying disease process and historical data. For example, when treating animals with gastrointestinal losses the approximate volume and frequency of vomiting and diarrhea is estimated. Obviously this predicted volume may be inaccurate; it allows calculation of an initial fluid therapy plan, but close patient monitoring and reevaluation are imperative. If the estimate of ongoing fluid losses is significantly inaccurate, the fluid plan should be altered accordingly.

64.5.4 Route of Administration

Although subcutaneous fluid administration can be effective in the management of fluid deficits, it is not adequate for the critically ill patient. Fluid therapy should be administered via an intravenous catheter that is checked regularly for evidence of phlebitis or inadvertent subcutaneous fluid administration.

64.6 FLUID TYPE

The type of fluid that should be administered depends on the individual patient. Options for the critically ill patient include replacement fluids, maintenance fluids, free water solutions, and synthetic colloids.

64.6.1 Replacement Fluids

Replacement fluids, also known as *isotonic crystalloids,* are electrolyte-containing fluids with a composition similar to that of the ECF. They have the same osmolality as plasma (290 to 310 mOsm/L); the electrolytes are small in size, and they do not significantly change the osmolality of the vascular or extravascular space in animals with a normal osmolality.[4,5] They may also contain acid-base components and dextrose. Isotonic crystalloids are commonly used to expand the intravascular and interstitial spaces and maintain hydration. The constituents of commonly used isotonic fluids can be found in Table 64-2. Additional electrolytes, such as potassium, may be added to maintenance or replacement fluids as needed for an individual patient (see Part V, Electrolyte and Acid-Base Disturbances).

Following infusion of isotonic crystalloids into the vascular space, the small electrolytes and water pass freely across the vascular endothelium. These fluids are extracellular-expanding fluids; 75% redistributes to the interstitial space, and only 25% remains in the vascular space after 30 minutes.[6] Although so-called *replacement fluids* are used commonly for maintenance of hydration, most animals are able to easily excrete the electrolyte constituents that are in excess of the body's needs. This practice is common, because most hospitalized animals have ongoing electrolyte losses and poor enteral intake, and it is much easier to hang one bag of isotonic crystalloids than two separate bags (one for replacement and one for maintenance). The rate of fluid replacement is determined as outlined earlier in this chapter.

Not all isotonic fluids are created equal, as seen in Table 64-2. Isotonic saline solution (0.9% NaCl) contains a higher concentration of sodium and chloride (154 mEq/L of each) than does normal blood, and will cause proportional changes (increases) in the recipient electrolytes. Therefore large amounts of 0.9% NaCl will cause a mild increase in serum sodium, a marked increase in chloride, and a moderate decrease in bicarbonate and potassium. The kidneys typically will compensate, if possible, by excreting the excess electrolytes and conserving potassium.

Isotonic crystalloids can cause harm, especially in critically ill animals. The interstitial fluid gain can lead to interstitial edema, pulmonary edema, and cerebral edema. Patients with a low COP, pulmonary contusions, cerebral trauma, fluid-unresponsive renal disease, or cardiac failure are at highest risk for complications. In addition, substantial hemodilution of blood constituents that are not found in the crystalloids can occur. Anemia, hypoproteinemia, and hypocoagulability can occur following large-volume crystalloid administration.

Although all isotonic crystalloids have a similar composition, there are situations in which a specific fluid type may be preferable over another. Specifically, animals with diabetic ketoacidosis or liver disease should not receive lactate-containing fluids because of their decreased ability to convert the lactate to bicarbonate in the liver. However, lactated Ringer's solution may be preferred in very young animals because lactate is the preferred metabolic fuel in neonates with hypoglycemia. Patients with a hypochloremic metabolic alkalosis will benefit from 0.9% sodium chloride, because this is the highest chloride-containing fluid, but animals with a severe acidosis may benefit from an alkalinizing fluid containing lactate, acetate, or gluconate (see Table 64-2). Animals with head trauma or increased intracranial pressure may benefit from 0.9% sodium chloride, because this isotonic crystalloid is least likely to cause a decrease in osmolality that might promote water movement into the brain interstitium.

64.6.2 Maintenance Fluids

Maintenance fluids refer to the volume of fluid and amount of electrolytes that must be consumed on a daily basis to keep the volume of total body water and electrolyte content within the normal range. Obligate fluid losses are hypotonic and hyponatremic, but contain relatively more potassium than does the ECF.[7] Maintenance fluids are therefore hypotonic crystalloids that are low in sodium, chloride, and osmolality, but high in potassium compared with normal plasma concentrations (Table 64-3). The inclusion of dextrose may make the fluid isoosmotic to plasma, but the dextrose is metabolized rapidly to carbon dioxide and water, so these fluids are still hypotonic in nature. As mentioned earlier, daily maintenance needs are calculated as $(BW_{kg} \times 30) + 70$ (mL per day). For animals that weigh less than 2 or more than 50 kg, an alternative formula should be used: $(BW_{kg}^{0.75})70$. Maintenance-type fluids are distributed into all body fluid compartments and should never be administered as a bolus or cerebral edema may result.

Table 64-2 Isotonic Crystalloid Compositions

Fluid Type	Osmolality	$[Na^+]$ (mEq/L)	$[K^+]$ (mEq/L)	$[Cl^-]$ (mEq/L)	$[Mg^{++}]$ (mEq/L)	$[Ca^{++}]$ (mEq/L)	Lactate (mEq/L)	Acetate (mEq/L)	Gluconate (mEq/L)
0.9% NaCl	308	154	—	154	—	—	—	—	—
Lactated Ringer's solution	273	130	4	109	—	3	28	—	—
Plasmalyte 148	295	140	5	98	3	—	—	27	23
Normosol-R	295	140	5	98	3	—	—	27	23

Table 64-3 Maintenance and Free Water Solution Compositions

Fluid Type	Osmolality	$[Na^+]$ (mEq/L)	$[K^+]$ (mEq/L)	$[Cl^-]$ (mEq/L)	$[Mg^{++}]$ (mEq/L)	$[Ca^{++}]$ (mEq/L)	Lactate (mEq/L)	Acetate (mEq/L)	Dextrose
0.45% NaCl	150	77	0	77	—	—	—	—	—
0.45% NaCl with 2.5% dextrose	203	77	—	77	—	—	—	—	2.5%
Plasmalyte 56	110	40	13	40	3	—	—	16	—
Normosol-M	110	40	13	40	3	—	—	16	—
1/2 LRS with 2.5% dextrose	265	130	4	109	—	3	28	—	2.5%
D5W	252	—	—	—	—	—	—	—	5%

D5W, 5% dextrose in water; *LRS,* lactated Ringer's solution.

64.6.3 Free Water Administration

In order to give free water (fluids with no electrolytes or buffers) intravenously without using a dangerously hypotonic fluid, the water is combined with 5% dextrose to yield an osmolality of 252 mOsm/kg (safe for intravenous administration). This fluid is indicated in animals with a free water deficit (i.e., hypernatremia) or severe ongoing free water losses (i.e., diabetes insipidus). In order to safely lower the sodium concentration by 1 mEq/hr, a rate of 3.7 ml/kg/hr is a good starting point and can be adjusted based on the patient's response. Close monitoring of electrolyte status is advised. Dextrose 5% in water should never be administered as a bolus because acute decreases in osmolality will cause potentially fatal cerebral edema.

64.6.4 Synthetic Colloids

The most commonly used synthetic colloid solutions include dextran-70 and hydroxyethyl starch (hetastarch). Colloids are large molecules (molecular weight >20,000 daltons) that do not readily sieve across the vascular membrane. The base solution of most products is 0.9% sodium chloride, and the colloidal particles are suspended within the crystalloid. These fluids are polydisperse (they contain molecules with a variety of molecular weights) and hyperoncotic to the normal animal, and therefore cause the movement of fluid from the extravascular to the intravascular space. Synthetic colloids lead to an increase in blood volume that is greater than that of the infused volume and also aid in the retention of this fluid in the vascular space (in animals with normal capillary permeability). Dextran-70 is a 6% colloidal solution with particles that range from 15,000 to 3,400,000 daltons, a number average molecular weight of 41,000, and a COP of 60 mm Hg in vitro. Hetastarch is also a 6% solution, with particles ranging from 10,000 to 1,000,000 daltons in molecular weight, a number average molecular weight of 69,000 daltons, and a COP of 34 mm Hg in vitro. Excessive volumes may lead to volume overload, coagulopathies, and hemodilution. Synthetic colloids typically are used in combination with isotonic crystalloids to maintain adequate plasma volume expansion with lower interstitial fluid volume expansion. Continuous rate infusions are commonly used at a rate of 0.5 to 2 ml/kg/hr in animals with acute decreases in COP or total protein levels.[7,8]

The use of fresh or stored whole blood, packed red blood cells, or plasma products is often necessary in critically ill animals. A thorough discussion of transfusion medicine can be found in Chapter 66.

64.7 MONITORING

Animals receiving intravenous fluids should be monitored closely. Body weight should be monitored daily (or more often if indicated) and a physical examination should be performed at least twice daily to assess the animal's mental status, skin turgor, heart rate and pulse quality, mucous membrane color, capillary refill time, extremity temperature, and respiratory rate and effort. Serial lung auscultation should be performed to monitor for increased breath sounds, crackles, or wheezes. Clinical signs in animals receiving too much fluid include serous nasal discharge, chemosis, jugular venous distention, and interstitial pitting edema. In the early stages of pulmonary edema, an increase in the respiratory rate will occur, followed by inspiratory crackles, wheezes, and dyspnea. It is therefore of utmost importance to monitor the respiratory rate and effort of all patients receiving fluid therapy.

If an indwelling urinary catheter is present, urine output can be compared with fluid input to help guide fluid 274
therapy and prevent the administration of too much or too little fluid. Serum blood urea nitrogen and creatinine 275
levels can be evaluated in conjunction with the urine specific gravity to determine whether there is prerenal or renal azotemia (or a combination of both). An increase in blood urea nitrogen and creatinine with an increase in urine specific gravity would suggest that the animal is receiving insufficient fluid volume. Inadequate tissue perfusion may result in an increase in blood lactate levels secondary to anaerobic metabolism. Serial lactate measurements may help guide fluid therapy as an indicator of tissue perfusion. Moderate to severely elevated lactate levels should alert the clinician that more aggressive treatment may be required.

If a central venous catheter is in place, central venous pressure monitoring may be used to help guide fluid therapy. Although this is a measurement of the pressure in the vena cava, it is used commonly to evaluate volume, because there is normally a direct relationship between the two parameters (see Chapter 203, Hemodynamic Monitoring). Additional monitoring techniques that might be helpful include arterial blood pressure, electrocardiogram, and repeated measurements of packed cell volume, total solids, blood glucose, electrolytes, and acid-base status. An increase in the activated partial thromboplastin time (APTT) may develop in animals that receive large amounts of synthetic colloid therapy, although the quantitative APTT change is not predictive of clinical bleeding. Coagulation times should be monitored and transfusion therapy initiated as needed. Pulmonary capillary wedge pressure monitoring, cardiac output monitoring, and mixed venous oxygen saturation measurements may be helpful in select patients.

64.8 DISCONTINUATION OF FLUID THERAPY

In most animals, fluid therapy should not be discontinued abruptly, especially if high flow rates are being administered. These animals may have renal medullary washout and therefore the urine concentrating ability will be impaired for several days. This can lead to severe dehydration and hypovolemia in animals that are not drinking large amounts of water. Ideally, intravenous fluid therapy should be decreased gradually over a 24-hour period. Some animals may require slower weaning protocols, especially those receiving high flow rates. Owners should be informed that the animal may have increased water requirements for a few days after the discontinuation of intravenous fluid therapy.

In conclusion, intravenous fluid therapy should be used to maintain normal water, electrolyte, and acid-base status in dogs and cats that are hemodynamically stable. The fluid plan should be tailored to the animal's state of hydration, continued maintenance needs, coexisting diseases, laboratory abnormalities, and anticipated ongoing losses. Critically ill animals commonly require intravenous fluid therapy, and an understanding of body fluid compartments and the distribution of various fluid types is essential when formulating a treatment strategy. Judicious monitoring is vital, and a gradual weaning from fluid therapy is recommended.

65 Chapter 65 Shock Fluids and Fluid Challenge

Janet Aldrich, DVM, DACVECC

65.1 KEY POINTS

- The primary goal of shock therapy is to improve delivery of oxygen and other nutrients to metabolically active cells.
- Isotonic crystalloids and colloids, each at their appropriate dosages, are equally effective for managing shock. Hypertonic saline is usually combined with a colloid.
- Fluids should be chosen with consideration of concurrent conditions, such as dehydration, active bleeding, or brain injury.
- The fluid challenge technique is useful for hemodynamically unstable patients to determine if inadequate resuscitation is the cause of instability.

65.2 SHOCK

Circulatory shock refers to states of inadequate tissue perfusion causing the partial pressure of oxygen at the tissues to fall below a critical level required to maintain adequate energy production.[1] Circulatory shock can be further categorized as hypovolemic, cardiogenic, obstructive, or distributive in nature.[2] Hypovolemic shock is due to an absolute or relative reduction in blood volume. Cardiogenic shock describes inadequate tissue perfusion as a consequence of cardiac disease. Obstructive shock occurs when there is an obstruction such as an embolus or pericardial effusion impeding blood flow out of the heart or venous return to the heart. Distributive shock is due to inappropriate generalized vasodilation leading to inadequate perfusion. This is generally a consequence of systemic circulation of inflammatory mediators as can occur with the systemic inflammatory response syndrome or anaphylaxis.

The primary goal of shock therapy is to improve delivery of oxygen and other nutrients to metabolically active cells. Intravenous fluid therapy is essential in the resuscitation of patients with hypovolemic, distributive, and obstructive shock.[3,4] There may be a role for fluid therapy in some specific instances of cardiogenic shock, but it must be administered with caution and requires intensive monitoring (see Chapter 35, Cardiogenic Shock).

Fluids that are effective volume expanders in shock are isotonic crystalloids, hypertonic crystalloids, and synthetic colloids suspended in isotonic crystalloid solutions.

65.3 ISOTONIC CRYSTALLOIDS

The composition of isotonic (or nearly isotonic) crystalloid fluids is similar to that of extracellular fluid. They have sodium concentrations in the 130 to 154 mEq/L range and concentrations of other ions (potassium, magnesium, calcium) similar to those in extracellular fluids, and may contain bicarbonate-like anions (Table 65-1).

Table 65-1 Shock Fluid Dosage Ranges

	Total Shock Dosage*		**Fluid Challenge**	
Fluid Type	**Dogs**	**Cats**	**Dogs**	**Cats**
Isotonic crystalloids	80 ml/kg	50 ml/kg	20 ml/kg	10 ml/kg
Synthetic colloids	10 to 20 ml/kg	5 to 10 ml/kg	5 ml/kg	3 ml/kg
Hypertonic saline 7.5%	4 to 6 ml/kg	3 to 4 ml/kg	—	—
Hypertonic saline 7.5% combined with a synthetic colloid	4 to 6 ml/kg	2 to 4 ml/kg	—	—

65.3.1 Physiology

Rapid intravenous infusion of isotonic crystalloids causes continuous vascular volume expansion until the infusion stops, at which time most of the administered volume is in the vascular compartment. When 80 ml/kg was administered in 12 minutes to experimental, healthy dogs, blood volume was increased by 76% at the end of the infusion, 35% after 30 minutes, and 18% after 4 hours.[5]

Because of the fairly rapid distribution out of the vascular space, isotonic crystalloids must be administered at rapid rates to get the desired vascular volume expansion. Isotonic crystalloids have little effect on intracellular volume (see Chapter 64, Daily Intravenous Fluid Therapy).

* Shock fluid therapy should be given in increments and the total dosage determined by the individual response.

65.3.2 Benefits

Isotonic crystalloids are inexpensive, readily available, and have a long track record of success as resuscitation fluids. The redistribution to the interstitium is beneficial for many dogs and cats in shock, because their underlying problem often involves preexisting severe salt and water losses that have depleted the extracellular volume (dehydration).

65.3.3 Adverse Effects

If isotonic crystalloids are delivered too slowly, the desired vascular volume expansion is not achieved but 75% 276 of the administered volume is still distributed to the interstitium, predisposing the patient to interstitial fluid 277 overload, possibly to pulmonary edema. However, the lung is richly supplied with lymphatic vessels, which, among other factors, can protect it from interstitial fluid overload. Large-volume isotonic crystalloid resuscitation did not cause increases in lung water or hypoxemia in a canine hemorrhagic shock model.[6] Inappropriate and overzealous administration of isotonic crystalloids risks adverse effects of worsened pulmonary edema, increased intracranial pressure, and abdominal compartment syndrome.

Isotonic crystalloids dilute all plasma elements except those ions present in the administered fluid at plasma concentrations. Of major concern is dilution of albumin and therefore decrease in colloid osmotic pressure, and dilution of the red blood cell mass. With redistribution of crystalloid fluids this effect will be reduced.

Alterations in immunologic and proinflammatory states, such as neutrophil activation or increase in apoptosis, have occurred in experimental animals treated for shock with lactated Ringer's solution.[7-9] Pulmonary apoptosis was increased when the D isomer of lactate was substituted for L isomer in lactated Ringer's solution.[10] Intestinal hyperpermeability was decreased in an experimental hemorrhagic shock model when Ringer's ethyl pyruvate solution was used.[11]

65.3.4 Fluid Prescription

The estimated dosage of isotonic crystalloids for treating shock is equal to the patient's healthy blood volume (approximately 80 ml/kg for dogs, 50 ml/kg for cats). The actual fluid requirements of each patient will vary and must be prescribed individually. The total amount administered depends on the response to treatment and is usually one half to one blood volume (see Table 65-1). One strategy is to set up the fluid delivery system to deliver the prescribed amount in 20 minutes, and to slow or discontinue the infusion if the tissue perfusion parameters improve before the end of the infusion.

Pressure bags are helpful for rapid administration of large volumes of isotonic crystalloids. For cats, rapid infusion of fluids can be performed easily with a 60-ml syringe. This allows accurate measurement of the volume given and avoids the risk of inadvertent fluid overload. Patients are monitored continually throughout the resuscitation period, and rapid administration is stopped when the goals of resuscitation are accomplished.

65.4 COLLOIDS

Synthetic colloids (hydroxyethyl starch, dextran, gelatins) are isotonic crystalloid solutions to which large molecules have been added to achieve colloid concentrations of about 6%. Hydroxyethyl starch is available suspended in either isotonic saline (Hespan) or a solution similar to lactated Ringer's (Hextend). Dextran-70 is suspended in isotonic saline.

65.4.1 Physiology

Synthetic colloids redistribute into the interstitial space at a much lower ratio than the isotonic crystalloid fluids. They are expected to increase serum colloid osmotic pressure, which will lead to movement of fluid from the interstitial space into the vascular space. Consequently, colloid administration will increase blood volume by an amount greater than the infused volume. This means that effective resuscitation may be possible by administering smaller volumes. When the full dose of 20 ml/kg was administered in 5 minutes to experimental healthy dogs, blood volume was increased by 25% at the end of the infusion, 36% after 30 minutes, and 26% after 4 hours.[5] These fluids are isoosmotic, so there is little effect on intracellular volume (see Chapter 64, Daily Intravenous Fluid Therapy).

65.4.2 Benefits

Colloid solutions produce vascular volume expansion with less interstitial expansion than do crystalloid solutions. They support colloid osmotic pressure and are useful in patients who are symptomatic from their hypoalbuminemia. In theory, the larger molecular weight colloids, because of their molecular size and configuration, might seal capillary leaks in patients with capillary leak syndrome.[12] Some have postulated that capillaries have both small pores, which reflect colloids, and large pores, which do not. The capillary leak syndrome that occurs in critical illness causes a change in the number of these pores but not in their size. For this reason, the molecular weight distribution of hydroxyethyl starch would not be a determining factor.[13] Some studies have supported the benefits of colloids in capillary leak,[14,15] others have not.[13,16]

65.4.3 Adverse Effects

The most important adverse effect of synthetic colloids is on coagulation. High molecular weight hydroxyethyl starch (the only available formulation in the United States) and dextran at dosages greater than 20 ml/kg q24h are likely to prolong clotting times.[17-19]

The causes of these changes in coagulation are many, including decreases in factor VIII and von Willebrand factor. Clinically significant bleeding associated with these products is unpredictable, probably because concurrent disease affects coagulation in many critically ill patients. They should be used in caution with patients already showing blood clotting abnormalities or in those in which blood clotting ability is a major concern, such as in those undergoing emergency surgery.

Colloids dilute red blood cell mass and albumin, as do crystalloids, and this effect is long lasting in proportion to the persistence of colloids in the vascular space. Allergic reactions to hydroxyethyl starch, dextran, and gelatin are reported but are extremely rare.

65.4.4 Fluid Prescription

In anticipation that most of the administered volume will remain in the vascular space, and because of potential toxicity, the dosage of colloids is smaller than that of crystalloids. The usual volume for management of shock is 10 to 20 ml/kg for dogs and 5 to 10 ml/kg for cats (see Table 65-1). As described for isotonic crystalloid resuscitation, colloid administration should be titrated according to the individual patient's response. The total volume usually is administered over 5 to 10 minutes.

65.5 HYPERTONIC SALINE

The usual concentration of hypertonic saline used to treat shock is 7.2% to 7.5%. The approximate osmolality is 2400 mOsm/L.

65.5.1 Physiology

Hypertonic saline creates an osmotic gradient from the intracellular to extracellular fluid space, leading to a reduction in intracellular volume and an increase in extracellular volume. The recruited fluid distributes in the extracellular space according to the 1:3 vascular-to-interstitial ratio. Consequently the increase in intravascular volume is greater than the infused volume. When 4 ml/kg was administered over 5 minutes to experimental healthy dogs, the increase in blood volume was 17% at the end of the infusion, 12% after 30 minutes, and 3% after 4 hours.[5] These fluids are highly efficient, because they expand blood volume about 3.5 times the amount administered. However, because the volume infused is small the absolute increase in vascular volume is small.

65.5.2 Benefits

The small volume of hypertonic saline to be administered in shock makes it attractive for situations in which limited support is available, such as in prehospital resuscitation in humans. Hypertonic saline is an effective resuscitation fluid despite its relatively small impact on vascular volume in comparison with other fluids. Its effectiveness has been attributed to other physiologic benefits such as vasodilation, increased cardiac contractility, and immunomodulatory effects. Hypertonic saline causes arteriolar vasodilation and improved microcirculatory perfusion. This leads to improved regional blood flow of coronary, renal, and intestinal circulations.

There is contradictory evidence in the literature regarding the effect of hypertonic saline on cardiac contractility. Some reports describe a direct positive inotropic effect, and others attribute all hemodynamic benefits of hypertonic saline to a combination of volume expansion and decreased afterload. In one study, hypertonic saline was found to be a negative inotrope in normovolemic dogs. The effect of hypertonic saline on cardiac contractility in clinical veterinary patients remains unclear.

Experimental studies have found numerous immunomodulatory effects of hypertonic saline, including increases in cell-mediated immune function, reduced antiinflammatory cytokine production, inhibition of neutrophil activation,[20] and altered pulmonary macrophage activity. These findings have led to the suggestion that hypertonic saline may be beneficial in the resuscitation of victims of trauma and patients in septic shock, but randomized clinical trials evaluating this therapy are lacking.

Hypertonic saline can be beneficial for intracranial hypertension by virtue of its hypertonicity, and has been suggested to be the resuscitation fluid of choice for patients with traumatic brain injury.[21,22]

65.5.3 Adverse Effects

Hypernatremia always follows administration of hyper-tonic saline. If excessive volumes are administered or if the patient's effective osmolality is already high, the hypernatremia could be severe enough to cause neurologic signs of tremors, altered mentation, and seizures. At recommended dosages, the hypernatremia is not associated with clinical complications. Overly fast administration (>1 ml/kg/min) of hypertonic saline can cause bradycardia, hypotension, and bronchoconstriction.[23,24]

In patients with decreased reservoirs of intracellular volume, the efficacy of hypertonic saline may be diminished. But, in a hemorrhagic shock model of pigs previously dehydrated by 8% of their body weight, the hemodynamic response to resuscitation was maintained.[25] Hypertonic saline may dilate precapillary sphincters and alter distribution of blood flow.

65.5.4 Fluid Prescription

Hypertonic saline (7.5%) can be administered at a dosage of 4 to 6 ml/kg in dogs and 3 to 4 ml/kg in cats over approximately 5 minutes (see Table 65-1). Hypertonic saline often is combined with a colloid fluid, to prolong the volume-expanding effect.

65.6 FLUID COMBINATIONS

More than one fluid type may be used for shock fluid administration. Two common combinations are crystalloids with colloids and hypertonic saline with colloids.[26-28] The rationale of these combinations is to provide the immediate volume-expanding effects of crystalloids or hypertonic saline with the advantage of longer lasting vascular volume expansion of colloids. Crystalloid-colloid combinations have also been used in patients with hypovolemic shock and concurrent hypoproteinemia, as seen in diseases such as hemorrhagic gastroenteritis. The fluid dosage of a crystalloid-colloid combination is determined by response to therapy. Each fluid is given in increments as previously described and the patient's clinical response evaluated before further administration. When hypertonic saline–colloid combinations are given, they generally are used together and administered rapidly.[29] Dextran-70 is used most commonly in this protocol, but it could be replaced by hydroxyethyl starch. Proposed dosages for a solution of 7.5% saline in a colloid (dextran-70 or hydroxyethyl starch) are 4 to 6 ml/kg in dogs, and 3 to 4 ml/kg in cats. Again, response to therapy should be monitored and the low end of the dosage range used for cats (see Table 65-1).

65.7 CHOOSING A FLUID FOR TREATMENT OF SHOCK

The fluids described have distinctly different characteristics. Although most patients in shock can be resuscitated satisfactorily with any of them, certain patients are likely to benefit more from one fluid than another.

65.7.1 Preexisting Losses

Most preexisting volume losses in dogs and cats are a combination of salt and water in nearly isotonic 278 proportions (urinary or gastrointestinal losses) such that the patient has extracellular volume depletion with 279 normal or nearly normal effective osmolality. Thus intracellular volume is normal. These patients are usually described as dehydrated (de = loss, hydra = water), but the term is taken to mean loss of both salt and water. Isotonic crystalloids are the resuscitation fluid of choice because they replace vascular and interstitial volume deficits. Failure to repair the interstitial deficit puts the patient at risk of inadequate resuscitation and recurrent episodes of hypovolemia, especially when colloid fluids are used.[30]

Preexisting losses that are entirely water come from all body compartments, with two thirds of the lost volume being taken from the intracellular space and one third from the extracellular compartment. The patient is hypernatremic. These patients are dehydrated in the strict sense of the word; they have suffered a water loss. Shock fluids should have a sodium concentration equal to the patient's current sodium concentration until signs of shock are resolved, in order to avoid sudden changes in serum sodium concentration that can have life-threatening consequences.

To create a shock resuscitation fluid for a hypernatremic patient, an appropriate amount of hypertonic saline is added to a bag of 0.9% saline. Hypertonic saline at a concentration of 23.4% (Na = 4 mEq/ml) is useful for this purpose. The aim is to make a fluid with a sodium concentration close (within 5 mEq/L) to the patient's serum sodium concentration. There is some variation in sodium concentration and in the actual volume (slightly overfilled) in bags of fluid. One can analyze the baseline sodium concentration of the fluid and weigh the bag before calculating the volume of hypertonic saline to add. The resultant fluid can be given safely as a bolus in large amounts, if needed, to the hypernatremic patient. Once the patient has been resuscitated, a fluid therapy plan to resolve the hypernatremia is indicated (see Chapter 54, Sodium Disorders).

65.7.2 Preexisting Volume Excess

Extracellular volume excess (edema) may occur from administration of isotonic crystalloid fluids in amounts that exceed the patient's output capacity. These patients have peripheral edema and are at risk for pulmonary edema. The vascular-to-interstitial volume ratio in these patients may be as high as 1:6 rather than the normal 1:3. If isotonic crystalloids are administered, they will redistribute out of the vascular space in accordance with the new vascular-to-interstitial volume ratio. Hence shock resuscitation of these patients with isotonic crystalloids is unlikely to provide the desired vascular volume expansion. Hypertonic saline and colloid solutions can be considered, with the caveat that colloid solutions contain isotonic saline.

65.7.3 Active Hemorrhage

In patients with hemorrhage, administration of large volumes of crystalloid or colloid fluids is likely to promote more bleeding. Restraint in the volume prescribed is suggested, but inadequate resuscitation puts the patient at risk for global impairment of tissue perfusion. Control of bleeding before administration of resuscitation (delayed resuscitation) may be feasible if the appropriate facilities and staff are available,[31] but limited early resuscitation to at least minimal end points is likely to be a better option.[32-34]

65.7.4 Brain Injury

Brain-injured patients suffering from shock must be resus-citated adequately. Outcomes have been shown to be poorer for human patients with brain injury when they are not fully resuscitated to end points such as restoration of adequ-ate blood pressure.[35] If otherwise indicated, hypertonic saline combined with a colloid is a good choice (see Chapters 100 and 152, Intracranial Hypertension and Traumatic Brain Injury, respectively).

65.8 CRYSTALLOIDS OR COLLOIDS

The increase in blood volume expected at the end of rapid infusion is different among isotonic or hypertonic crystalloids or colloids. In experimental healthy dogs given the usual doses at rapid rates, the end-infusion blood volume was about 76% for isotonic saline (80 ml/kg in 12 minutes), 25% for colloids (20 ml/kg in 5 minutes), and 17% for hypertonic saline (4 ml/kg in 5 minutes). At 30 minutes post infusion the blood volume for isotonic crystalloids or colloids was approximately equal at 35%, and was 12% for hypertonic saline. What is not established is whether the initial, larger increase in blood volume obtained with isotonic crystalloids is better than the more modest increase gained with colloids. Hypertonic saline should usually be combined with another fluid to ensure more vascular volume expansion. The volume expansion achieved at the end of rapid infusion is dependent on the volume administered, and that obtained after 30 minutes is dependent on the characteristics of the fluid.

Many randomized, controlled clinical trials of crystalloids compared with colloids for treatment of shock in human patients have been performed and several metaanalyses of these trials published.[36-38] Overall, there were no consistent differences in outcome. However, subgroup analysis showed that the use of isotonic crystalloids in trauma patients was associated with improved survival. A recent review concluded that there was no evidence that resuscitation with colloids reduced the risk of death.[39]

A clinical trial in dogs suffering from trauma compared a hypertonic saline and dextran combination with isotonic crystalloids for resuscitation and found no significant differences in the responses measured.[40] Considering these and other clinical trials, and especially considering the differences among patients, it is likely that equivalent effects can be expected when any of these fluids is used appropriately and titrated to the same end points.

65.8.1 Venous Access and Fluid Delivery Systems

Fluids for shock are delivered intravenously or by the intraosseous route. Other routes, such as subcutaneous and intraperitoneal, are not desirable, because shock-induced vasoconstriction impairs absorption by these routes. The fluid delivery system should be chosen so that a large volume can be delivered at a fast rate. The best choice is usually a large-gauge, short catheter with a short length of tubing between the fluid and the patient. The flow rate can be raised by adding a pressure bag to the delivery system.

65.8.2 End Points of Resuscitation

Fluid therapy for shock is continued until end points have been reached. The most common end points are improvements in mental state, mucous membrane color, capillary refill time, pulse rate, and pulse quality. Improvements in hyperlactatemia or base deficit are expected, if these were abnormal before treatment. Other end points of resuscitation, such as mixed venous oxygen saturation and oxygen extraction ratio, have also been used. Early goal-directed therapy where end points of resuscitation such as oxygen content and central venous hemoglobin saturation were maximized early was found to be beneficial in human patients in septic shock and is recommended.[41]

65.8.3 Fluid Challenge

One of the limits of the physical examination is the evaluation of vascular volume status. This is a significant limit, because vascular volume is an important contributor to delivery of oxygen and other nutrients to metabolically active cells, which is the goal of fluid therapy for shock. A practice that is complementary to physical evaluation of vascular volume status is to use response to therapy, also called *fluid challenge,* which has been reviewed.[42] The fluid challenge technique is for hemodynamically unstable patients. The goal is to optimize cardiac filling pressures and forward blood flow. If the parameters of concern (restoration of arterial blood pressure, improvement of physical parameters related to tissue perfusion, and improved diuresis) improve after the fluid challenge, then there was a vascular volume deficit even if the physical examination did not clearly identify it. Also, failure to respond to a fluid challenge raises the question of whether the patient has a cause of shock other than vascular volume deficit. In such patients more advanced hemodynamic monitoring may be indicated (see Chapters 203 and 212, Hemodynamic Monitoring and Cardiac Output Monitoring, respectively). The fluid challenge technique is useful in patients whose physical examination is equivocal.

For a fluid challenge to be effective it must be of sufficient volume and be given rapidly enough that a change in cardiovascular status can be appreciated. Suggested dosages are 10 to 20 ml/kg of an isotonic crystalloid fluid (for cats and dogs, respectively) or 3 to 5 ml/kg of a colloid fluid (for cats and dogs, respectively) infused over 10 minutes (see Table 65-1).

66 Chapter 66 Transfusion Medicine

Urs Giger, PD, Dr.Med.Vet., MS, FVH, DACVIM, DECVIM, DECVCP

66.1 KEY POINTS

- Transfusion therapy refers to the safe and effective replacement of blood or one of its components, thereby offering support for many critically ill anemic or bleeding patients.
- The indications for transfusions need to be clearly determined, and ideally only the deficient blood component is replaced at the appropriate dosage.
- Although red blood cells and plasma clotting factors are crucial, the indications and efficacy of transfusing platelets, leukocytes, and other plasma proteins are limited.
- Blood products represent a limited resource; hence they should be given only when indicated, using the minimal dosage required and after carefully considering all alternatives.
- All canine and feline donor blood must be typed for the dog erythrocyte antigen (DEA) 1.1 and the feline AB blood groups, respectively, and all donors must have regular health examinations including blood and infectious disease screening.
- All canine and feline recipient blood should be typed for DEA 1.1 and feline AB blood groups, respectively. Blood from any previously transfused (more than 4 days prior) animal should also be crossmatched before receiving another red blood cell transfusion.
- Although acute hemolytic transfusion reactions are feared most, they can be avoided by prior compatibility testing; other transfusion reactions may not be predictable.
- The efficacy and survival of transfused blood cells and plasma proteins should be monitored during and after transfusion using appropriate clinical and laboratory parameters.

66.2 INTRODUCTION

Since the early 1980s, blood product administration to treat critically ill animals or those undergoing surgical procedures has increased tremendously. However, it is important to note that blood products are obtained from donor animals and represent a limited resource that is not available in all situations. Because they are biologic products, they bear the inherent risks of transmitting infectious diseases or causing other adverse reactions. Clinicians in the critical care setting play a key role in providing safe and effective transfusion therapy and therefore should be aware of the principles of transfusion medicine. The interested reader is referred at the end of the chapter to more comprehensive reviews and books on veterinary transfusion medicine.

66.3 INDICATIONS FOR TRANSFUSION THERAPY

Blood transfusions are indicated for management of anemia, coagulopathy, and rarely for other conditions such as thrombocytopenia, thrombopathia, and hypoproteinemia (Table 66-1). The disorders that lead to these medical problems and their detailed management are described in separate chapters. Fresh whole blood (FWB) contains all cellular and plasma components of blood, but specific blood component therapy provides the most effective and safest support and allows for optimal use of every donation. The decision to transfuse is based on the overall clinical assessment of a patient's history and clinical signs, routine laboratory test results, underlying cause, and sound clinical judgment. Although the optimal packed cell volume (PCV) may be above 30%, oxygen delivery in a normovolemic resting animal can be maintained down to a Hct of 10% (although this is inadequate under most disease conditions). Thus there is no specific transfusion trigger in all patients (i.e., certain PCV or coagulation times). Because transfusion carries inherent risks, blood should never be given without a clear indication or before exhausting alternative therapies. Furthermore, blood components represent a scarce resource and should therefore not be used without a proper indication and assessment of the prognosis.

66.3.1 Red Blood Cell Transfusions

The most common indication for transfusions in dogs and cats is anemia (see Chapter 120, Anemia). Transfusions are generally required after loss of the blood's oxygen-carrying capacity (i.e., loss of hemoglobin) and subsequent tissue/organ ischemia, and not as a simple volume expander. Depending on the type, degree, rapidity, and course of the anemia, a transfusion with blood products, such as stored packed red blood cells (pRBCs), fresh whole blood FWB, or stored whole blood, may be warranted. Animals with rapidly progressive anemia should be transfused when the Hct is approximately 20% to 25%, and a patient with chronic anemia may not require transfusion despite having a much lower Hct.

Healthy animals can readily tolerate a loss of up to 20% of blood volume (blood donors regularly give 20 ml/kg body weight q6-12wk) without any ill effects. However, animals with acute hemorrhage exceeding 20% of the blood volume may require a blood transfusion in addition to the initial shock fluid therapy (see Chapter 65, Shock Fluids and Fluid Challenge). It should be noted that animals with peracute blood loss will not show a drop in Hct for hours following hemorrhage, until intercompartmental fluid shifts occur or fluid therapy is instituted. Hence, other parameters are used to decide if transfusion therapy is indicated, such as mucous membrane color, capillary refill time, heart rate, blood pre-ssure, and possibly blood lactate levels. An assessment of an arterial blood gas and respiratory rate and effort are useful to evaluate animals with coexisting respiratory disease (ventilation-perfusion mismatch). In most animals with anemia secondary to acute blood loss, fluid therapy alone 281 will restore 282 vital organ perfusion, although pRBCs should be considered in any animal with evidence of tissue hypoxia. A falling Hct is not a contraindication of fluid administration, although excessive blood collection for diagnostic tests may necessitate blood replacement in a sick animal. Animals that require anesthesia and surgery should have a Hct of at least 20% to ensure adequate oxygen-carrying capacity during anesthesia.

Table 66-1 Blood Products, Storage Guidelines, and Indications

Blood Product	Storage	Temperature in Celsius	Indications
Fresh whole blood (FWB)	<8 hours	2 to 24	Combined red blood cell and plasma deficiency with need for platelets
FWB	<24 hours	4	Combined red blood cell and plasma deficiency without need for platelets
Stored whole blood (SWB)	28 to 35 days	4	Anemia Hypoproteinemia
pRBC	28 to 35 days	4	Anemia
Platelet rich plasma (PRP) or platelet concentrates	24 hours*	20-24	Thrombocytopenia with life-threatening bleeding
Fresh frozen plasma (FFP)	1 year	<−20 to −40	Any coagulation factor deficiencies; hypoproteinemia
Stored plasma	1 to 2 years	<−20 to −40	Hypoproteinemia
Cryoprecipitate (CRYO)	1 year	<−20 to −40	von Willebrand disease Hemophilia A (but not B) Hypofibrinogenemia
Cryoprecipitate-poor plasma (CRYO-poor)	1 year	<−20 to −40	Hypoproteinemia Some coagulopathies (factors II, VII, IX, XI)

In animals with immune-mediated hemolytic anemia (see Chapter 121, Acute Hemolytic Disorders), red blood cell transfusions have proven lifesaving and there is no evidence that transfused red blood cells are destroyed more rapidly than the patient's own erythrocytes. There are no data to show that the transfused cells “add fuel to the fire.” The administration of a bovine hemoglobin solution (Oxyglobin) has also shown beneficial effects.

* If constantly mixed gently.

66.3.2 Fresh Frozen Plasma

Fresh frozen plasma (FFP) is used most commonly in veterinary practice to treat coagulopathies causing serious bleeding, because this product contains all coagulation factors. FFP is commonly used in animals with hemorrhage secondary to acquired coagulopathies (i.e., liver disease and anticoagulant rodenticide intoxications) or patients with hereditary coagulopathies and subsequent bleeding. Sudden hemorrhage caused by therapeutically used heparin (including accidental use of undiluted heparin flushes) or warfarin to counter thrombosis can also be corrected with FFP, although protamine can also reverse the heparin-induced effects. The use of FFP (with or without heparin) to replace deficient coagulation factors and antithrombin to treat patients with immune-mediated hemolytic anemia or disseminated intravascular coagulation is controversial. There are no studies documenting a definitive beneficial effect. Similarly, evidence for the use of FFP in animals with acute pancreatitis (to replace α-macroglobulins and antiproteases) or in parvovirosis (to provide antiparvovirus antibodies and additional immunoglobulins and to stop gastrointestinal hemorrhage) is lacking. FFP is also commonly used to correct hypoproteinemias in cases of protein-losing nephropathies and enteropathies, but its effect on oncotic pressure in these animals is minimal at clinically used dosages, especially when compared with synthetic hyperoncotic agents such as dextran-70 or hydroxyethyl starch. Critically ill animals with albumin concentrations less than 1.5 g/dl may benefit from plasma therapy, because this protein is an important carrier of certain drugs, hormones, metals, chemicals, toxins, and enzymes.

66.3.3 Other Blood Products

Other blood products are used less commonly in dogs and are not generally available for cats. Cryoprecipitate is rich in fibrinogen, fibronectin, factor VIII, and von Willebrand factor and is the preferred treatment for bleeding dogs with these plasma protein deficiencies. If available, cryoprecipitate-poor plasma may be administered to many coagulopathic and hypoproteinemic dogs when synthetic plasma expanders are of limited use or have undesirable side effects. Because platelets are relatively short-lived (1 week) and cannot readily be stored for any length of time (<24 hours at room temperature), they rarely are transfused. Hemorrhage caused by thrombocytopenia in anemic dogs could be treated with FWB, but generally requires only pRBCs to correct the anemia. Rarely, platelet-rich plasma (PRP) and platelet concentrates are required to control life-threatening bleeding (see Chapter 119, Thrombocytopenia). Furthermore, in dogs with immune-mediated thrombocytopenia, transfused platelets have a very short half-life (hours) and will not result in any appreciable platelet rise, but they may transiently stop severe hemorrhage. Althouh cryopreserved platelets are currently available for use in dogs, there is insufficient information to document their efficacy or to recommend routine use of the product. Research is ongoing. Because of the very short half-life of granulocytes (hours), leukocyte transfusions are not generally practiced in human or veterinary medicine.[1]

66.4 BLOOD TYPING

To ensure efficacious and safe transfusions, blood from both donor and recipient should be typed and, if previously 282
283 transfused, a crossmatch should also be performed. Blood types are genetic markers on erythrocyte surfaces that are species-specific and antigenic in individuals that lack the same markers. This antigenicity results in the development of alloantibodies, so that the administration of a small volume (as little as 1 ml) of incompatible blood can result in life-threatening reactions. Blood typing is therefore clinically important to ensure blood compatibility and is recommended for any animal in need of a transfusion, any animal becoming a blood donor, and before breeding type B queens to avoid neonatal isoerythrolysis (NI). Unless blood typing is performed regularly, it is best to send ethylenediaminetetraacetic acid (EDTA) blood to a laboratory for typing.[2,3]

66.4.1 Canine Blood Types

Dogs have more than a dozen blood group systems known as DEAs. Canine erythrocytes are either positive or negative for a blood type (e.g., DEA 4 positive or negative), and these blood types are thought to be codominantly inherited. In the DEA 1 system, which represents an exception, DEA 1.1 (A_1) and 1.2 (A_2) are allelic, and there may even be a DEA 1.3 (A_3). Thus a dog can be DEA 1.1 positive or DEA 1.1 negative, and only DEA 1.1-negative dogs can be DEA 1.2 positive or DEA 1.2 negative. There are no clinically important alloantibodies present before sensitization of a dog with a transfusion (pregnancy has never been reported to cause sensitization).[2,4,5]

The most important canine blood type is DEA 1.1. DEA 1.1 (A_1) elicits a strong alloantibody response after sensitization of a DEA 1.1-negative dog by a DEA 1.1-positive transfusion. This can lead to an acute hemolytic transfusion reaction in a DEA 1.1-negative dog previously transfused with DEA 1.1-positive blood. Transfusion reactions against other blood types in previously transfused dogs have been described rarely. They include reactions against the DEA 4,[6] Dal in Dalmatians, and another common red blood cell antigen in a Whippet. Additional clinically important blood types may yet be discovered.[7]

Simple blood typing cards using a DEA 1.1 monoclonal antibody are available for DEA 1.1 typing of dogs (DMS Laboratories, Flemington, NJ), but there is some concern that weak agglutination reactions may be caused by the DEA 1.2 antigen. More recently, a reliable gel column procedure has been introduced (DiaMed, Cressier, Switzerland) for clinical pathology laboratories. Ethylenediaminetetraacetic acid is preferred over other anticoagulants.[8] Dogs that are DEA 1.1 negative are considered universal blood donors for a dog that has never been transfused. Canine blood typing sera for DEA 1.1, 1.2, 3, 4, and 7 and limited typing services are available (Midwest Blood Services, East Lansing, MI), but other blood groups of clinical importance can be identified by crossmatching previously transfused dogs. Persistent autoagglutination following saline washing of the recipient's blood negates any typing and crossmatch testing. Unless a bitch has been transfused previously, there is no concern for NI.

66.4.2 Feline Blood Types

The main blood group system recognized in cats is known as the *AB blood group system* and consists of three types: type A, type B, and the extremely rare type AB. Type A is dominant over B.[9-11] Thus cats with type A blood have the genotype a/a or a/b, and only homozygous b/b cats express the type B antigen on their erythrocytes. In the extremely rare AB cat, a third allele recessive to a or codominant to b (or both) leads to the expression of both A and B substances. Cats with type AB blood are not produced by mating of a cat with type A to a cat with type B unless the cat with type A carries the rare AB allele. Cats with type AB blood have been seen in many breeds, including domestic shorthaired cats. The frequency of feline A and B blood types varies geographically and among breeds. For instance, all Siamese cats have type A blood, and Turkish Vans and Angoras have equal numbers of type A and B blood. Most domestic shorthaired cats have type A blood, but the proportion of cats with type B blood can be substantially different in certain geographic areas. All donor blood must be typed. Most blood donors have type A blood, but some clinics also keep cats with the rare type B and type AB blood as donors.[2]

Cats have naturally occurring alloantibodies.[9] All cats with type B have very strong naturally occurring anti-A alloantibodies. Kittens receive alloantibodies through the colostrum from type B queens and develop high alloantibody titers (>1:32) after a few weeks. Anti-A alloantibodies are responsible for serious transfusion reactions and NI in kittens with type A and AB born to type B queens. Cats with type A blood have weak anti-B alloantibodies, and their alloantibody titer is usually very low (1:2). Nevertheless cats with type A blood can also develop hemolytic transfusion reactions when given B blood, but no type A queen has had a litter with NI caused by AB incompatibility. Cats with type AB blood have no alloantibodies, although it is recommended that these cats receive type A pRBCs if type AB blood is not available. Furthermore, additional blood group systems are being identified, such as the Mik red blood cell antigen in domestic shorthaired cats. It is thought that Mik-negative cats may produce naturally occurring alloantibodies, leading to blood incompatibility reactions beyond the AB blood group system.[12]

Simple AB blood typing cards are available for use in practice (DMS Laboratories, Flemington, New Jersey), but there are occasionally concerns that cats with type AB are not being recognized. More recently, a gel test (DiaMed, Cressier, Switzerland) has been introduced as an accurate laboratory method, in addition to the regular tube and slide tests used in laboratories.[13]

66.5 BLOOD CROSSMATCHING

The blood crossmatch detects the serologic compatibility between the anemic recipient and potential donor, and must be performed in cats if blood typing is not available and in dogs or cats that have previously received transfusion therapy.[1,2,10] This test looks for the presence or absence of alloantibodies in dogs or cats without determining the blood type; it does not replace blood typing. Crossmatching is done with anticoagulated blood from the recipient and the potential donor and requires some technical expertise, but may be performed in practice along with blood typing. Gel-based techniques for standardized crossmatching are being introduced. The major crossmatch tests for alloantibodies in the recipient's plasma against donor cells. The minor crossmatch tests for alloantibodies in the donor's plasma against recipient's red blood cells and is of lesser importance, because the donor's plasma will be diluted. It is also of lesser importance if all donors' types are known and if the donors have never received transfusions (i.e., no prior sensitization). Autoagglutination or severe hemoglobinemia (secondary to fragile red blood cells) precludes testing. Washing the red blood cells three times with physiologic saline may prevent autoagglutination and rouleaux formation.

Because dogs do not have naturally occurring alloantibodies, the initial crossmatch of a dog that has not previously been transfused should be compatible.[4] A compatible crossmatch in a dog does not prevent sensitization against donor cells within 1 to 2 weeks. Thus a dog that was previously given a compatible transfusion from a donor dog may become incompatible with blood from the same donor 1 to 2 weeks later. Because cats have naturally occurring alloantibodies, a blood crossmatch test can detect an A-B mismatch as well as other incompatibilities (e.g., Mik). Mixing a drop of donor blood with recipient plasma (or vice versa) will detect the strong A-B incompatibilities. The practice of administering a small amount of blood to the recipient animal to test for compatibility should be abandoned, because it may result in fatal transfusion reactions.

66.6 BLOOD DONORS AND SOURCES

Many larger veterinary hospitals have permanent canine and feline blood donors to cover their transfusion requirements or in case FWB or PRP (platelet concentrates) is needed. Several larger voluntary blood donor programs have emerged with client-owned or staff-owned dogs. More than a dozen commercial canine blood banks have been established in the United States that deliver blood products overnight; however, there is generally a blood shortage. Some blood banks are also providing feline products. Autologous (self) transfusion refers to the donation of blood by a patient from 4 weeks to a few days before a surgical procedure during which large surgical blood loss is anticipated. Blood can also be collected immediately before surgery. The patient's blood is diluted with crystalloid and colloid solutions, and the previously drawn blood is replaced when excessive bleeding occurs during or after surgery. Autotransfusion is another autologous transfusion technique in which shed blood salvaged intraoperatively or following intracavitary hemorrhage is reinfused after careful filtering. However, blood from longstanding (more than 1 hour), contaminated, or malignant hemorrhagic effusions should not be reinfused.

Blood donors should be young adult, lean, and good-tempered animals and weigh at least 25 kg for dogs to donate 450 ml or 4 kg for cats to donate 40 ml. They should have no history of transfusion and be regularly vaccinated and healthy as determined by history, physical examination, and laboratory tests (complete blood cell count, chemistry screen and fecal parasite examination every 6 to 12 months), as well as free of infectious diseases. Testing depends on species, breed, and geographic area but may include regular microfilaria, *Brucella, Babesia, Ehrlichia, Anaplasma, Borrelia,* and *Leishmania* spp testing in dogs and feline leukemia virus, feline immunodeficiency virus, feline infectious peritonitis, and *Mycoplasma haemofelis* (previously named *Haemobartonella felis*) testing in cats. Donors should receive a well-balanced, high-performance diet, and may be supplemented twice weekly with oral ferrous sulfate (Feosol, 10 mg/kg q24h) if bled every 4 weeks. PCV or hemoglobin concentration should be over 40% and more than 13 g/dl, respectively, in canine donors and over 30% and more than 10 g/dl, respectively, in cats.[14]

66.7 BLOOD COLLECTION

Canine donors generally are not sedated, but cats regularly require sedation. Some sedatives, such as acepromazine, interfere with platelet function and induce hypotension and therefore should not be used. Blood is collected aseptically by gravity flow or blood bank vacuum pump from the jugular vein over a 5- to 10-minute period. Plastic blood bags (Fenwal) containing citrate-phosphate-dextrose-adenine (CPD-A_1), with or without satellite bags for blood component separation, are optimal. These commercial blood bags represent a closed collection system in which the blood does not come into contact with the environment at any time during collection or separation into blood components, thus minimizing the risk of bacterial contamination and allowing for rapid storage of the blood products. Large plastic syringes containing 1 ml CPD-A_1 or 3.8% citrate per 9 ml blood and connected to a 19-gauge butterfly needle are used commonly for blood collection in cats. This represents an open collection system in which connections allow exposure of blood to the environment.[15] Because of the risk of bacterial contamination, blood collected via an open system should not be stored for more than 48 hours. Vacuum glass bottles containing acid-citrate-dextrose allow rapid collection, but are not recommended because blood components are damaged readily and cannot be separated and stored for long periods. The maximal blood volume to be donated is 20 ml blood/kg or one regular blood bag unit of 450 ± 50 ml per ≥25-kg dog and 10 ml blood/kg or 40 ml blood (one typical feline unit) per ≥4-kg cat.

Blood components are prepared from a single donation of blood by simple physical separation methods such as centrifugation within 8 hours of collection; thereby, FWB can be separated into pRBCs, PRP or platelet concentrates, FFP, cryoprecipitate, and cryoprecipitate-poor plasma according to the *Technical Manual of the American Association of Blood Banking,* but this does require some expertise and equipment. Blood component preparation is best accomplished by using plastic blood bags with satellite transfer containers to ensure sterility. Fluctuations in storage temperature significantly alter the length of storage; thus, FWB and pRBCs should be kept at 4° C ± 2° C and all plasma products at less than −20°C using blood bank refrigerators and freezers with alarms, if possible. Alternative refrigerator-freezer devices may be used as long as the temperature is monitored and the unit is not opened frequently. Storage of canine pRBCs will result in a gradual reduction of erythrocytic 2,3-diphosphoglyceride and accumulation of ammonia, but these metabolites are rapidly regenerated or eliminated, respectively, and do not typically affect pRBC efficacy or safety. Caution must be exercised, however, in animals that have severe liver insufficiency and subsequent hyperammonia. Blood components that have been warmed to room or body temperature should not be recooled or stored again because of safety (affects product quality). Similarly, partially used or opened blood bags should be used within 24 hours because of the risk of contamination and product damage.

66.8 ADMINISTRATION OF BLOOD PRODUCTS

For routine transfusion therapy in anemic patients, it is not necessary to warm blood after removal from the refrigerator. Warming may accelerate the deterioration of stored red blood cells and permit rapid growth of contaminating microorganisms. However, there are specific clinical situations (such as transfusion of neonates or resuscitation of trauma patients) that necessitate the administration of rapid, massive transfusions such that warming of the blood products is indicated to prevent complications associated with hypothermia (e.g., cardiac arrhythmias and coagulopathies). A temperature-controlled waterbath or bowl (39° C or 102.2° F) is used to warm the blood products. Care should be taken to maintain absolute sterility and not to overheat any part of the blood products to over 39° C.

Blood bags are connected to infusion sets that have an in-line microfilter. A long (85 cm) blood infusion set with a drip chamber for medium to large dogs and a short infusion set that can be attached to a syringe for small dogs and cats are available. A latex-free infusion set should be used for platelet administration to prevent aggregation. Microfilters with 170-μm pores are used commonly to remove clots and larger red blood cell and platelet aggregates. Finer filters with 40-μm pores will remove most platelets and microaggregates, but these commonly clog or become dysfunctional after 50 to 100 ml of blood is run through them. Leukocyte reduction filters may be used at the time of blood collection to decrease febrile adverse reactions to white blood cell components, but they are expensive. Sterility must be maintained when connecting the blood component bag to the infusion set and the tubing to the catheter.

Blood components are best administered intravenously. An intramedullary (intraosseous) catheter may be used when venous access cannot be obtained (see Chapter 62, Intraosseous Catheterization). Intraperitoneal administration is not generally recommended because absorption time is delayed. Concurrent administration of drugs or fluids other than physiologic saline should be avoided to prevent lysis of erythrocytes or coagulation. Thus fluids containing calcium or glucose, or hypotonic or hypertonic solutions should not be administered simultaneously through the same intravenous line.

The rate of transfusion depends on the cardiovascular status, hydration status, degree of anemia, and general condition of the recipient. The initial rate should be slow, starting with 1 to 3 ml over the first 5 minutes, to observe for any transfusion reactions, even with blood-typed or crossmatched transfusions. In animals with cardiac failure, 4 ml/kg/hr should be used for administration, and close monitoring is of utmost importance. Transfusion of a single bag should be completed within 4 hours to prevent functional loss or bacterial growth. The volume of the blood component to be administered depends on the type of deficiency and size of the animal. For treatment of anemia:

> Volume (ml) of whole blood = 2 × PCV rise desired (%) × body weight (kg). In other words, administration of 2 ml whole blood/kg body weight raises the PCV by 1%. If pRBCs are used without prior resuspension in a red blood cell preservative, half the volume should be administered, because pRBCs have a PCV of 70% to 80%.

In the absence of bleeding and hemolysis, at least 70% of transfused erythrocytes survive 24 hours (required blood bank standard) and transfused erythrocytes may thereafter be expected to have a near normal life span (approximately 70 days in cats, 110 days in dogs). The response to the transfusion is monitored by obtaining a PCV and total protein reading before, during, and 6 and 24 hours after transfusion, and the clinician must consider continued blood loss and hemolysis when interpreting values.

In animals with thrombocytopenia or thrombopathia, one unit of platelet concentrates, PRP, or FWB will increase the platelet count by approximately 10,000/μL in a recipient weighing 30 kg. In animals with serious or life-threatening bleeding, the platelet count should be increased to greater than 20,000 to 50,000/μl. Platelet counts should be monitored before and 1 and 24 hours after platelet transfusion.

> In bleeding animals with coagulopathies and von Willebrand disease, FFP is initially administered at a dosage of 6 to 10 ml/kg to stop bleeding or prevent excessive bleeding during surgery.

In some cases, larger volumes may be needed to control bleeding, and depending on the coagulopathy, repeated administration of FFP may be required. Because of the short half-life of factors VII, VIII, and von Willebrand factor, deficient animals may need treatment 2 to 4 times daily. Animals with other coagulopathies may be treated daily. Plasma support should be provided for an additional 1 to 3 days after the bleeding has been controlled to prevent rebleeding and enhance healing.

> Cryoprecipitate at a dosage of 1 CRYO unit/10 kg or 1 to 2 ml/kg body weight twice daily is ideal to treat a bleeding animal with hemophilia A and/or von Willebrand disease.

66.9 ADVERSE TRANSFUSION REACTIONS

Although transfusion of blood and its components is usually a safe and temporarily effective form of therapy, there is always some risk involved. Adverse reactions usually occur during or shortly after the transfusion and can be caused by any component of the infused blood product. Most transfusion reactions can be avoided by carefully selecting only healthy donors, using appropriate collection, storage, and administration techniques, performing blood-typing and crossmatching, and administering only necessary blood components. The most common clinical sign of a transfusion reaction is fever, followed by vomiting and hemolysis; any reaction should lead to immediate cessation of the transfusion. Hemolytic transfusion reactions can be fatal and are therefore most important, but fever and vomiting are usually self-limiting. Adverse effects of transfusions can be divided into nonimmunologic reactions (pyrogen-mediated fever, transmission of infectious agents, vomiting, mechanical hemolysis, congestive heart failure, hypothermia, citrate toxicity, and pulmonary complications) and immunologic reactions (acute and delayed hemolytic transfusion reactions, manifestations ranging from urticaria to anaphylaxis, and graft versus host disease). Note that some clinical signs may be caused by both mechanisms.

Diphenhydramine (2 to 4 mg/kg IM, SC, or IV once) and glucocorticoids (antiinflammatory dose equivalents) may be given therapeutically and the transfusion may be continued, if necessary, as long as a hemolytic reaction or 285
bacterial contamination has been excluded and the clinical signs are minimal. Prophylactic use of these medications 286
has not been documented, but withholding food and any other medications during the transfusion does prevent some reactions. Anaphylaxis occurs very rarely and is treated like any other serious allergic reaction (i.e., epinephrine). There is no specific therapy for hemolytic transfusion reactions, but supportive care is indicated. Fortunately, companion animals are resistant to heme protein–induced renal shutdown (also known as pigment nephropathy).

66.10 ALTERNATIVES

Because blood is a scarce resource and may cause significant transfusion reactions, alternatives should be considered. In many animals, treatment of the underlying disease and other supportive measures are all that is needed. Crystalloid and colloid fluids are appropriate when hypovolemia and low oncotic pressure are the main concerns. In the case of tissue hypoxia due to a lack of red blood cells (hemoglobin), bovine ultrapurified hemoglobin solution (Oxyglobin) can be used as a blood substitute in place of pRBCs, although its future availability is questionable. Oxyglobin is approved for dogs and has been effective and safe as a transient oxygen carrier in various clinical case series in cats. Because of its strong oncotic properties, hypervolemia and pulmonary edema are of particular concern in cats and otherwise compromised patients when large volumes are administered. Furthermore, the potential benefit of perfusing the capillary beds with oxygen transported by free hemoglobin rather than red blood cells may be countered by some of the adverse cardiovascular effects of Oxyglobin. Placing a critically ill animal in an oxygen cage with an inspired oxygen concentration greater than 21% adds little to the oxygen delivery in an anemic patient (due to a lack of hemoglobin), but it does allow the animal to rest away from the hustle of a busy treatment room and will increase the oxygen content slightly. Furthermore, anemic animals with concomitant pulmonary disease (as often occurs with immune-mediated hemolytic anemia due to pulmonary thromboemboli or pneumonia) will benefit from oxygen supplementation. Although human recombinant erythropoietin has a role in the treatment of anemia due to chronic renal failure and a few other types of anemia, its effect is delayed and it is thus not effective for the critical care patient and does carry the risk of causing crossreacting anti-erythropoietin antibodies.

Although various recombinant human products are available as alternatives for supplementation of plasma proteins in human medicine, these treatment options have not been evaluated completely in small animals and may not be safe or cost effective. Human albumin concentrates have been used in dogs and cats with severe hypoalbuminemia, but serious concerns have arisen regarding its safety and efficacy (lack of impact on survival in humans). Recombinant coagulation factors have drastically reduced the use of FFP in human patients. For instance, recombinant human FVIIa has been evaluated in dogs with factor VII deficiency and other hemostatic diatheses. Similarly, there is no commercial product of a canine or feline immunoglobulin concentrate, and thus human intravenous immunoglobulin has been used successfully in the acute treatment of dermal and systemic toxic drug reactions, as well as the treatment of severe immune-mediated diseases. Again, these are human products that bear the risk of reactions, especially with repeated use. In conclusion, a good understanding of transfusion medicine and its benefits and risks is crucial for today's emergency clinician.

67 Chapter 67 Diabetic Ketoacidosis

Rebecka S. Hess, DVM, DACVIM

67.1 KEY POINTS

- Diabetic ketoacidosis (DKA) is a severe form of complicated diabetes mellitus that requires emergency care.
- Acidosis and electrolyte abnormalities can be life threatening.
- Fluid therapy and correction of electrolyte abnormalities are the two most important components of therapy.
- Concurrent disease increases the risk for DKA and must be addressed as part of the diagnostic and therapeutic plan.
- Bicarbonate therapy usually is not needed and its use is controversial.
- About 70% of treated dogs and cats are discharged from the hospital after 5 to 6 days of hospitalization.
- The degree of base deficit is associated with outcome in dogs with DKA. Additionally, dogs that have concurrent hyperadrenocorticism are less likely to be discharged from the hospital.

67.2 INTRODUCTION

Diabetic ketoacidosis (DKA) is a severe form of complicated diabetes mellitus that requires emergency care. Ketones are synthesized from fatty acids as a substitute form of energy, because glucose is not transported into the cells. Excess ketoacids result in acidosis and severe electrolyte abnormalities, which can be life threatening.

67.3 PATHOPHYSIOLOGY

Ketone bodies are synthesized as an alternative source of energy when intracellular glucose concentration can not meet metabolic demands. Ketone bodies are synthesized from acetyl-coenzyme A (acetyl-CoA) which is a product of mitochondrial β-oxidation of fatty acids. This adenosine triphosphate (ATP)-dependent catabolism of fatty acids is associated with breakdown of two carbon fragments at a time and results in formation of acetyl-CoA. Synthesis of acetyl-CoA is facilitated by a decreased insulin concentration and increased glucagon concentration. The anabolic effects of insulin include conversion of glucose to glycogen, storage of amino acids as protein, and storage of fatty acids in adipose tissue. Similarly, the catabolic effects of glucagon include glycogenolysis, proteolysis, and lipolysis. Therefore a low insulin concentration and elevated glucagon concentration contribute to decreased mobilization of fatty acids into adipose tissue and increased lipolysis, resulting in elevated acetyl-CoA concentration. In nondiabetics acetyl-CoA and pyruvate enter the citric acid cycle to form ATP. However, in diabetics, glucose does not enter the cells in adequate amounts, and production of pyruvate by glycolysis is decreased. The activity of the citric acid cycle is therefore diminished, resulting in decreased utilization of acetyl-CoA. The net effect of increased production and decreased utilization of acetyl-CoA is an increase in the concentration of acetyl-CoA, which is the precursor of ketone body synthesis.[1]

The three ketone bodies synthesized from acetyl-CoA are β-hydroxybutyrate, acetoacetate, and acetone. Acetyl-CoA is converted to acetoacetate by two metabolic pathways, and acetoacetate is then metabolized to β-hydroxybutyrate or acetone. One of the pathways of acetoacetate synthesis involves condensation of two acetyl-CoA units and the other utilizes three units of acetyl-CoA. Ketone bodies are synthesized in the liver.[1]

Acetoacetate and β-hydroxybutyrate are anions of moderately strong acids. Therefore accumulation of these ketone bodies results in ketotic acidosis. Metabolic acidosis may be worsened by vomiting, dehydration, and renal hypoperfusion.[1] Metabolic acidosis and the electrolyte abnormalities that ensue are important determinants in the outcome of patients with DKA.[2]

One of the beliefs regarding the pathophysiology of DKA had been that individuals that develop DKA have zero or undetectable endogenous insulin. However, in a study that included seven dogs with DKA, five had detectable endogenous serum insulin concentrations, and two of these dogs had endogenous serum insulin concentration within the normal range.[3] Therefore it is possible that other factors, such as an elevated glucagon concentration (or less likely cortisol or catecholamines), contribute to DKA. Glucagon concentration may be elevated as a result of concurrent disease.

67.4 RISK FACTORS

The median age of dogs with DKA is 8 years (range 8 months to 16 years).[2] The mean age of cats with DKA is 9 years (range 2 to 16 years).[4] Breed or sex has not been shown to increase the risk of DKA in dogs or cats.[2,4,5]

Concurrent disease has been documented in about 70% of dogs with DKA and 90% of cats with DKA. The most common concurrent diseases noted in dogs with DKA are acute pancreatitis, bacterial urinary tract infection, and hyperadrenocorticism.[2] The most common concurrent diseases noted in cats with DKA are hepatic lipidosis, chronic renal failure, acute pancreatitis, bacterial or viral infections, and neoplasia.[4] It is possible that concurrent disease results in an elevated glucagon concentration and increased risk of DKA. The role of cortisol and catecholamines remains to be elucidated.

Most dogs and cats with DKA are newly diagnosed diabetics. It is possible that insulin treatment reduces the risk of DKA in dogs and cats.[2,4]

67.5 CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Clinical signs and physical examination findings may be attributed to chronic unmanaged diabetes mellitus, concurrent disease, and the acute onset of DKA. The most common clinical signs in dogs or cats with DKA are polyuria and polydipsia, lethargy, inappetence or anorexia, vomiting, and weight loss.[2,4] Common abnormalities noted on physical examination of dogs with DKA are subjectively overweight or underweight body condition, dehydration, cranial organomegaly, abdominal pain, cardiac murmur, mental dullness, dermatologic abnormalities, dyspnea, coughing, abnormal lung sounds, and cataracts.[2] Common abnormalities noted in cats with DKA are subjectively underweight body condition, dehydration, icterus, and hepatomegaly.[4]

67.6 CLINICAL PATHOLOGY

Approximately 50% of dogs with DKA have a nonregenerative anemia (which is not associated with hypophosphatemia), left shift neutrophilia, or thrombocytosis.[2] Anemia and left shift neutrophilia are also common features of feline DKA.[4] These cats also have significantly more red blood cell Heinz body formation than do normal cats, and the degree of Heinz body formation is correlated with plasma β-hydroxybutyrate concentration.[6]

Persistent hyperglycemia is apparent in all dogs and cats diagnosed with DKA, unless they receive insulin.[2] Alkaline phosphatase activity is elevated in almost all dogs with DKA.[2] Alanine aminotransferase activity, aspartate aminotransferase activity, and cholesterol concentration are increased in about half of the dogs with DKA.[2] Elevations in alanine aminotransferase activity and cholesterol concentration are also commonly observed in cats with DKA.[4] Azotemia is reported more commonly in cats than in dogs with DKA.[2,4]

Electrolyte abnormalities are common in both dogs and cats with DKA.[2,4] Initially, an animal with DKA may appear to have extracellular hyperkalemia due to dehydration, decreased renal excretion, hypoinsulinemia, decreased insulin function, hyperglycemia, and acidemia (leading to movement of hydrogen ions into the cells and potassium ions out to maintain cellular electronegativity). However, with rehydration, potassium ions are lost from the extracellular fluid and a true hypokalemia from depletion of total body potassium stores becomes apparent. Hypokalemia may be exacerbated by binding of potassium to ketoacids, vomiting, inappetence, and anorexia, and osmotic diuresis. Insulin therapy may worsen extracellular hypokalemia as insulin shifts potassium into cells.[7] The most important clinical manifestation of hypokalemia in DKA is profound muscle weakness, which may result in respiratory paralysis in extreme cases.

An apparent hypophosphatemia often develops when phosphate shifts from the intracellular space to the extracellular space as a result of hyperglycemia, acidosis, and hypoinsulinemia. Dehydration and decreased phosphorus excretion by the kidneys also contributes to this finding. Osmotic diuresis or fluid therapy along with insulin therapy causes extracellular phosphate depletion, leading to whole body phosphate depletion.[7] Hypophosphatemia related to DKA has been associated with hemolysis (in a cat) and seizures (in a dog).[8] Additional clinical signs that may develop because of hypophosphatemia include weakness, myocardial depression, and arrhythmias.

Decreased plasma ionized magnesium (iMg) concentration has been documented in four of seven cats with DKA, and may be due to increased urinary excretion of magnesium.[9] The clinical significance of hypomagnesemia in cats is unknown. The clinical consequence of hypomagnesemia in humans with diabetes includes insulin resistance, hypertension, hyperlipidemia, and increased platelet aggregation. Dogs with DKA usually do not have low iMg concentrations at the time of initial examination.[2,10] In one study of 78 dogs with uncomplicated diabetes mellitus, 32 dogs with DKA, and 22 control dogs, plasma iMg concentration at the time of initial examination was significantly higher in dogs with DKA than in dogs with uncomplicated diabetes mellitus and control dogs.[10] Hyponatremia, hypochloremia, and decreased ionized calcium concentration have also been documented in about 50% of dogs with DKA. Low sodium concentration may be secondary to the hyperglycemia, leading to a 1 mEq/L decrease in sodium concentration for every 62 mg/dl increase in glucose concentration in humans, and is often referred to as *pseudohyponatremia*. Venous pH is less than 7.35 in all dogs and cats with DKA. Lactate concentration is elevated in about one third of dogs with DKA and is not correlated with degree of acidosis.[2]

Urinalysis is usually indicative of glucosuria. Proteinuria or ketonuria may also be apparent. Ketonuria may not be detected because the nitroprusside reagent in the urine dipstick reacts with acetoacetate and not with β-hydroxybutyrate, which is the dominant ketone body in DKA. Measurement of serum β-hydroxybutyrate is more sensitive than measurement of urine ketones.[11] On urinalysis, the number of white blood cells per high-power field is usually five or fewer, although 20% of dogs with DKA have aerobic bacterial growth on culture of urine obtained by cystocentesis.[2] This is likely a result of immunosuppression of diabetics and decreased ability to mobilize white blood cells to the site of infection.

Results of additional clinicopathologic or imaging tests such as urine culture, abdominal ultrasonography, thoracic radiographs, adrenal or thyroid axis testing, pancreatic lipase immunoreactivity, liver function tests, or liver biopsy depend on concurrent disorders.

67.7 DIFFERENTIAL DIAGNOSIS

Differential diagnoses for ketosis include DKA, acute pancreatitis, starvation, low-carbohydrate diet, persistent hypoglycemia, persistent fever, or pregnancy. Differential diagnoses for a primary metabolic acidosis include DKA, renal failure, lactic acidosis, toxin exposure, severe tissue destruction, severe diarrhea, and chronic vomiting.

67.8 TREATMENT

Administration and careful monitoring of intravenous (IV) fluid therapy is the most important component of treatment (see Chapters 64 and 65, Daily Intravenous Fluid Therapy and Shock Fluids and Fluid Challenge, 289 respectively). Any commercially 290 available isotonic crystalloid solution may be used. The use of 0.9% saline has been advocated because of its relatively high sodium concentration[7]; however, it may be contraindicated in hyperosmolar diabetics. Additionally, 0.9% saline may contribute further to the acidosis because of the high chloride concentration and lack of a buffer. Lactate (contained in lactated Ringer's solution) and acetate (contained in Plasma-Lyte and Normosol-R) are converted to bicarbonate and may contribute to management of acidosis. Another advantage of these buffer-containing crystalloids is that they contain some potassium, which may blunt the acute decline in potassium concentration that the animal could suffer with initiation of fluid and insulin treatment. As long as the patient is monitored carefully, particularly in regard to hydration, mental status, and electrolyte concentrations, any of the above crystalloids can be used for management. Fluid therapy may contribute to a decrease in blood glucose concentration by improving renal perfusion and decreasing the concentration of counter regulatory hormones, most importantly glucagon.[12]

Correction and monitoring of electrolyte abnormalities is the second most important component of therapy. Electrolyte supplementation must be monitored frequently, because frequent adjustments may be required. An animal that appears hyperkalemic at the time of initial examination may become hypokalemic shortly after fluid therapy has begun. Hypokalemia can be treated by administering potassium as an IV constant rate infusion (CRI) at a rate that should generally not exceed 0.5 mEq/kg/hr (Table 67-1). If higher dosages are required, continuous electrocardiographic monitoring should be performed simultaneously.

Hypophosphatemia is corrected with an IV CRI of potassium phosphate (solution contains 4.4 mEq/ml of potassium and 3 mM/ml of phosphate) at a rate of 0.03 to 0.12 mM/kg/hr. Serum potassium concentration must be taken into account when giving potassium phosphate for correction of hypophosphatemia. A magnesium sulfate solution (containing 4 mEq/ml) given intravenously as a CRI of 1 mEq/kg q24h has been used successfully for correction of hypomagnesemia (range 0.5 to 1 mEq/kg q24h). Toxicity from erroneously administered intravenously magnesium has been reported in one diabetic cat and one dog with acute renal disease.[13] Signs of magnesium toxicity in these animals included vomiting, weakness, generalized flaccid muscle tone, mental dullness, bradycardia, respiratory depression, and hypotension.[13] Care must be taken to administer intravenous magnesium only to patients that have documented decreased iMg concentrations. As the hyperglycemia resolves, the sodium concentration is expected to appear higher secondary to the decrease in osmolality and subsequent movement of free water from the intravascular space. If the hyponatremia and hypochloremia persist, they are corrected by administering a 0.9% saline solution.

Table 67-1 Potassium Supplementation in Hypokalemic Animals*

Serum Potassium Concentration (mmol/L)	Potassium (mEq) Added to 250-ml Fluid Bag
1.6–2	20
2.1–2.5	15
2.6–3	10
3.1–3.5	7

Hyperglycemia is corrected with insulin therapy. Although several new rapid-acting products are being used successfully in humans with DKA, their use in dogs and cats has not yet been investigated. Therefore regular insulin is recommended (Humulin R, Novolin R). Regular insulin is administered as an intravenous CRI (Table 67-2)[14] or intramuscularly .[15] When intravenous regular insulin is administered as a CRI, blood glucose is measured every 2 hours. When insulin is administered intramuscularly, it is given every hour, and blood glucose is measured every hour. The initial dose of intramuscular therapy is 0.2 U/kg regular insulin, followed by 0.1 U/kg regular insulin IM 1 hour later. Treatment with IM regular insulin is continued with 0.05 U/kg/hr, 0.1 U/kg/hr, or 0.2 U/kg/hr if blood glucose drops more by than 75 mg/dl/hr, by between 50 and 75 mg/dl/hr, or by less than 50 mg/dl/hr, respectively.[7]

Acidosis is usually corrected with intravenous fluid administration and insulin therapy alone.[2,4,12] Bicarbonate administration for correction of acidosis in humans with DKA is controversial.[12,16-18] The American Diabetes Association recommends bicarbonate supplementation only in patients with DKA in which arterial pH remains less than 7.0 after 1 hour of fluid therapy.[16] Risks associated with bicarbonate treatment in humans with DKA include exacerbation of hypokalemia, increased hepatic production of ketones, paradoxical cerebrospinal fluid acidosis, cerebral edema, and worsening intracellular acidosis due to increased production of carbon dioxide (also known as paradoxical cerebral acidosis).[12,17,18] Bicarbonate treatment is not needed in most dogs and cats with DKA.[2,4] However, a recent retrospective study of 127 dogs with DKA reported that the degree of acidosis was associated with poor outcome.[2] The same study reported that intravenous sodium bicarbonate therapy was also associated with poor outcome.[2] It is not known if bicarbonate therapy in itself, or the severe degree of acidosis that prompted such therapy, was the cause of poor outcome in dogs treated with bicarbonate.

One bicarbonate treatment protocol is to administer sodium bicarbonate at ½ to ⅓ of (0.3 × body weight × negative base excess) over a 20-minute interval every hour, while monitoring venous pH every hour. However, there are no studies to support this or any other bicarbonate treatment protocol in dogs and cats with DKA. The American Diabetes Association recommends treating pediatric patients with DKA who maintain a pH of less than 7.0 after 1 hour of fluid therapy with 2 mEq/kg sodium bicarbonate added to 0.9% sodium chloride, in a solution that does not exceed 155 mEq/L of sodium, over 1 hour.[16] The pH is monitored every hour and treatment is repeated until pH is 7.0 or greater.[16]

Table 67-2 Administration of IV Insulin in Patients With DKA*

Blood Glucose Concentration (mg/dl)	Fluid Composition	Rate of Administration (ml/hr)
>250	0.9% NaCl	10
200 to 250	0.45% NaCl + 2.5% dextrose	7
150 to 200	0.45% NaCl + 2.5% dextrose	5
100 to 150	0.45% NaCl + 5% dextrose	5
<100	0.45% NaCl + 5% dextrose	Stop fluid administration

DKA, Diabetic ketoacidosis; *IV,* intravenous; *NaCl,* sodium chloride.

Concurrent disease is believed to contribute to DKA. Therefore identification and treatment of concurrent disease are indicated. It is possible that the latter decreases glucagon secretion and contributes to improved diabetic regulation and resolution of DKA.

* Not to exceed 0.5 mEq/kg/hr without electrocardiographic monitoring.

* 2.2 U/kg of regular crystalline insulin added to 250 ml of 0.9 % NaCl solution. The administration set must be flushed with 50 ml of the mixture before administering the solution to the animal.

67.9 OUTCOME

Most dogs and cats (70%) treated for DKA survive to discharge from the hospital.[2,4] Median hospitalization time for dogs and cats with DKA is 6 and 5 days, respectively.[2,4] At least 7% of dogs and up to 40% of cats experience recurring episodes of DKA.[2,4] Dogs with coexisting hyperadrenocorticism are less likely to be discharged from the hospital, and the degree of base deficit in dogs is associated with outcome.[2]

68 Chapter 68 Hyperglycemic Hyperosmolar Syndrome

Amie Koenig, DVM, DACVIM, DACVECC

68.1 KEY POINTS

- Hyperglycemic hyperosmolar syndrome (HHS) is a form of diabetic crisis marked by severe hyperglycemia (>600 mg/dl) and hyperosmolality with no or minimal urine ketones.
- Absence or resistance to insulin and increases in diabetogenic hormone levels stimulate glycogenolysis, and gluconeogenesis, hyperglycemia, osmotic diuresis, and dehydration result.
- Reduction of glomerular filtration rate (GFR) is essential to attain the severe, progressive hyperglycemia associated with HHS.
- Renal failure and congestive heart failure are common concurrent diseases. These likely contribute to HHS via effects on reduction of GFR.
- The most important goals of therapy are to replace fluid deficits and then slowly decrease the glucose concentration, thereby avoiding rapid intracranial shifts in osmolality and preventing cerebral edema. Fluid therapy will start to reduce blood glucose levels via dilution and by increasing GFR and subsequent urinary glucose excretion.
- Prognosis for HHS patients is poor, primarily as a result of concurrent disease.

68.2 INTRODUCTION

Nonketotic HHS is an uncommon form of diabetic crisis marked by severe hyperglycemia (>600 mg/dl), minimal or absent urine ketones, and serum osmolality more than 350 mOsm/kg.[1] Other names for this syndrome include *hyperosmolar hyperglycemic nonketotic state* and *hyperosmolar nonketotic coma*. These terms have been replaced by *hyperglycemic hyperosmolar syndrome* in human medicine to better reflect the variable degrees of ketosis and inconsistent incidence of coma that occur with this syndrome.[2,3] Coma appears to be an uncommon form of this syndrome in animals.

Hyperglycemic Hyperosmolar Syndrome (HHS) is an infrequent, albeit well documented, complication of diabetes mellitus.[4-7] The incidence in human diabetics has been estimated to represent less than 1% of all human diabetic hospital admissions.[3,8,9] In comparison, HHS accounted for 6.4% of total emergency room visits by diabetic cats in one retrospective study.[4] The incidence in dogs is unknown.

This chapter will review the pathogenesis, clinical findings, diagnostic evaluation, and treatment of HHS.

68.3 PATHOGENESIS

Pathogenesis of HHS involves hormonal alterations, reduction of glomerular filtration rate (GFR), and contributions from concurrent disease.

68.3.1 Hormonal Alterations

HHS begins with a relative or absolute lack of insulin coupled with increases in circulating levels of counterregulatory hormones including glucagon, epinephrine, cortisol, and growth hormone. These counterregulatory hormones are elevated in response to an additional stressor, such as concurrent disease. Epinephrine and glucagon inhibit insulin-mediated glucose uptake in muscle and stimulate hepatic glycogenolysis and gluconeogenesis, increasing circulating glucose concentration. Cortisol and growth hormone inhibit insulin activity and potentiate the effects of glucagon and epinephrine on hepatic glycogenolysis and gluconeogenesis. In conjunction with insulin deficiency, increases in the diabetogenic hormones increase protein catabolism, which in turn impairs insulin activity in muscle and provides amino acids for hepatic gluconeogenesis.[10] Pathogenesis of HHS is very similar to that of diabetic ketoacidosis, except that in HHS it is believed that small amounts of insulin and hepatic glucagon resistance inhibit lipolysis, thereby preventing ketosis[3,11,12] and instead promoting HHS. Lower levels of growth hormone have also been documented in patients with HHS.[12,13]

Hyperglycemia is the primary result of these hormonal alterations. It promotes osmotic diuresis, and osmotic diuresis increases the magnitude of the hyperglycemia, thus leading to a vicious circle of progressive dehydration and hyperosmolality. Neurologic signs are thought to develop secondary to cerebral dehydration induced by the severe hyperosmolality. In humans, elevated blood urea nitrogen (BUN) levels, acidemia, elevated sodium concentration and osmolality, but not glucose concentration, are correlated with the severity of neurologic signs.[14]

68.3.2 Reduction of Glomerular Filtration Rate

Osmotic diuresis, additional losses such as via vomiting, and decreased water intake contribute to progressive dehydration, hypovolemia, and ultimately a reduction in the GFR as the syndrome progresses. Severe hyperglycemia can occur only in the presence of reduced GFR, because there is no maximum rate of glucose loss via the kidney.[15,16] That is, all glucose that enters the kidney in excess of the renal threshold will be excreted in the urine. An inverse correlation exists between GFR and serum glucose in diabetic humans.[15] Reductions in GFR increase the magnitude of hyperglycemia, which exacerbates glucosuria and osmotic diuresis. Human HHS survivors have also shown a reduced thirst response to rising vasopressin levels, which may also contribute to dehydration[17] and decreased GFR.

68.3.3 Influence of Concurrent Disease

Concurrent disease is important for initiating the hormonal changes associated with HHS and can also be important for exacerbating hyperglycemia. Diseases that are thought to predispose previously stable diabetics to a diabetic crisis include renal failure, congestive heart failure (CHF), infection, neoplasia, and other endocrinopathies,[1,18] although any disease can occur. Pancreatitis and hepatic disease seemed to be uncommon concurrent diseases in cats with HHS.[4]

Renal failure and CHF also exacerbate the hyperglycemia associated with HHS because of their effects on GFR. Decreased GFR is inherent to renal failure. Inability to concentrate urine provides another source for obligatory diuresis. Myocardial failure, diuretic use, and third spacing of fluids associated with CHF may decrease GFR.

Cardiac medications such as β-blockers and diuretics are also known to alter carbohydrate metabolism, thus predisposing to diabetic crisis.[3]

68.4 HISTORY AND CLINICAL SIGNS

Animals diagnosed with HHS may be previously diagnosed diabetics receiving insulin or may be newly diagnosed at the time HHS is recognized. The most common client complaints are fairly nonspecific and include decreased appetite, lethargy, vomiting, and weakness. Owners may report polyuria, polydipsia, and polyphagia consistent with diabetes, although these clinical signs may have gone unrecognized. History may also reveal recent onset of neurologic signs including circling, pacing, mentation changes, or seizure. Weight loss is an inconsistent finding.

68.5 PHYSICAL EXAMINATION

Vital parameters (temperature, pulse, and respiration) and body weight vary considerably with severity of the syndrome and presence and chronicity of comorbid diseases. Hypothermia is not uncommon as the syndrome progresses. Dehydration, marked by decreased skin turgor, dry or tacky mucous membranes, sunken eyes, and possibly prolonged capillary refill time, are common findings on physical examination. Mentation changes are also common. Most animals are reported as being depressed, but severely affected patients may be obtunded, stuporous, or comatose. Additional neurologic abnormalities including weakness or ataxia, abnormal pupillary light reflexes or other cranial nerve abnormalities, twitching, or seizure activity may be noted. Plantigrade stance, especially in cats, may be present subsequent to unregulated diabetes mellitus.

Other findings in patients with HHS are dependent on coexisting diseases. Animals should be examined closely for signs of heart disease which may include any of the following: heart murmur, gallop, bradycardia, tachycardia or other arrhythmias, dull lung sounds, crackles, increased respiratory rate and effort, pallor, prolonged capillary refill time, and decreased blood pressure. Increased respiratory rate and effort may suggest cardiac failure but could also be secondary to infection, hyperosmolality, acidosis, asthma, or neoplasia. Animals with renal failure may have kidneys of abnormal size, oral ulceration, and pallor from anemia and may smell of uremia.

68.6 DIAGNOSTIC CRITERIA

The standard criteria for diagnosis of HHS in veterinary medicine are a serum glucose concentration greater than 292 600 mg/dl, absence of urine ketones, and serum osmolality greater than 350 mOsm/kg.[1] In humans, the criteria for 293 diagnosis of HHS require a serum glucose greater than 600 mg/dl, arterial pH over 7.3, serum bicarbonate greater than 15 mmol/L, effective serum osmolality greater than 320 mOsm/kg, and anion gap less than 12 mmol/L. In addition, humans with HHS may have small quantities of urine and serum ketones, measured by the nitroprusside method.[2,3]

Glucose concentrations can reach 1600 mg/dl in severely affected animals.[1] Blood glucose concentration may exceed the readable range on patient-side analyzers. Clinical suspicion for HHS should remain high in this situation and additional diagnostic methods should be instituted to better define the severity of hyperglycemia, state of diabetes, and presence of coexisting diseases. Measuring glucose is also vital to rule out hypoglycemia as a cause of neurologic signs.

Osmolality measured by freezing point depression is not a commonly available patient-side test. Estimated serum osmolality can be calculated using the following formula[19]:

$$\text{Serum osm}_{(\text{cak})} = 2(\text{Na}^{+} + \text{K}^{+}) + (\text{BUN} \div 2.8) + (\text{glucose} \div 18)$$

BUN and glucose are measured in mg/dl.

Because BUN equilibrates readily across cell membranes and effects of potassium on osmolality are small, calculating effective osmolality may be a better estimate[19]:

$$\text{Effective osm} = 2(\text{Na}^{+}) + (\text{glucose} \div 18)$$

BUN and glucose measured in mg/dl.

Normal serum osmolality is 290 to 310 mOsm/kg. Neurologic signs have been documented in animals when osmolality exceeds 340 mOsm/kg[20] (Box 68-1).

Urine ketones can be assessed quickly using urine dipsticks. If urine is not available, serum ketones may be assessed by placing a few drops of serum on urine dipsticks.

68.6.1 Additional Diagnostic Evaluation

Additional diagnostic parameters, including serum chemistry analysis (with precise glucose measurement), complete blood count, urinalysis, urine culture, and (venous) blood gas, should be pursued in patients with confirmed or suspected HHS. Blood cell count abnormalities are varied and nonspecific. The packed cell volume and total solids level may be high secondary to dehydration. Chemistry abnormalities are dependent on degree of dehydration and presence of underlying disease. The most common biochemical abnormalities in cats with HHS include azotemia, hyperphosphatemia, elevated aspartate transaminase, acidosis, elevated lactate concentration, and hypochloremia.[4] Azotemia may be prerenal or renal in origin.

68.6.1.1 Box 68-1 Important Calculations

Dehydration deficit:

Fluid deficit (ml) = body wt (kg) × % dehydration (as decimal) × 1000 (ml/L)

Osmolality:

$$\text{Serum osm}_{(\text{calc})} = 2(\text{Na}^{+} + \text{K}^{+}) + (\text{BUN} \div 2.8) + (\text{glucose} \div 18)$$

Effective osmolality:

$$\text{Effective osm} = 2(\text{Na}^{+}) + (\text{glucose} \div 18)$$

Corrected sodium:

$$\mathrm{Na}^{+}_{(\mathrm{corr})} = \mathrm{Na}^{+}_{(\mathrm{measured})} + 1.6([\text{measured glucose} - \text{normal glucose}] \div 100)$$

BUN, Blood urea nitrogen; *K^+,* potassium; *Na^+,* sodium; *osm,* osmolality. BUN and glucose measured in mg/dl.

Venous blood gas analysis should be used to assess the degree of acidemia. It is not possible to differentiate HHS from DKA in cats based on the degree of metabolic acidosis.[4] In HHS, metabolic acidosis is caused by accumulation of uremic acids and lactic acid, rather than ketones. Lactic acidosis is an indicator of poor tissue perfusion secondary to dehydration and hypovolemia.

Serum electrolytes should be monitored to help in choosing fluid therapy and to calculate the osmolality. Sodium concentration is the prime determinate of serum osmolality. In HHS, the true magnitude of sodium concentration will be masked by the hyperglycemia. Measured serum sodium is reduced by hyperglycemia-induced osmotic pull of water into the vasculature.[21]

Sodium level should be expected to rise as glucose levels return to normal. Calculating the corrected serum sodium value can give a better indication of severity of free water loss (see Box 68-1). For every 100 mg/dl increase in glucose above normal, the measured serum sodium decreases by 1.6 mEq/dl.[21] A corrected serum sodium level can be calculated using the following formula:

$$\mathrm{Na}^{+}_{(\mathrm{corr})} = \mathrm{Na}^{+}_{(\mathrm{measured})} + 1.6([\text{measured glucose} - \text{normal glucose}] \div 100)$$

Animals in diabetic crisis are classically expected to have low total body potassium concentrations,[1] although cats with HHS tend to have a normal serum potassium concentration.[4] Potassium losses are expected via diuresis, vomiting, and decreased intake; increases in potassium may occur secondary to acidosis, severe hyperosmolality,[22] insulin deficiency, and poor renal perfusion. Potassium levels are expected to decrease as acidosis improves and with insulin-induced cotransport of glucose and potassium into cells.

A thorough search for underlying disease should be undertaken in all patients with HHS. Additional diagnostic techniques including thoracic and abdominal radiographs, abdominal ultrasonography, echocardiogram, retroviral testing (cats), and endocrine testing (especially thyroid hormone levels in cats) may be indicated based on historical or physical findings or results of preliminary diagnostic results.

68.7 TREATMENT

Goals of therapy for patients with HHS include replacing the fluid deficit, slowly reducing serum glucose levels, addressing electrolyte abnormalities, and treating concurrent disease.[2]

To prevent exacerbation of neurologic signs, it is important not to lower the serum glucose or sodium too rapidly. Hyperosmolality induces formation of osmotically active idiogenic osmoles in the brain. These idiogenic osmoles protect against cerebral dehydration by preventing movement of water from the brain into the hyperosmolar blood.

Because idiogenic osmoles are eliminated slowly, rapid reduction of serum osmolality establishes an osmotic gradient across the blood-brain barrier, leading to cerebral edema and neurologic signs.[23]

The first goal of therapy is to replace dehydration deficits slowly using an isotonic crystalloid solution. Initially, 0.9% sodium chloride solution is the fluid of choice, because it will both address the fluid deficits and replace glucose with sodium in the extracellular space, thus preventing a rapid shift in osmolality. Hypernatremia should be corrected slowly with a decrease of no more than 1 mEq/L/hr.[24]

The fluid therapy plan should include dehydration deficit, ongoing losses and maintenance fluid needs (see Box 68-1). Fluid deficit (in ml) should be calculated by multiplying body wt (kg) × % dehydration (expressed as decimal) × 1000 (ml/L). On its own, fluid therapy will start to reduce blood glucose levels via dilution and by increasing GFR and subsequent urinary glucose excretion.[25] Ideally, the dehydration deficit should be replaced over 24 hours. Treating a patient with HHS and concurrent CHF presents a dilemma. Even maintenance amounts of parenteral fluids could be detrimental, so rehydration must be done more slowly and with care. Forced enteral fluid supplementation, as via a nasoesophageal tube, may be a viable option to aid in rehydration of some patients with CHF that are not vomiting.

Insulin should not be given until the hypovolemia and dehydration have improved. Unlike in DKA where insulin therapy is vital because of its role in reducing ketogenesis, insulin therapy is not as critical for resolution of HHS, because much of the syndrome can be improved just by correcting fluid deficit. Mechanics of insulin therapy for HHS are similar to those used in DKA, with protocol changes designed to lower the glucose levels more slowly. Using regular insulin as part of either intramuscular or intravenous protocols, at dosages 50% of those used for DKA, should prevent rapid decline in serum glucose.[1] Insulin therapy should be instituted after a minimum of 4 to 6 hours of fluid therapy and only if the potassium is at least 3.5 mmol/L. Intravenous constant rate infusion of 0.025 to 0.05 U/kg/hr can be made by adding 0.5 U/kg (cat) to 1 U/kg (dog) regular insulin to 250 ml 0.9% sodium chloride; the resulting solution should be started at 10 ml/hr via a dedicated intravenous line. For the intramuscular protocol, 0.1 U/kg of regular insulin should be given, followed by 0.05 U/kg q1-2h until the glucose is less than 300 mg/dl, then q4-6h. With both protocols, the goal is to decrease the glucose levels by no more than 50 to 75 mg/dl/hr.[2,26] If the glucose is dropping too rapidly, the insulin dosage should be decreased by 25% to 50%. If the glucose is less than 250 to 300 mg/dl, 5% dextrose should be added to the fluids. Regular insulin should be continued until the animal is eating. Once the animal is eating and drinking, long-acting insulin therapy, dietary management, and monitoring should be started as for a standard diabetic. Vigilant therapy and careful monitoring of concurrent diseases are essential.

68.8 MONITORING

Glucose should initially be measured every 1 to 2 hours, and ketones should be checked daily. Serial neurologic examinations should be performed to monitor for signs of cerebral edema. Potassium, phosphorus, and magnesium levels should be monitored at least once daily and supplemented in fluids as needed. Electrocardiogram, blood pressure, and central venous pressure may be helpful in monitoring patients with HHS. Multilumen central venous catheters will facilitate glucose and central venous pressure monitoring and administration of multiple infusions.

68.9 PROGNOSIS

The mortality rate for patients with HHS is high because of the severity of the syndrome as well as presence of concurrent disease. In humans, the mortality rate is consistently 15% to 17% of HHS admissions, and many outcome predictors have been identified.[14,27-29] There are no clear predictors of survival from HHS for animals. In one feline study, in-hospital mortality was 64.7% and long-term (>2 month) survival was only 12%.[4] Outcome was not predicted by presence of neurologic signs, serum glucose concentration, measured serum sodium concentration, corrected serum sodium concentration, or total and effective serum osmolality. Long-term survivors had curable concurrent diseases.

69 Chapter 69 Hypoglycemia

Amie Koenig, DVM, BS, DACVIM, DACVECC

69.1 KEY POINTS

- Normoglycemia is maintained by a balance between the glucose-lowering hormone insulin and glucose-elevating hormones glucagon, cortisol, epinephrine, and growth hormone.
- Hypoglycemia occurs via one of several mechanisms: inadequate dietary intake, excessive glucose utilization, dysfunctional glycogenolytic or gluconeogenic pathways or inadequate precursors for these pathways, or endocrine abnormalities.
- The most common causes of hypoglycemia include exogenous insulin overdose, hypoglycemia of puppies and toy breeds, sepsis, insulinoma and other insulin analog-secreting tumors, hypoadrenocorticism, and severe liver disease.
- Neuroglycopenia causes alterations in mentation, seizures, blindness or alterations in vision, somnolence, and weakness or ataxia.
- Adrenergic stimulation in response to declining blood glucose accounts for other common clinical signs of restlessness, anxiety, tachypnea, vomiting or diarrhea, and trembling.
- In hypoglycemic crises, parenteral dextrose administration is the most effective therapy. Food should be offered as soon as possible. Glucagon infusion may be used for cases of intractable hypoglycemia secondary to insulinoma or insulin analog-secreting neoplasms.

69.2 INTRODUCTION

Euglycemia is maintained by a balance of glucose production, storage, and release from storage forms. Many disease processes can interfere with normal glucose homeostasis and lead to hypoglycemia. This chapter will review normal glucose homeostatic mechanisms, clinical signs and causes of hypoglycemia, and treatment of a hypoglycemic crisis.

69.3 NORMAL GLUCOSE HOMEOSTASIS

Glucose comes from three sources: (1) intestinal absorption of glucose from digestion of carbohydrates; (2) breakdown of the storage form of glucose (glycogen) via glycogenolysis; and (3) production of glucose from precursors lactate, pyruvate, amino acids, and glycerol via gluconeogenesis. Glucose homeostasis is maintained by a balance between the glucose-lowering hormone insulin and glucose-elevating hormones, primarily glucagon, epinephrine, cortisol, and growth hormone.

Insulin is secreted by β-cells of the pancreas in response to the rising concentrations of glucose, amino acids, and gastrointestinal (GI) hormones (gastrin, secretin, cholecystokinin, and gastric inhibitory peptide) present after a meal.[1] Insulin inhibits gluconeogenesis and glycogenolysis, promotes glycogen storage, stimulates glucose uptake and utilization by insulin-sensitive cells, and decreases glucagon secretion. Insulin also promotes triglyceride formation in adipose tissue and the synthesis of protein and glycogen in muscle. Decreased levels of insulin stimulate gluconeogenesis and reduce glucose used by peripheral tissues.

As blood glucose concentrations fall, the counter-regulatory hormones glucagon, epinephrine, cortisol, and growth hormone are released. Both glucagon and epinephrine levels rise within minutes of hypoglycemia and have a transient effect on increasing glucose production; they subsequently support basal rates of glucose production.[2] Cortisol and growth hormone are released after a few hours, but their effects are also longer lasting.

Glucagon is secreted from pancreatic α-cells. It acts on the liver to stimulate glycogenolysis and, to a lesser extent, gluconeogenesis, thereby increasing hepatic glucose production. This is transient, however, and glucose production quickly declines toward basal rates as increasing levels of insulin counteract the effects of glucagon. Glucagon directly stimulates hepatic glycogenolysis and gluconeogenesis, mobilizes gluconeogenic precursors, and reduces peripheral glucose utilization. Epinephrine limits insulin secretion and increases glucagon secretion. Cortisol increases glucose-facilitating lipolysis and release of amino acids from muscle for gluconeogenesis in the liver. Growth hormone antagonizes effects of insulin by decreasing peripheral glucose utilization and promoting lipolysis.

Hypoglycemia results when glucose utilization exceeds glucose entry into circulation. General mechanisms of hypoglycemia include: (1) inadequate dietary intake, (2) excessive glucose utilization, (3) dysfunctional glycogenolytic or gluconeogenic pathways or inadequate precursors for these pathways, and (4) endocrine abnormalities. On its own accord, inadequate dietary intake is unlikely to cause hypoglycemia, because gluconeogenic and glycolytic pathways dominate during periods of fast. In most animals, a concurrent defect in one of the other mechanisms is required.

69.4 CLINICAL SIGNS AND CONSEQUENCES OF HYPOGLYCEMIA

Glucose is an obligate energy source for the brain. The brain has limited ability to use other substrates, can store minimal amounts of glycogen, and cannot manufacture glucose; therefore the brain relies on a constant stream of glucose for its energy needs.[3] Glucose enters the brain by facilitated diffusion. Adequate arterial glucose concentration is essential to maintaining a diffusion gradient. Because brain cells rely so heavily on glucose for 295 energy, neuroglycopenia, or hypoglycemia of the central nervous system (CNS), results primarily in 296 neurologic signs. The degree, rate of decline, and duration of hypoglycemia all contribute to type and severity of symptoms.

Neuroglycopenic signs occur as a direct result of CNS hypoglycemia. These include altered mentation or dullness, sleepiness, weakness or recumbency, ataxia, blindness or altered vision, and seizures.[2,4] Prolonged neuroglycopenia can lead to permanent brain injury and neurologic signs, especially blindness, that persist beyond resolution of the hypoglycemia. Neurogenic signs result from activation of the adrenergic system in response to the hypoglycemia. Humans describe being hungry, a tingling sensation, tremors or shakiness, a pounding heart, and anxiety or nervousness.[2] Similar signs noted in hypoglycemic dogs and cats include anxiety manifest as pacing, vocalizing or restlessness, and shaking or trembling.[4] Vomiting, anorexia, panting or tachypnea, diarrhea, and urination have been noted in hypoglycemic dogs and cats. Bradycardia and circulatory collapse have also been documented.[5] Signs may be episodic. Some animals, especially those with prolonged hypoglycemia, demonstrate no associated signs.[4] This hypoglycemia unawareness may occur in patients whose brains are induced by chronic or recurrent hypoglycemia to upregulate cerebral glucose uptake, thereby decreasing the perception of peripheral hypoglycemia by the brain.[3]

69.5 DIAGNOSIS OF HYPOGLYCEMIA

By definition, hypoglycemia is diagnosed by a blood glucose level of 60 mg/dl or less, although clinical signs often do not develop until the level is less than 50 mg/dl. Whipple's triad provides guidelines for identifying hypoglycemia: clinical signs consistent with hypoglycemia, a low blood glucose level, and abatement of signs with correction of the hypoglycemia.[2]

Hand-held glucometers tend to underestimate serum glucose.[6] Low glucose values obtained on a hand-held glucometer should be confirmed via other methods. Falsely low glucose values, or pseudohypoglycemia, can be obtained if the serum is not separated from the red blood cells within 30 minutes of collection, because the red blood cells continue to consume glucose for glycolysis.[7] If centrifugation and serum separation must be delayed longer than 30 minutes, collection in a sodium fluoride tube will arrest glycolysis.

Once hypoglycemia is identified, additional diagnostic modalities may be indicated to identify its etiology. Complete blood cell count, serum chemistry analysis, urinalysis, chest and abdominal radiographs, abdominal ultrasonography, insulin levels, and other endocrine testing may be indicated.

69.6 CAUSES OF HYPOGLYCEMIA

Many causes of hypoglycemia (Box 69-1) fall into the categories of excess insulin or insulin analog, inadequate glucose production, and excess cellular glucose consumption.

69.6.1 Excess Insulin or Insulin Analogs

69.6.1.1 Exogenous Insulin Overdose

Exogenous insulin overdose is possible in any animal receiving insulin therapy, whether for diabetes mellitus or for treatment of other disorders such as hyperkalemia or calcium channel blocker overdose. Insulin overdoses in diabetic animals occur more commonly in cats than dogs, in obese animals, and in cats receiving more than 6 units of insulin per injection.[4]

Anorexic or hyporexic diabetics receiving insulin are also at risk. Clinical signs are consistent with hypoglycemia. Treatment includes discontinuation of insulin therapy, feeding the animal as soon as possible, and administration of intravenous dextrose if the animal is too severely affected to eat. Duration of the hypoglycemia varies and is not necessarily dependent on the amount and type of insulin that caused the overdose.[4] Once the animal is stabilized and eating, the dextrose infusion can be tapered off while blood glucose levels continue to be monitored.

Some diabetic animals may not need insulin for several days, and others will become hyperglycemic more quickly. The animal should be monitored for onset of polyuria and polydipsia and hyperglycemia to verify need for insulin. Remission in transiently diabetic cats may be marked by a hypoglycemic episode. Once the need to restart insulin is confirmed, it is prudent to reduce the dosage by 25% to 50% initially and follow up with normal diabetic monitoring to attempt regulation.[8,9] There may be another underlying problem that predisposed the animal to hypoglycemia, and additional workup is warranted if hypoglycemia is ongoing or if the animal has additional history or signs unrelated to hypoglycemia.

69.6.1.1.1.4

Decreased Glucose Production

- Neonatal hypoglycemia
- Hepatic dysfunction
  - Portosystemic shunt
  - Inflammatory or infectious hepatitis
  - Hepatic lipidosis
  - Cirrhosis
  - Neoplasia
  - Glycogen storage disease
- Hypocortisolism
- Counterregulatory hormone deficiencies
  - Glucagon, growth hormone
  - Thyroid hormone, catecholamines

- Hypopituitarism

Glycogenic or gluconeogenic enzyme deficiencies

β-Blockers

*Cause of apparent, not true, hypoglycemia.

69.6.1.2 Insulinoma

Insulinomas are insulin-secreting, usually malignant, tumors of the pancreas. They are described more commonly in middle-aged to older dogs than in cats.[9–14] Patients often exhibit weakness or collapse, and severe hypoglycemia is an unexpected and isolated finding. Other clinical pathology data are generally unremarkable. Diagnosis is made by evaluating blood insulin concentration on a sample taken during an episode of hypoglycemia. High or sometimes normal insulin levels in the face of hypoglycemia is indicative of insulinoma. Some animals will have intermittent episodes of hypoglycemia and hyperinsulinemia that may require a supervised fast or multiple samples to identify.[15] Low fructosamine values may also lend support to a diagnosis.[16] If insulin levels are equivocal, an amended insulin-to-glucose ratio (AIGR) can be calculated.

$$\text{AIGR} = (\text{insulin} \times 100) \div (\text{plasma glucose} - 30).$$

A denominator of 1 is used if the plasma glucose is less than 30 mg/dl. An AIGR over 30 suggests insulinoma,[17] although is not definitive.[9] Abdominal ultrasonography may or may not reveal a mass or nodule in the pancreas. Computed tomography, scintigraphy, and surgical exploration are other options for attempted localization of insulinoma.[9,18–20]

Emergency treatment for symptomatic hypoglycemia is outlined below. The treatment of choice for insulinoma is surgical excision. Medical options for animals not undergoing surgery or for those with metastatic disease and persistent hypoglycemia include small frequent feedings of a food low in simple sugars and glucocorticoids (prednisone 0.5 to 1 mg/kg in divided doses PO q12 h[21]). Higher doses of glucocorticoids and diazoxide (10 mg/kg initially up to 60 mg/kg, divided q12 h[21]), which directly inhibits pancreatic insulin secretion, can be used in patients with refractory disease. Other adjunctive therapies include streptozocin[22] (which selectively destroys pancreatic β-cells), somatostatin analogs such as octreotide[23,24] (which suppress synthesis and secretion of insulin), or alloxan (a β-cell cytotoxin).[9]

Prognosis is guarded and depends on the extent of both disease and treatment. In one study, median survival time was 74 days for dogs with medical treatment only, and 381 days for dogs undergoing surgery.[25] In another study, median survival time was 18 months for dogs with disease confined to the pancreas and local lymph nodes, and less than 6 months for dogs with distant metastases.[10] Nelson and Feldman reported that 10% to 15% of dogs undergoing surgery died or were euthanized within 1 month of surgery, 25% died within 6 months, and 60% to 70% lived more than 6 months, with many living longer than 1 year and some even longer than 2 years.[9]

69.6.1.3 Paraneoplastic Hypoglycemia

Although any tumor can be associated with hypoglycemia, the most commonly described non–β-cell neoplasms associated with hypoglycemia include hepatomas and hepatocellular carcinoma, leiomyomas and leiomyosarcomas, and other carcinomas or adenocarcinomas (especially those of pulmonary, mammary, and salivary origin),[26] lymphoma, plasmacytoid tumors, oral melanoma, and hemangiosarcoma. Neoplasia can cause hypoglycemia via secretion of insulin or insulin-like peptides, accelerated consumption of glucose by the tumor cells, or by failure of glycogenolysis or gluconeogenesis by the liver. Historical and clinical findings and treatment are consistent with the specific tumor.

69.6.1.4 Toxins and Medications

Certain toxins have been associated with hypoglycemia in dogs and cats. Excessive dosages of oral glucose-lowering agents such as the sulfonylurea drugs chlorpropamide and glipizide may cause hypoglycemia. These drugs are thought to stimulate insulin secretion from the pancreas, enhance tissue sensitivity to insulin, and decrease basal hepatic glucose production.[21] Xylitol-sweetened products, such as sugar-free gum, can cause hypoglycemia in dogs via its stimulation of insulin release from β-cells.[27] β-Blockers, such as atenolol, are also thought to contribute to hypoglycemia via interference with adrenergic counterregulatory mechanisms.

A history of exposure or known ingestion coupled with consistent signs or low blood glucose levels would substantiate the diagnosis. In addition to treating hypoglycemia, induced emesis and activated charcoal administration may be indicated if the ingestion is identified early and the patient is not clinically impaired by hypoglycemia (see Chapter 77, Approach to Poisoning and Drug Overdose).

69.6.2 Inadequate Glucose Production

69.6.2.1 Hypoglycemia of Puppies and Toy Breeds

Most commonly, hypoglycemia of neonatal and pediatric animals stems from inadequate substrate for glycolysis or gluconeogenesis. Glycogen stores are small and easily depleted in the face of inadequate food intake. Hepatic enzyme systems may also be immature.[28] Additionally, the brain accounts for most of the basal metabolic rate in the neonate, thus contributing to the frequent development of hypoglycemia in the young. In the nursing puppy, factors predisposing to hypoglycemia include premature birth, debilitation of the bitch at parturition, being the runt of the litter, and diabetes in the bitch.[28] Toy or small breed dogs are also at risk. In the weaned puppy, factors predisposing to hypoglycemia include concurrent infection, vaccinations, vigorous exercise, GI upset, hypothermia, poor nutrition, and extended fast.[28] Most puppies and toy breeds respond readily to supplementation and increased feeding frequency. Recurrent or persistent hypoglycemia warrants further investigation. Other differentials for hypoglycemia that must be considered in a hypoglycemic puppy or kitten include portosystemic shunt or other hepatic disease, sepsis, glycogen storage disease, and counterregulatory hormone deficiency.

69.6.2.2 Hepatic Disease

Portosystemic shunt, glycogen storage disease, severe inflammatory or infectious hepatitis, hepatic lipidosis, cirrhosis, and hepatic neoplasia are specific etiologies of hepatic failure that can lead to hypoglycemia via dysfunctional glycogen storage, glycogenolytic, and gluconeogenic capabilities. Euglycemia usually is maintained until late in the course of hepatic disease until approximately 70% of hepatic function is lost.[7] Patients with portosystemic shunt and glycogen storage disease are usually young and may be small or unthrifty. Evaluation of an animal with severe liver disease may reveal a poor body condition score, microhepatica or enlarged liver, icterus, ascites, melena, vomiting, diarrhea, anorexia, or signs of hepatic encephalopathy such as depression or seizures. Clinical pathology data may show hypoalbuminemia, low blood urea nitrogen, hypocholesterolemia, hyperbilirubinemia, elevated liver enzyme activities, and low urine specific gravity (see Chapters 126, 127, and 146, Hepatitis and Cholangiohepatitis, Hepatic Failure, and Portosystemic Shunt Management, respectively).

297
298

69.6.2.3 Hypocortisolism and Other Counterregulatory Hormone Deficiencies

Hypoadrenocorticism, specifically hypocortisolism, may lead to hypoglycemia via loss of cortisol-induced counter-regulatory mechanisms. History may include anorexia, vomiting, diarrhea, melena or hematochezia, weakness, and possibly polyuria and polydipsia. Physical examination may reveal dehydration, bradycardia, muffled heart sounds, poor pulse quality, hypotension, and shock. Clinical pathology evaluation may reveal lack of stress leukogram, azotemia, hypercalcemia, hyponatremia, hypochloremia, and hyperkalemia. Confirmation of hypocortisolism is via the adrenocorticotropic hormone stimulation test. Treatment includes physiologic doses of glucocorticoids, and either fludrocortisone acetate (Florinef) or desoxycorticosterone pivalate if mineralocorticoids are also deficient. Fluid therapy is required in Addisonian crisis (see Chapter 76, Hypoadrenocorticism).

Deficiencies in other hormones such as glucagon, growth hormone, thyroid hormone, and catecholamines can all lead to hypoglycemia due to interference with counterregulatory mechanisms designed to prevent hypoglycemia. These occur uncommonly.

69.6.3 Excess Glucose Utilization

Infection, extreme exercise, polycythemia or leukocytosis, and pregnancy can all lead to excessive cellular glucose consumption.

69.6.3.1 Infection

Sepsis is a common cause of hypoglycemia. Decreased intake, decreased hepatic function and, most significantly, non–insulin-mediated increased consumption play a role in sepsis-induced hypoglycemia. Increased glucose consumption is believed to be induced by inflammatory mediators, such as tumor necrosis factor, especially in macrophage-rich tissues such as the spleen, liver, and lungs.[29] Hypotension or hypoxemia may also induce excess glucose consumption via increases in anaerobic glycolysis.

Patients with sepsis will be extremely ill. Vasodilatory shock may be evident by injected mucous membranes and hypotension. Other clinical signs will depend on the type and location of infection. A complete workup and blood cultures are indicated (see Chapters 106 and 107, Sepsis and Septic Shock, respectively). Canine babesiosis is an infection specifically associated with hypoglycemia.[30,31] Hypoglycemia at admission is a poor prognostic indicator in canine babesiosis and may occur secondary to the same mechanisms as bacterial sepsis or by consumption of glucose by the parasites.

69.6.3.2 Exercise-Induced Hypoglycemia

Exercise-induced hypoglycemia, also called *hunting dog hypoglycemia,* is generally seen in lean hunting or working dogs engaging in vigorous exercise. Glucose utilization by muscle markedly increases during exercise and endogenous glucose production, via glycolysis and gluconeogenesis, increases to meet this demand.[2] This form of hypoglycemia is believed to occur secondary to glycogen depletion in the face of increased glucose utilization. Affected animals should be fed small amounts frequently during exercise or should discontinue working if hypoglycemia continues.

69.6.3.3 Polycythemia and Leukocytosis

Hypoglycemia in polycythemia occurs secondary to increased metabolism of glucose by the large red blood cell mass.[7] Massive leukocytosis can have the same effect.

69.7 TREATMENT OF HYPOGLYCEMIC CRISIS

Initial treatment for a symptomatic hypoglycemic patient, regardless of etiology, is usually intravenous dextrose. A bolus of 1 ml/kg of 50% dextrose (0.5 g/kg) can be diluted 1:2 to 1:4 and is then given intravenously over 5 minutes. This solution is hypertonic and can cause phlebitis. In the absence of intravenous access, such as in the home setting, Karo syrup, pancake syrup, or honey can be applied to the oral mucous membranes.

Marked improvements in neuroglycopenic signs usually are seen within 1 to 2 minutes of supplementation. If the patient is alert and it is not contraindicated, the animal should be offered small frequent meals that are low in simple sugars. Otherwise, a constant rate infusion (CRI) of 2.5% to 5% dextrose should be administered until the cause of the hypoglycemia is identified and resolved. Dextrose infusions should be formulated by adding the appropriate amount of 50% dextrose to an isotonic fluid such as lactated Ringer's solution or 0.9% saline. Dextrose 5% in water should not be used as the sole fluid for hypoglycemia treatment, because it can result in severe, possibly life-threatening electrolyte abnormalities. Blood glucose should be monitored frequently to assess response to therapy. If a solution containing greater than 5% dextrose is needed to maintain blood glucose concentrations, it should be administered via a central line.

Care should be taken using intravenous dextrose in animals with suspected insulinoma or other tumors secreting insulin-like analogs. In these patients, a bolus of intravenous dextrose can stimulate release of even more insulin from the tumor, leading to a vicious cycle of dextrose infusion followed by rebound hypoglycemia. Additionally, hyperinsulinemia has been shown to depress glucagon secretion in humans, thus removing one of the counterregulatory mechanisms vital to maintaining euglycemia.[32] Glucagon CRI is another option for treating animals with insulin or insulin-like peptide-secreting tumors that are in a hypoglycemic crisis.[33] Glucagon is reconstituted according the manufacturer's instructions and diluted in 0.9% saline. This resulting 1000 ng/ml solution is first administered as a bolus of 50 ng/kg followed by a CRI of 5 to 40 ng/kg/min,[21] the lowest rate necessary to maintain low normal euglycemia.

70 Chapter 70 Diabetes Insipidus

Richard E Goldstein, DVM, DACVIM, DECVIM-CA

70.1 KEY POINTS

- Diabetes insipidus results from a lack of secretion of or a lack of an appropriate renal response to a hormone known as *vasopressin* or *antidiuretic hormone*.
- Primary diabetes insipidus is most commonly acquired and central in origin. Common causes include trauma and intracranial masses.
- Secondary diabetes insipidus is usually renal in origin. Common causes include hypercalcemia, gram-negative sepsis, and severe hypokalemia.
- The manifestation of diabetes insipidus that requires emergency intervention is severe hypernatremia and dehydration caused by urinary free water losses without appropriate intake.
- The water deprivation test does provide valuable diagnostic information and can be dangerous, resulting in severe dehydration and hypernatremia.

70.2 INTRODUCTION

By definition diabetes *insipidus* is the tasteless or nonsweet diabetes. This differentiates it, of course, from the sweet diabetes, the better known diabetes *mellitus*. Diabetes insipidus is caused by a lack of the hormone vasopressin (otherwise known as *antidiuretic hormone* or *ADH*), a lack of renal receptors to vasopressin, or an inability of those receptors to respond to vasopressin. The presence of vasopressin and its ability to activate renal receptors are crucial to the kidneys' urine concentration capabilities. Vasopressin is a nonapeptide (nine amino acids) composed of six amino acids in a disulfide ring and three amino acids in a tail. In small animals the eighth amino acid in vasopressin is arginine, sometimes also called *AVP* or *arginine vasopressin*. [1]

70.2.1 Urine Concentration Mechanism

In a normally functioning kidney, as the solute within the tubule travels through the thick ascending loop of Henle, sodium (and subsequently chloride) is extracted by an energy-requiring ion pump from the solute in an area that is impermeable to water. This unusual feat renders the remaining solute hyposthenuric, or of lower osmolality than serum. The final urine concentration then depends on the presence and function of vasopressin. When the presence and/or function of vasopressin is lacking (diabetes insipidus), the final urine concentration will remain hyposthenuric, or perhaps isosthenuric or mildly hypersthenuric with partial disease.

70.2.2 Vasopressin Secretion and Sodium Homeostasis

Whole body water and sodium concentrations are kept constant despite a huge variability in dietary sodium intake and hydration status. Much of this control is due to vasopressin release from the neurohypothesis. The neurohypothesis consists of hypothalamic nuclei that secrete oxytocin and vasopressin. Following the nuclear synthesis of these hormones they are transported in their axons and finally secreted from the termini in the posterior lobe of the pituitary gland. Important stimuli for vasopressin release include low arterial blood pressure sensed by low-pressure receptors located in the heart and arterial vasculature, increased osmolality as sensed by central nervous system osmoreceptors, and increased angiotensin II levels.[2]

70.2.3 Antidiuretic Effects of Vasopressin

The antidiuretic effects of vasopressin occur in response to the binding of vasopressin to its receptor on the cells of the distal tubule and collecting duct. These are V_2 cyclic adenosine monophosphate-dependent receptors, which when activated cause an increase in water permeability of the luminal membrane by the insertion of aquaporin-2 water channels in the apical membrane of the renal epithelial cells. This allows a more rapid passive flow of water from the lumen through the epithelial cells and into the solute rich, concentrated interstitium, causing a rapid and marked increase in osmolality within the tubular lumen.[3] Theoretically the maximum urine concentration of a given animal would be equal to the maximum solute concentration of the medullary interstitium. Thus in times of hypernatremia due to excess salt intake or, more commonly, free water loss, resulting in a free water deficit or a hyperosmolar contraction of the extracellular space, the secretion of vasopressin causes an increase of water reabsorption from the kidney, a decrease in water excretion, and the normalization of sodium concentration.

70.3 CENTRAL DIABETES INSIPIDUS

Central diabetes insipidus (CDI) is the most common primary cause of diabetes insipidus. It is caused by a complete or partial lack of secretion of vasopressin from the axon termini in the anterior lobe of the pituitary gland. Documented causes of CDI in small animals include neoplastic, traumatic, inflammatory, congenital, and idiopathic conditions.[4,5] Glucocorticoid administration is thought to decrease vasopressin release in dogs, and therefore can be included in the causes of canine acquired CDI.[1]

In humans CDI is associated most commonly with brain surgery, trauma, and immune-mediated disease. Neoplasia, infectious disease, and hereditary disorders are also relatively common in this population.[6] Following brain trauma, at least 25% of long-term survivors suffer from what is defined in humans as *posttraumatic hypopituitarism.* [7] This syndrome most often includes suppression of hormone release from the anterior pituitary gland, but can also include decreased vasopressin secretion from the posterior pituitary gland. Posttraumatic CDI is thought to resolve within a few days in most human cases[8] but may also be a sign of permanent or late brain damage. Postsurgical CDI may be the most common cause in humans. As intracranial surgery, including hypophysectomies, and better care of head trauma become more and more common in small animal practice, veterinary intensive care units will likely experience more of these cases, as well. In humans pituitary gland radiation therapy can cause long-lasting pituitary gland damage with hormonal deficiencies. Interestingly, these rarely, if ever, include CDI. In dogs, there are no large case series reporting the most common causes of CDI. Documented causes have included traumatic,[9] neoplastic, and idiopathic conditions[4] and have occurred secondary to iatrogenic steroid administration or hyperadrenocorticism.[1]

70.4 NEPHROGENIC DIABETES INSIPIDUS

Nephrogenic diabetes insipidus (NDI) is caused by the failure of the kidney to respond to vasopressin. It is commonly divided into primary and secondary causes. Although primary NDI is uncommon and often congenital, secondary NDI is extremely common and likely the most common cause of diabetes insipidus seen in veterinary practice and intensive care units.

Primary NDI is most often hereditary in humans. Early diagnosis of this condition in humans through genetic screening has allowed for better care and increased survival. Most humans with congenital NDI have the X-linked form, causing the disease to manifest almost exclusively in male children.[10] In small animal patients primary or congenital NDI has been documented in a few rare reports in young dogs, never in cats. The canine reports included a Miniature Poodle, a German Shepherd, and a family of Huskies.[1]

By far the more common form of NDI in human[11] and veterinary patients is the acquired form. A partial list of causes of acquired NDI is included in Box 70-1. This syndrome is commonly seen in the emergency or critical care setting, caused by conditions such as pyometra or other causes of gram-negative sepsis, hypercalcemia, hypokalemia, liver failure, and hypoadrenocorticism. Each of these conditions causes an inability of the vasopressin to effectively bind and activate its receptor. In gram-negative sepsis bacterial endotoxins, especially from *Escherichia coli,* are thought to compete with vasopressin for binding sites on the tubular cell membranes, resulting in marked polyuria and polydipsia, and possibly hypernatremia if water intake is insufficient. Similarly, hypercalcemia and severe hypokalemia are thought to interfere with vasopressin binding and subsequent activation of the V_2 receptor.

Another common mechanism of secondary NDI is the abolition of the medullary hypertonicity gradient. As mentioned previously the presence and proper function of vasopressin and its receptors allow water channels to be open in the tubular cells of the collecting duct. The passage of water, then, from the tubular lumen into the interstitium is still passive and based on the hypertonicity of the renal medulla, enabled by the renal counter-current mechanism. If this hypertonicity, a condition referred to as *medullary washout,* is absent the urine will not become concentrated; it will be isosthenuric or even hyposthenuric. Medullary washout occurs in small animal patients for two common reasons:

1. Washout results from large amounts of urine passing through the tubules. This can occur in severely polyuric and polydipsic animals, such as dogs with hyperadrenocorticism or dogs and cats receiving high volumes of intravenous fluids for extended periods.
2. The solutes necessary to produce the medullary hypertonicity gradient are lacking, such as insufficient urea in dogs and cats with hepatic insufficiency or insufficient sodium in dogs with hypoadrenocorticism. In both instances these animals may be severely polyuric and have a functional secondary NDI, despite absolutely normal renal function and normal vasopressin concentrations.

70.5 DIAGNOSING DIABETES INSIPIDUS

Diabetes insipidus should be high on the differential diagnosis list for any dog or cat with severe polyuria and 300
polydipsia, especially when the urine is hyposthenuric. The first step in the diagnosis of primary diabetes insipidus 301
is to exclude most other common causes of polyuria and polydipsia. This can be accomplished by evaluating the signalment and complaint, a complete history, physical examination, a serum biochemistry profile, and a complete urinalysis and urine culture.

70.5.1

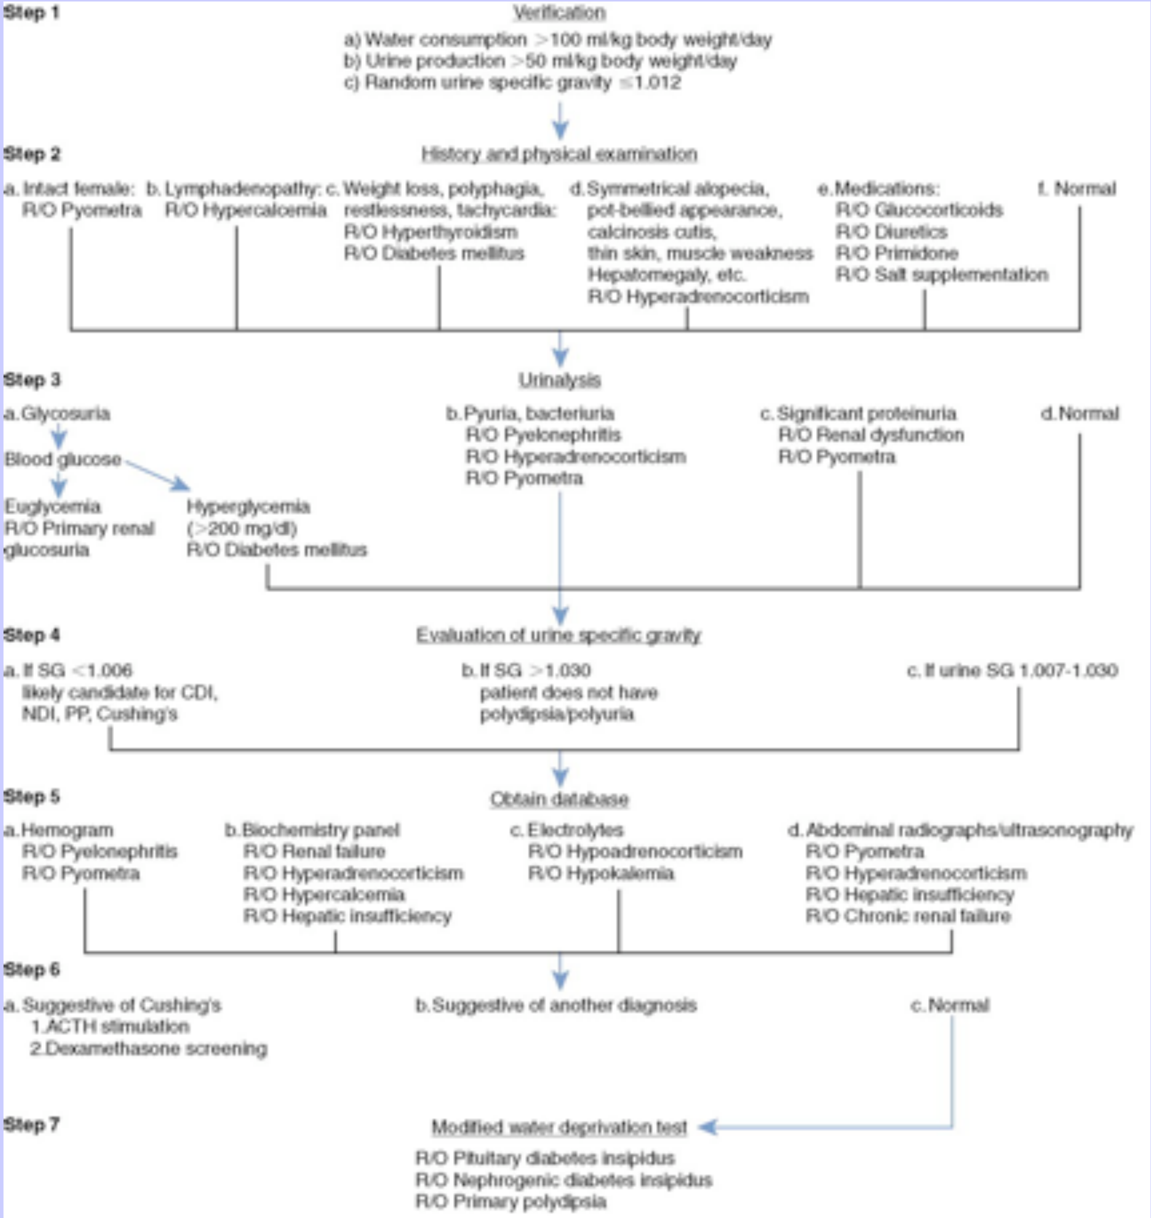
Box 70-1 Common Causes of Secondary Nephrogenic Diabetes Insipidus in Dogs and Cats

- Hypercalcemia
- Hypokalemia
- Pyelonephritis
- Pyometra and gram-negative sepsis
- Portal systemic shunts
- Liver insufficiency
- Hypoadrenocorticism (more common in dogs)
- Hyperthyroidism (more common in cats)

Normal serum biochemistry results would rule out many causes of secondary NDI, including hypercalcemia, severe hypokalemia, low serum urea concentrations associated with liver disease, and low sodium concentrations associated with Addison's disease. Normoglycemia would rule out diabetes mellitus and a cause of polyuria and polydipsia. Normal urinalysis results and negative urine culture findings would exclude diabetes mellitus and primary renal glycosuria, and would make pyelonephritis much less likely (Figure 70-1).

Additional testing may also be necessary when appropriate, including preprandial and postprandial serum bile acid concentrations to further exclude liver disease, serum T_4 concentrations to exclude hyperthyroidism, and imaging. Chronic kidney disease as a cause of polyuria and polydipsia is unlikely if the urine is hyposthenuric. If the urine is consistently isosthenuric, with normal or high-normal serum concentrations of blood urea nitrogen and creatinine, then a glomerular filtration study may be necessary to definitively rule out chronic kidney disease.

Figure 70-1 The diagnostic plan in a dog or cat with severe polydipsia and polyuria. *ACTH*, Adrenocorticotropic hormone; *CDI*, central diabetes insipidus; *NDI*, nephrogenic diabetes insipidus; *PP*, primary (psychogenic) polydipsia; *R/O*, rule out (a diagnosis); *SG*, specific gravity. From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, ed 3, St Louis, 2004, Saunders.



Step 1
Verification
a) Water consumption >100 ml/kg body weight/day
b) Urine production >50 ml/kg body weight/day
c) Random urine specific gravity ≤1.012
Step 2
History and physical examination
a. Intact female: R/O Pyometra
b. Lymphadenopathy: R/O Hypercalcemia
c. Weight loss, polyphagia, restlessness, tachycardia: R/O Hyperthyroidism R/O Diabetes mellitus
d. Symmetrical alopecia, pot-bellied appearance, calcinosis cutis, thin skin, muscle weakness Hepatomegaly, etc. R/O Hyperadrenocorticism
e. Medications: R/O Glucocorticoids R/O Diuretics R/O Primidone R/O Salt supplementation
f. Normal
Step 3
Urinalysis
a. Glycosuria
Blood glucose
Euglycemia R/O Primary renal glucosuria
Hyperglycemia (>200 mg/dl) R/O Diabetes mellitus
b. Pyuria, bacteriuria R/O Pyelonephritis R/O Hyperadrenocorticism R/O Pyometra
c. Significant proteinuria R/O Renal dysfunction R/O Pyometra
d. Normal
Step 4
Evaluation of urine specific gravity
a. If SG <1.006 likely candidate for CDI, NDI, PP, Cushing's
b. If SG >1.030 patient does not have polydipsia/polyuria
c. If urine SG 1.007-1.030
Step 5
Obtain database
a. Hemogram R/O Pyelonephritis R/O Pyometra
b. Biochemistry panel R/O Renal failure R/O Hyperadrenocorticism R/O Hypercalcemia R/O Hepatic insufficiency
c. Electrolytes R/O Hypoadrenocorticism R/O Hypokalemia
d. Abdominal radiographs/ultrasonography R/O Pyometra R/O Hyperadrenocorticism R/O Hepatic insufficiency R/O Chronic renal failure
Step 6
a. Suggestive of Cushing's 1. ACTH stimulation 2. Dexamethasone screening
b. Suggestive of another diagnosis
c. Normal
Step 7
Modified water deprivation test
R/O Pituitary diabetes insipidus
R/O Nephrogenic diabetes insipidus
R/O Primary polydipsia

A relatively common scenario we are faced with is an older dog with severe polyuria, polydipsia, and hyposthenuric urine, and no abnormal findings on a physical examination, a complete blood count, serum biochemistry profile, urinalysis (except the hyposthenuria), urine culture, and abdominal radiographs or ultrasonography. At this point in our diagnostic workup, the most likely remaining causes of the severe polyuria and polydipsia in this dog are hyperadrenocorticism, CDI or NDI, and primary or psychogenic polydipsia. The latter is a condition which is sometimes referred to as *psychogenic diabetes insipidus,* in which a dog drinks excessively for no apparent physiologic reason. Often these dogs are thought to drink this way because they are bored, stressed, or perhaps just enjoy drinking water.

The next step in the diagnosis is to attempt to exclude hyperadrenocorticism and psychogenic polydipsia. The first can be deemed much less likely based on a urine cortisol-to-creatinine ratio within the reference range or a low-dose dexamethasone suppression test with results within the reference range. An adrenocorticotropic hormone stimulation test is a less advisable option for this purpose, because in many dogs with hyperadrenocorticism the results of an adrenocorticotropic hormone stimulation test lie within the normal reference range. It is absolutely essential to make every effort to exclude hyperadrenocorticism in these cases. If this step is missed and a water deprivation test or desmopressin acetate trial is used to confirm CDI, a misdiagnosis may occur. Dogs with hyperadrenocorticism may appear to have CDI per results of these tests, and therefore will be mistakenly treated with desmopressin acetate instead of the proper diagnosis and treatment of their hyperadrenocorticism.

A random serum osmolality test may be used to attempt to diagnose psychogenic polydipsia. In this case dogs drink excessively as their primary disturbance and as a consequence are also polyuric. This is in contrast to diabetes insipidus, hyperadrenocorticism, and other causes or polyuria and polydipsia in which the primary disturbance is excessive urination. The polydipsia then, in these dogs, is an attempt to remain hydrated or to “catch up” with their urination. Theoretically the dogs with primary or psychogenic polydipsia should always be slightly overhydrated (with a low serum sodium concentration and low serum osmolality), and dogs with other causes of polyuria and polydipsia including diabetes insipidus should be slightly dehydrated (with a relatively high serum sodium concentration and serum osmolality).

On a random serum osmolality assay a result of less that 280 mOsm/L would be most consistent with psychogenic polydipsia. A result greater than 280 mOsm/L is hard to interpret, because even if the dog did have psychogenic polydipsia, if it did not drink excessively that day (possibly due to the visit to the veterinarian), the osmolality could be over 280 mOsm/L. If the random serum osmolality was indeed over 280 mOsm/L, an additional test to confirm the diagnosis of primary diabetes insipidus and to differentiate between the more common CDI and the rare primary NDI is warranted. Two options are available to achieve these goals, a modified water deprivation test and a desmopressin acetate (synthetic vasopressin) trial.

70.5.2 Modified Water Deprivation Test

A modified water deprivation test is based on the premise that a dog that truly suffers from diabetes insipidus will not be able to concentrate its urine even under conditions of moderate dehydration. This is because of either a lack of vasopressin (CDI) or lack of an appropriate renal response to vasopressin (NDI). An appropriate rise in urine specific gravity while dehydrated would be suggestive of psychogenic polydipsia. Once dehydration has been achieved without an appropriate rise in urine concentration, desmopressin is given intramuscularly. A marked increase in urine specific gravity at that time would be diagnostic for CDI, and a complete lack of response to desmopressin would be suggestive of NDI. Although in many cases this test does provide a definitive diagnosis of diabetes insipidus, we do not recommend its routine use. This is because many problems and possible misdiagnoses are associated with the analysis of the test results and, more importantly, grave risks can be associated with this test including severe dehydration, hypernatremia, and even death.[1]

70.5.2.1 Problems and Risks

70.5.2.1.1 Causes of Misdiagnoses

1. Medullary washout may occur. If the medullary interstitium has been "washed out" of solutes because of chronic severe polyuria and polydipsia for any reason, no urine concentration will occur despite the presence of endogenous vasopressin, desmopressin, and intact renal V_2 receptors. These dogs are then mistakenly diagnosed as suffering from NDI. The modified water deprivation test protocol attempts to eliminate this problem by recommending mild water restriction for a number of days before the test. Although helpful, this does not always eliminate the problem, is not always possible, and can be dangerous if dehydration is induced at home without proper monitoring.

2. Partial CDI, or a relative lack of vasopressin, can be very hard to diagnose, because a rise in urine specific gravity will be induced by dehydration. This rise, though, will be of inappropriately low magnitude, a very subjective value, and these dogs can be misdiagnosed as having psychogenic polydipsia. An additional rise in urine specific gravity should occur after desmopressin is given. Their response should be more dramatic, though, than in dogs with psychogenic polydipsia. This is a subjective value, making a definitive diagnosis of partial CDI very difficult.

3. Dogs with hyperadrenocorticism may appear to have CDI or partial CDI per a water deprivation test, leading to a misdiagnosis. This underlines the importance of establishing or excluding a diagnosis of hyperadrenocorticism in dogs before administering this test.

70.5.2.1.2 Associated Risks

The main and most important risk, and the reason why we do not recommend the routine use of this test, is severe dehydration than can be associated with acute severe hypernatremia. This occurs in cases of CDI or NDI when dehydration continues past 5% of body weight because of a lack of intensive monitoring. In cases of complete diabetes insipidus this could happen in a very short time (a few hours). This may be accompanied with a rapid rise in serum sodium concentrations resulting in neurologic symptoms. Despite aggressive fluid therapy, normal sodium concentrations may be difficult to restore. Desmopressin therapy is warranted in this case to slow the free water loss associated with the marked polyuria and to allow normalization of serum sodium concentrations.

Prevention of this complication includes only mild water deprivation at home during the days before the test, as well as aggressive monitoring of body weight, serum sodium, urea nitrogen, and creatinine frequently (at least hourly) during the test. The test should be stopped at 5% loss of body weight or any marked increase in the above serum values. Water, intravenous fluids (an intravenous catheter should be preplaced), and desmopressin should be available for immediate use.

70.5.3 Desmopressin Acetate Trial

The other diagnostic option available for the diagnosis of diabetes insipidus is the desmopressin acetate trial. 302

Although this test does not yield immediate results, it is a much safer option for most dogs than the modified 303 water deprivation test. This test is performed at home by the owner. The owner is instructed to collect urine, first thing in the morning, for a few days; to slightly limit access to water, if possible, for a few days; and then to begin therapy with desmopressin.

On days 5, 6, and 7 of this therapy urine is again collected first thing in the morning. All urine should be refrigerated after collection. At the end of the trial the urine samples are brought to the veterinarian for specific gravity measurement or, ideally, osmolality assays. The owners are encouraged to measure water intake during the trial, if possible.

The theory behind this therapeutic trial is that given mild water deprivation and desmopressin, the dog's urine concentration will steadily increase over the trial period. Medullary washout will be eliminated slowly if it was present initially, and a dog with CDI should have a marked increase in urine concentration. No increase in urine concentration by the end of the trial would be consistent with NDI or psychogenic polydipsia. Because primary NDI is so uncommon in an adult dog, this is usually not a big problem. A definitive differentiation between those two conditions would require a modified water deprivation test.

70.5.4 Imaging Following a Diagnosis of CDI

An extremely high percentage of adult dogs with acquired CDI appear to have intracranial mass lesions identifiable with magnetic resonance or computed topography imaging.[4] Such imaging is therefore recommended following the diagnosis of CDI, and radiation therapy is recommended if a lesion is identified.

70.6 Treatment of Diabetes Insipidus

A list of treatment options for CDI and NDI is included in Box 70-2. Most commonly CDI (partial or complete) is treated with desmopressin (oral or human nasal preparation given as eye drops). This treatment is extremely effective and when given consistently will enable the dog to concentrate urine normally. Other therapies can also be used in those with CDI as well as those with NDI. These include therapies aimed at lowering total body sodium and commonly include thiazide diuretics and salt-restricted diets. These therapies typically have minimal success in those with NDI.

Another option for owners of pets suffering from CDI or NDI is not to treat. Theoretically, as long as these animals are allowed free access to water, allowed to urinate outside, and are kept in conditions that help prevent dehydration through additional fluid loss (shade, no strenuous exercise in warm conditions), they will remain hydrated and may exhibit no clinical signs. This is especially important because of the high cost of desmopressin therapy for dogs with CDI and the lack of effective therapy for dogs with NDI.

70.6.1 Emergency Treatment

The most challenging aspect of this condition to an emergency or critical care clinician is the treatment of the severe dehydration, ongoing free water losses, and marked hypernatremia associated with small animals suffering from diabetes insipidus (primary or secondary) that for some reason have not had adequate access to water. This can be a result of vomiting or adipsia from an additional disease process, water deprivation by the owner (because of a belief that this will prevent urination in the house, or accidentally), the pet being lost without water, and animals that have sustained trauma (e.g., dog with diabetes insipidus that has been hit by a car and is presented in for veterinary care hours or days later). In these instances the clinician is presented with a patient with inappropriately high free water losses, dehydration, and high sodium concentrations. The first challenge is recognition of this state by the clinician, and then aggressive medical therapy. Aggressive therapy includes fluids, therapy for acute or chronic hypernatremia, and possibly desmopressin. Desmopressin therapy (injectable or eye drops) should be considered when dehydration and hypernatremia persist despite appropriate fluid therapy, urine volumes are high, and urine concentration is inappropriately low for the degree of clinical dehydration (see Chapter 54, Sodium Disorders).

70.6.1.1

Box 70-2 Therapies Available for Polydipsic/Polyuric Dogs With CDI, NDI, or Primary (Psychogenic) Polydipsia

A Central diabetes insipidus (severe)

  1 DDAVP (desmopressin acetate)

    a Effective

    b Expensive

    c May require drops in conjunctival sac if oral is ineffective

  2 LVP (lypressin [Diapid])

    a Short duration of action; less potent than DDAVP

    b Expensive

    c Requires drops into nose or conjunctival sac

  3 No treatment—provide continuous source of water

B Central diabetes insipidus (partial)

  1 DDAVP

  2 LVP

  3 Chlorpropamide

    a 30% to 70% effective

    b Inexpensive

    c Pill form

    d Takes 1 to 2 weeks to obtain effect of drug

    e May cause hypoglycemia

  4 Clofibrate—untested in veterinary medicine

  5 Thiazides

    a Mildly effective

- b Inexpensive
- c Pill form
- d Should be used with low-sodium diet

6 Low-sodium diet

7 No treatment—provide continuous source of water

C Nephrogenic diabetes insipidus

1 Thiazides—as above

2 Low sodium diet

3 No treatment—provide continuous source of water

D Primary (psychogenic) polydipsia

1 Water restriction at times

2 Water limitation

3 Behavior modification

- a Exercise
- b Another pet
- c Larger living environment

From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction*, ed 3, St. Louis, 2004, Saunders.

70.7 PROGNOSIS

The prognosis for dogs with CDI is good if they respond to therapy. Unfortunately, because of an apparently high incidence of intracranial masses in these dogs, the prognosis must remain guarded until advanced imaging can be pursued. The prognosis for dogs with primary NDI is guarded because of the lack of therapy for this condition. The prognosis for dogs with severe dehydration and hypernatremia is guarded, as well, especially if the condition is chronic. Proper medical therapy can often induce complete resolution of these complications and allow long-term medical treatment of CDI or the primary cause of secondary NDI.

71 Chapter 71 Syndrome of Inappropriate Antidiuretic Hormone

C.B. Chastain, DVM, MS, DACVIM

71.1 KEY POINTS

- Hyponatremia is the cardinal finding of the symptomatic syndrome of inappropriate antidiuretic hormone (SIADH).
- SIADH can be caused by cerebral disorders, pulmonary disease, or adverse effects of medications. Idiopathic causes have been reported in dogs.
- Hyponatremia of SIADH is characterized by hypoosmolality and inappropriately concentrated urine and urine sodium excretion.
- Renal, adrenal, and thyroid functions are normal, and neither edema, dehydration, nor azotemia is present in animals with SIADH.

71.2 INTRODUCTION

One of the most frequent electrolyte abnormalities in veterinary patients is hyponatremia. Most cases are temporary and without symptoms. One cause of hyponatremia that may be associated with symptoms and can be fatal is Syndrome of inappropriate antidiuretic hormone (SIADH).

Antidiuretic hormone (ADH) deficiency is relatively well known and is referred to as *central diabetes insipidus*. The antithesis of diabetes insipidus, an excess of ADH remains an obscure rarity in animals based on the frequency of case reports,[1-6] but its true incidence may be more common than diabetes insipidus. SIADH, also called *Schwartz-Bartter syndrome,* is characterized clinically in people by symptoms of depression and confusion. Affected animals may have central nervous system disease, pulmonary disease, or conditions requiring drugs that can cause SIADH.

The failure to recognize the true incidence of SIADH may be caused by lack of clinical suspicion, transient nature of some forms of SIADH, insufficient monitoring, rapid demise of the patient, or clinician distraction from investigating and managing concurrent diseases. Recognition of SIADH is important for many reasons, including causes that can be iatrogenic and remedied by drug withdrawal, or patient death that can be iatrogenic if SIADH is managed too aggressively.

71.3 CAUSES

ADH, also known as vasopressin, normally is secreted in response to an increase in serum osmolality (serum sodium concentration) or to maintain normal blood pressure and intravascular volume (see Chapter 177, Vasopressin). ADH actions are achieved by the promotion of free water resorption by the kidneys. Serum osmolality is monitored by the anterior portion of the hypothalamus. If blood pressure is normal or elevated, ADH secretion normally is inhibited by pressure receptors in the atria and great veins. A rise in serum osmolality is a more sensitive monitor (1% rise) and typical stimulus for ADH secretion than a decrease in blood pressure (9% decrease).[7,8] SIADH is defined as an excess of ADH without hypovolemia or hyperosmolality.

SIADH can be caused by cerebral disorders, pulmonary disease, or adverse effects of medications (Box 71-1).[7] The cause in some cases remains idiopathic. Three cases of idiopathic SIADH have been reported in dogs.[2,3] Cerebral causes of SIADH in humans include hypothalamic tumors, head trauma, meningitis, encephalitis, cerebrovascular accidents, and hydrocephalus. Hypothalamic tumors, granulomatous meningoencephalitis, and probable distemper encephalitis have been reported to cause SIADH in dogs.[5,6] Intracranial disease may directly stimulate the supraoptic or paraventricular nuclei to secrete ADH or may alter the osmoreceptors to inappropriately stimulate ADH secretion. Other cerebral causes of SIADH are perception of nausea, pain, and psychologic stress.[7]

Pulmonary diseases causing SIADH include tumors that ectopically produce ADH or diseases that interrupt the inhibitory impulses in vagal afferents from stretch receptors in the atria and great veins. Examples in humans have included tuberculosis pneumonia, aspergillosis, and lung abscesses. A dog had SIADH associated putatively with dirofilariasis.[1] Rarely, SIADH in humans has been caused by malignant tumors outside the thorax that have ectopically produced ADH.[7] In addition, positive-pressure ventilation may inhibit low-pressure baroreceptors and stimulate the release of ADH.

71.3.1 Box 71-1 Some Causes of the Syndrome of Inappropriate Secretion of ADH[7]

71.3.1.1 Central Nervous System Disorders

- Head trauma
- Hydrocephalus
- Cerebrovascular accidents
- Brain tumor
- Meningitis
- Encephalitis

71.3.1.2 Pulmonary Lesions

- Bacterial pneumonia
- Aspergillosis
- Lung tumors
- Positive-pressure ventilation

- Dirofilariasis

71.3.1.3 Malignancies

- Pancreatic carcinoma
- Prostatic carcinoma
- Thymoma
- Osteosarcoma

71.3.1.4 Drugs

- Antidepressants
- Neuroleptics
- Antineoplastics
- Nonsteroidal antiinflammatory drugs
- Opioids

71.3.1.5 Others

- Pain
- Nausea
- Psychological stress

ADH, Antidiuretic hormone.

Drugs may either increase ADH secretion or potentiate its action.[7,8] Drugs that are known to increase ADH secretion in humans include antidepressants (especially tricyclic antidepressants and monoamine oxidase inhibitors), anticancer drugs (intravenous cyclophosphamide and vinca alkaloids), opioids, and neuroleptics. Drugs that potentiate ADH action include cyclophosphamide and nonsteroidal antiinflammatory drugs.

The thirst center in the hypothalamus monitors plasma osmolality and extracellular fluid volume. If the patient is conscious, psychologically normal, and has a normal thirst center, water intake will subside to compensate for the reduction in plasma osmolality and expanded extracellular fluid volume of SIADH.[8] Patients receiving fluid therapy, under sedation or anesthesia, that are psychologically deranged, or with CNS disease affecting the thirst center have impaired ability to compensate for SIADH.

71.4 CLINICAL SIGNS

The clinical signs found in patients with SIADH depend on the cause of the syndrome and on the serum sodium concentration. Signs of a CNS disease, pulmonary disorder, surgical or traumatic stress, or drug intoxication may overshadow signs of SIADH. This may account, in part, for its rare recognition in companion animals. Regardless of its cause, if the serum sodium is severely decreased (less than 120 mEq/L), signs of hyponatremia may prevail. These include nausea, anorexia, vomiting, irritable behavior, confusion, head pressing, seizures, cardiac arrhythmias, and coma. Neither hypertension nor edema will be present.

71.5 LABORATORY FINDINGS

The outstanding initial abnormal laboratory finding in patients with clinical manifestations of SIADH is hyponatremia secondary to renal retention of free water and ongoing urinary sodium losses. Sodium is lost in the urine despite hyponatremia, because the secretion of renin and aldosterone is inhibited by normovolemia with expanding extracellular fluid caused by water retention. Serum osmolality will be less than 280 mOsm/kg, urine osmolality will be more than 150 mOsm/kg; urine sodium values are usually more than 20 mEq/L. Atrial natriuretic peptide is secreted in response to expanding extracellular fluid volume, which further inhibits renin and aldosterone and promotes natriuresis. Even though water is retained, edema usually does not develop because of continuing natriuresis. The degree of natriuresis is quite variable and is dependent on the quantity of dietary sodium.[7]

Other serum constituent concentrations, such as potassium and chloride, may also be diluted. Hypochloridemia may be severe enough to cause metabolic alkalosis. Blood urea nitrogen and uric acid concentrations are decreased by dilution and increased glomerular clearance.[7] An increased blood urea nitrogen concentration excludes a diagnosis of SIADH.

305

306

71.6 DIAGNOSTIC IMAGING FINDINGS

If non–drug-induced SIADH is suspected, evidence for possible intrathoracic or intracranial lesions should be sought by routine radiographs and, in some cases, computed tomography or magnetic resonance imaging.

71.7 DIAGNOSIS

A clinical diagnosis can be based on finding the characteristic clinical features of SIADH and the exclusion of other causes of hyponatremia. Plasma ADH determination is unnecessary for diagnosis. The water loading test can aggravate water intoxication of SIADH and is unnecessarily hazardous.

The clinical features of SIADH are most easily confused with those of primary hypoadrenocorticism. It differs from primary hypoadrenocorticism in having normal to low levels of blood urea nitrogen and serum potassium concentrations. Primary hypoadrenocorticism is associated with azotemia and hyperkalemia. Other differential diagnoses for hyponatremia include congestive heart failure, nephrosis, severe liver disease, hyperglycemia, and hyperlipidemia. In SIADH without unrelated disease, renal, adrenal, cardiac, and liver functions are normal, and blood glucose concentration is normal.

71.8 TREATMENT

Whenever possible, the cause for SIADH should be determined and corrected. The treatment of choice is discontinued fluid administration and restricted access to water. However, this may be insufficient in severe cases.

In acute severe cases, emergency treatment may include hypertonic (3%) saline, which should be given slowly in an intravenous dose over 2 to 4 hours if neurologic signs are thought to be secondary to acute hyponatremia and resulting cerebral edema. Isotonic saline infusion is unsuitable because of its low concentration of sodium, which will be excreted in the urine while the water will be retained, worsening the hyponatremia. When hyponatremia may have been present for more than 48 hours, care must be taken to prevent central pontine myelinolysis (osmotically induced demyelination).[9] Serum sodium should not increase with treatment by more than 12 mEq/L q24h. The initial goal should be to increase serum sodium concentration to 125 to 130 mEq/L in a carefully controlled manner. When hypertonic saline is used, furosemide may also be beneficial to inhibit reabsorption of water in the renal tubules to reduce the risk of volume overload. Sodium and potassium should be supplemented as needed.

A tetracycline, demeclocycline, inhibits the action of ADH on the renal tubules. It has been effective in treating humans with SIADH caused by excessive secretion from hypothalamic nuclei or by the secretion of ectopic ADH. However, it is potentially nephrotoxic and renal function must be monitored closely. Improvement from demeclocycline treatment may take 1 to 2 weeks. A safe and effective dosage of demeclocycline in dogs has not been established. Lithium will also inhibit the action of ADH on the renal tubules, but its use is precluded by its toxicity, which is greater than that of demeclocycline.

71.9 PROGNOSIS

The prognosis for patients with SIADH depends on the cause. If caused by infection or drugs, withdrawal of the drug and successful treatment of the infection will lead to a cure. If secondary to a malignant tumor that cannot be excised completely or destroyed by radiation, SIADH usually is incurable but can be controlled with water restriction and sodium supplementation.

72 Chapter 72 Thyroid Storm

Cynthia R. Ward, VMD, PhD, DACVIM

72.1 KEY POINTS

- Thyroid storm is a newly described syndrome of acute thyrotoxicosis in veterinary patients that occurs primarily in hyperthyroid cats.
- The pathogenesis is unknown but probably results from rapid increases in serum thyroid hormone levels coupled with activation of the sympathetic nervous system.
- An event often triggers thyroid storm, although the event may not be readily apparent.
- Clinical signs may include hyperthermia, central nervous system disturbances, acute or severe vomiting and diarrhea, abdominal pain, icterus, cardiac murmurs with or without arrhythmias, pleural effusion, pulmonary edema, tachypnea, hypertension, retinopathies, extreme muscle weakness and cervical ventroflexion, thromboembolic disease, and sudden death.
- Diagnosis is based on clinical signs and evidence of elevated serum thyroid hormones.
- Treatment is aimed at reducing production and secretion of thyroid hormones, blocking peripheral actions of thyroid hormones, systemic support, and elimination of the precipitating event.
- Successful outcome depends on rapid recognition of the clinical syndrome and aggressive therapy.

72.2 INTRODUCTION

Thyroid storm is a syndrome described in human medicine to define a multisystem disorder resulting from organ exposure to excessive amounts of thyroid hormone. This form of acute thyrotoxicosis can be life threatening and is a significant cause of mortality in human emergency rooms. Thyrotoxicosis describes any condition in which there is an excessive amount of circulating thyroid hormone, whether from excess production and secretion from an overactive thyroid gland, leakage from a damaged thyroid gland, or from an exogenous source. In contrast, hyperthyroidism describes thyroid gland hyperfunction. Therefore acute thyrotoxicosis may occur in the absence of thyroid gland hyperfunction, although this is rare in veterinary medicine.

In humans, thyroid storm can occur at any age. It can be present in euthyroid patients as well as treated and partially treated hyperthyroid patients. Although this is a well-recognized syndrome in human medicine, it has not been described as a clinical entity in veterinary medicine. Hyperthyroidism is common in older feline patients. It is also seen rarely in dogs with thyroid carcinoma or extreme oversupplementation of thyroid replacement hormone in hypothyroid dogs. Hyperthyroid cats that experience an acute exacerbation of thyrotoxicosis may be said to have thyroid storm. This chapter will discuss the human syndrome and define a similar syndrome in hyperthyroid veterinary patients. The clinical signs of and treatment modalities for feline patients suffering from thyroid storm will also be presented.

72.3 PATHOGENESIS

Although the exact pathogenesis of thyroid storm remains to be elucidated, several factors appear to be involved, including high levels of circulating thyroid hormones, rapid increases in circulating thyroid hormones, hyperactivity of the sympathetic nervous system, and an increased cellular response to thyroid hormone.

72.3.1 High Levels of Circulating Thyroid Hormones

Although one would expect circulating thyroid hormones to be increased in patients with thyroid storm, in human medicine there is no difference between serum thyroid hormone levels in these patients and in more stable hyperthyroid patients. The diagnosis is therefore made primarily based on clinical signs.[1]

72.3.2 Rapid, Acute Increases in Circulating Thyroid Hormones

The magnitude of change in the serum thyroid hormone levels may be more important than the actual levels themselves. This would explain the occurrence of thyroid storm following radioactive iodine therapy and thyroid surgery that damage the thyroid gland and cause release of hormone or following abrupt cessation of antithyroid medication resulting in the rapid rise of serum thyroid hormone levels.[2] Certainly, nonthyroidal illness, known to be a precipitating factor in human medicine, has been shown to alter binding of thyroid hormones to their carriers and could be responsible for rapid alteration of circulating thyroid hormone as well.

72.3.3 Hyperactivity of the Sympathetic Nervous System

Activation of the sympathetic nervous system has been implicated in the onset of thyroid storm.[3] Many of the clinical signs and physiologic signs are similar to those seen during catecholamine excess. Serum and urine catecholamine levels in humans are within normal limits during thyroid storm. However, thyroid hormones can alter tissue sensitivity to catecholamines at the cell surface receptor as well as the intracellular signaling levels, and this increased sensitivity may result in the clinical signs seen during thyroid storm. In addition, many of these clinical signs are controlled by β-adrenergic blockade.

72.3.3.1 Box 72-1 Potential Precipitating Events for Feline Thyroid Storm

- Radioactive iodine therapy
- Thyroidal or parathyroidal surgery
- Abrupt withdrawal of antithyroid medications
- Stress
- Nonthyroidal illness
- Administration of iodinated contrast dyes
- Administration of stable iodine compounds

- Vigorous palpation of the thyroid

72.3.4 Increased Cellular Response to Thyroid Hormones

This effect has been implicated in the cause of thyroid storm resulting from infection, sepsis, hypoxemia, hypovolemia, and lactic acidosis or ketoacidosis.[4]

72.4 PRECIPITATING EVENTS

In most cases of thyroid storm in humans, a precipitating event can be identified, although no known cause is found in up to 2% of cases.[5] The most common precipitating events are infection, thyroidal and nonthyroidal surgery, radioactive iodine therapy, administration of iodinated contrast dyes, administration of stable iodine, withdrawal of antithyroid medication, amiodarone therapy, ingestion of excessive amounts of exogenous thyroid hormone, vigorous palpation of the thyroid gland, severe emotional stress, and a variety of acute nonthyroidal illnesses. Common events that may precipitate thyroid storm in feline hyperthyroid patients may include radioactive iodine therapy, abrupt withdrawal of antithyroid medication, thyroid surgery, vigorous thyroid palpation, stress, administration of stable iodine compounds, as well as any of the other precipitating factors found in humans (Box 72-1).

72.5 CLINICAL SIGNS

Thyroid storm is the acute exacerbation of clinical signs of thyrotoxicosis; however, the diagnosis of thyroid storm in human medicine is based on the prevalence of four major clinical signs. These include (1) fever, (2) central nervous system (CNS) effects from mild agitation to seizures or coma, (3) gastrointestinal (GI) and hepatic dysfunction ranging from vomiting, diarrhea, and abdominal pain to unexplained jaundice, and (4) cardiovascular effects including sinus tachycardia, atrial fibrillation, ventricular tachycardia and congestive heart failure. The combination of these clinical signs along with identification of a precipitating event allows for the diagnosis of thyroid storm.[5] In cats with presumed thyroid storm, many of these clinical signs also occur (Box 72-2).

Auscultation may reveal a cardiac murmur or arrhythmia (most often a gallop rhythm). Inspiratory crackles or dullness in the lung fields may be heard if pulmonary edema or pleural effusion is present, respectively.[6] Mild to severe hypertension may also be present during thyroid storm in cats.[7] Retinopathies, including hemorrhage, edema, degeneration, or even retinal detachment may be found, especially in hypertensive thyrotoxic cats.[8] Tachypnea and hyperthermia may be present, and absent limb motor function may be detected as a result of thromboembolic disease occurring from acute thyrotoxicosis.[9] Sudden death may also occur. Severe, acute muscle weakness and ventroflexion of the neck may be seen in acutely thyrotoxic cats, often associated with hypokalemia.

72.5.1 Box 72-2 Clinical Signs Associated With Feline Thyroid Storm

72.5.1.1 Constitutional Signs

Hyperthermia

Dehydration

72.5.1.2 Cardiovascular Signs

Arrhythmias

Atrial fibrillation, ventricular tachycardia

Gallop rhythm

Sinus tachycardia

Congestive heart failure

Cardiomegaly

Pleural effusion

Pulmonary edema

Hypertension

Thromboembolic disease

72.5.1.3 Respiratory Signs

Tachypnea

72.5.1.4 Neuromuscular Signs

Behavior changes

Seizures

Muscle weakness

Cervical ventroflexion

72.5.1.5 Gastrointestinal and Hepatic Signs

- Abdominal discomfort or pain
- Vomiting
- Diarrhea
- Icterus

72.5.1.6 Ocular Signs

- Hyphema
- Retinal lesions
- Retinal detachment

72.6 DIAGNOSIS

The diagnosis of thyroid storm is based on identification of thyrotoxicosis, clinical signs, and evidence of a precipitating event.[5] Thyrotoxicosis in hyperthyroid cats is demonstrated by an elevated total T_4 level, or a total T_4 level in the high-normal range combined with an elevated free T_4 level. The total T_4 level may be in the normal range in a hyperthyroid cat, but it is expected that in cases of thyroid storm, the total T_4 and free T_4 levels will be above the normal range. In human medicine, thyroid storm is diagnosed based on a point system assigned to each of the main clinical components: fever, CNS signs, GI signs, and cardiovascular signs, as well as presence or absence of a precipitating event.[5] In hyperthyroid feline patients, thyroid storm may be diagnosed based on clinical 308
signs of acute thyrotoxicosis. In some cases a precipitating event may be identified. 309

72.7 LABORATORY ABNORMALITIES

Laboratory abnormalities result from uncomplicated thyrotoxicosis[10]; there is no distinguishing laboratory value for feline thyroid storm. In the hyperthyroid cat, hematologic abnormalities may include a mild erythrocytosis, macrocytosis, and Heinz body formation. In humans with thyroid storm, a leukocytosis with left shift in the absence of active infection or inflammation has been identified.[11] In hyperthyroid cats a mature neutrophilia, lymphopenia, and eosinopenia are more commonly identified as a stress response. Biochemical abnormalities seen in people with thyroid storm include a mild hyperglycemia and hypercalcemia. Elevated liver enzyme values are often seen as well, and hyperbilirubinemia may occur in severe cases; this finding carries a poor prognosis. In hyperthyroid cats, elevated liver enzyme levels, a mild hyperglycemia, and severe hypokalemia may be seen in patients with acute thyrotoxicosis. A decreased sodium-to-potassium ratio may be seen in thyrotoxic cats who experience heart failure with pleural effusion.[12] Radiographs may reveal cardiomegaly and/or evidence of congestive heart failure.

72.7.1 Treatment

Treatment of thyroid storm is aimed at controlling the four major problematic areas: (1) to reduce the production and/or secretion of thyroid hormones, (2) to counteract the peripheral effects of thyroid hormones, (3) to provide systemic support, and (4) to identify and eliminate the precipitating factor.[13]

72.7.1.1 Reduction in the Production or Secretion of New Thyroid Hormones

The thioimidazole compound methimazole inhibits iodine incorporation into tyrosyl residues of thyroglobulin and thus prevents the synthesis of active thyroid hormone. In this way, methimazole should be the first line of defense against thyroid storm. However, it does not prevent the secretion of already formed thyroid hormones. Methimazole may be given orally, transdermally, or even rectally in cats. The dosage should be at the high end in cats that have normal renal function (5 mg per cat PO q12h). If there is suspected renal insufficiency or failure, the dosage of methimazole should be reduced by half to prevent a rapid decrease in renal blood flow.

Methimazole will block the formation of new, active thyroid hormone, but other measures must be instituted to prevent further secretion of formed hormone, which is stored in high concentrations in the thyroid gland. This can be done with stable iodine compounds such as potassium iodide. These compounds, in large dosages, can also decrease the synthesis rate of thyroid hormone. They must be given 1 hour after methimazole administration, because a large load of iodine will initially stimulate thyroid hormone production. Potassium iodide may be given at 25 mg PO q8h. Instead of potassium iodide, lipid-soluble radiographic contrast agents, such as iopanoic acid, may be given at 100 mg per cat q12h. Although iopanoic acid is available in parenteral form, oral administration is safer because it is a very hyperosmolar agent. This compound has the additional advantages of blocking peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3), blocking T_3 from binding to its receptor, and inhibiting thyroid hormone synthesis.

72.7.1.2 Inhibition of Peripheral Effects of Thyroid Hormone

The most rapid relief of signs caused by thyroid storm is accomplished with medications that block the β-adrenergic receptors, such as propranolol and atenolol. Propranolol, a nonselective β-adrenergic blocker, is used most commonly as a sympatholytic agent in human medicine, but it is inherently difficult to use in cats because of its poor oral bioavailability and short half-life, requiring administration every 8 hours in this species. The use of propranolol has been largely superseded by atenolol because of its selectivity and once-daily administration. However, propranolol inhibits the peripheral conversion of T_4 to T_3, although this effect happens slowly.[14] Therefore propranolol may be advantageous in severely thyrotoxic cats. High-end dosages of propranolol should be used to ensure β-adrenergic blockade at 5 mg PO q8h or 0.02 mg/kg IV over 1 minute. Alternatively, atenolol, a selective β_1-adrenergic blocker that has better oral bioavailability, may be used at 1 mg/kg q12-24h. In emergent situations, the short-acting β_1-blocker esmolol constant rate infusion [CRI] may be used intravenously at a loading dose of 0.1 to 0.5 mg/kg over 1 minute, followed by a CRI of 10 to 200 μg/kg/min (see Chapters 190 and 191, Antiarrhythmic Agents and β-Blockers, respectively).

An extreme method to counteract the peripheral actions of excess thyroid hormones is to reduce the systemic levels that are already present. Peritoneal dialysis, plasmapheresis, and hemodialysis have been used in human medicine, as has cholestyramine, which binds to thyroid hormone in the GI tract, and inhibits enterohepatic circulation. These methods rarely are used in human patients and probably have limited use in veterinary patients with thyroid storm.

72.7.1.3 Systemic Support

The third arm of treatment for thyroid storm involves reversing the effects of thyroid hormones on the body. Hyperthermia should be treated with judicious use of parenteral fluids and fans. Volume depletion is another common systemic effect of thyroid storm and this should be treated with intravenous isotonic crystalloid fluid replacement. Colloid fluid therapy is generally not indicated unless severe GI disease or another syndrome resulting in low oncotic pressure is present. Potassium supplementation should be added as necessary (some patients with thyroid storm become acutely hypokalemic). Dextrose supplementation of 5% to 10% should be considered, if needed, and B vitamin supplementation may prevent thiamine deficiency in hyperthyroid cats.

Cardiac disturbances are common in humans with thyroid storm, and it is not uncommon for cats with thyroid storm to arrive in cardiac failure. β-Adrenergic blockade therapy, as described earlier, may be also be helpful for managing cardiac failure because of its effects in reducing the elevated heart rate caused by thyrotoxicosis. Furosemide (1 to 4 mg/kg IV or IM q1-6h as needed; 0.5 to 2 mg/kg PO q6-24h), angiotensin-converting enzyme inhibitors (enalapril or benazepril at 0.5 to 2 mg/kg PO q12h), isosorbide dinitrate (0.5 to 2 mg/kg PO q8-12h), nitroglycerin (0.25 to 1.5 inch q6-12h topically), or hydralazine (0.5 to 1 mg/kg IV; 0.5 to 2 mg/kg PO, SC, or IV q8-12h) may be useful to manage feline heart failure, but must be used with care in patients with renal compromise (see Chapters 178, 179, and 180, Antihypertensives, Nitroglycerin, and Diuretics, respectively). In all cases, medications should be started at the lowest dosages and titrated upward to effect with close blood pressure monitoring.

Supraventricular arrhythmias are common in humans with thyroid storm, with the most common disturbance being atrial fibrillation. Atrial fibrillation or ventricular tachycardias can also occur in thyrotoxic feline patients. β-Adrenergic receptor blockade as described above is a first-line defense in treating these arrhythmias. A possible sequela in feline patients with heart failure or atrial fibrillation is thromboembolic disease. Anticoagulation should be considered using low-dose aspirin (5 mg/cat q72h), heparin (200 to 400 U/kg SC q6-8h until activated partial thromboplastin time is 1.5 to 2 times prolonged) and low-molecular-weight heparin (100 U/kg SC q6h).

Hypertension is often a complication of thyroid storm in cats. Blood pressure should be checked and antihypertensive therapy instituted as appropriate to include β-blockade as discussed previously or amlodipine (0.625 to 1.25 mg PO or rectally q12-24h). In acute cases of hypertension, nitroprusside may be used as an intravenous CRI at 0.5 to 5 μg/kg/min or nicardipine at 0.5 to 5 mg/kg/min.

In humans with thyroid storm, a relative adrenal insufficiency may occur secondary to increased cortisol clearance. This prompts the administration of glucocorticoids. Studies have not been done in feline patients, and glucocorticoid therapy in patients with thyroid storm remains controversial.

72.7.1.4 Eradication of the Precipitating Factor

In human patients with thyroid storm, a precipitating factor is one of the criteria that define the disease. Precipitating factors should also be investigated thoroughly in cats with thyroid storm. A full workup, including full hematology studies, biochemical analysis, urinalysis, retroviral testing, blood pressure measurement, and imaging studies should be performed. Abnormal findings should be further examined by culturing potentially infected fluids, detailed imaging studies, endoscopy, or other specialized testing. If another abnormality is identified, it should be treated in order to prevent recurrence of thyroid storm.

72.7.2 Outcome

Although thyroid storm is an uncommon finding in human emergency rooms, the mortality rate in patients with this syndrome is significant. Rapid recognition of the problem and aggressive treatment are necessary for a successful outcome. Thyroid storm is not as well defined in feline medicine, although acute manifestations of thyrotoxicosis result in a syndrome that can be considered a feline thyroid storm. Veterinary recognition of this syndrome may be lacking, so it is unknown what the true incidence and mortality from thyroid storm may be in cats. However, it is certainly recognized that death may arise from untreated, acute thyrotoxicosis. As in humans, it is anticipated that early recognition and aggressive treatment of feline thyroid storm will improve veterinary patient survival.

73 Chapter 73 Myxedema Coma

Rebecka S. Hess, DVM, DACVIM

73.1 KEY POINTS

- Myxedema coma is a misnomer. Many patients in a hypothyroid crisis are not comatose and do not have myxedema.
- Myxedema coma is difficult to diagnose, because it is rare and the clinical and clinicopathologic abnormalities may be nonspecific.
- Rottweiler dogs are at increased risk for a hypothyroid crisis.
- Concurrent disease, most commonly infection (pneumonia), may increase the risk for a hypothyroid crisis. Treatment with steroids, nonsteroidal medication, or surgery may also increase the risk for a hypothyroid crisis.
- Myxedema, obesity, mental dullness, hypercholesterolemia, and nonregenerative anemia are observed in many, but not all, dogs in a hypothyroid crisis.
- Intravenous (IV) administration of levothyroxine at a dosage of 5 μg/kg q12h is a safe and effective treatment for dogs in a hypothyroid crisis.
- Subjective improvement in mentation or ambulation occurs within 24 to 30 hours of IV levothyroxine administration in most dogs.
- When treated appropriately with supportive care and IV levothyroxine, most dogs with myxedema coma respond well and are discharged from the hospital.

73.2 INTRODUCTION

Canine myxedema coma is a rare, life-threatening complication of hypothyroidism.[1-7] In human beings the name *myxedema coma* is considered a misnomer, because human patients with this condition are rarely comatose and do not usually have myxedema.[8,9] Diagnosis of myxedema coma is difficult because it is rare, and therefore little is known of the condition.[1] Diagnosis is further complicated by nonspecific clinical signs. Recognition of an acute hypothyroid crisis in dogs that do not have coma or myxedema may advance the understanding and improve the outcome of dogs with suspected myxedema coma.[1]

73.3 PATHOPHYSIOLOGY

The pathophysiology of myxedema coma is incompletely understood. Thyroid hormones regulate cell function in many organs by binding intranuclear receptors and promoting expression of various enzymes.[10] Thyroid hormones exert chronotropic and inotropic effects in the heart, as well as catabolic, metabolic, calorigenic, and developmental effects in other organs.[10] Therefore decreased thyroid hormone function has a profound effect on many body systems. The clinical hallmarks of myxedema coma in human beings are altered mental status, inadequate thermoregulation, decreased respiratory and cardiovascular function, and concurrent disease.[9,11]

In human beings, altered mental status may be limited to disorientation, confusion, or lethargy.[9] Coma is unusual.[8,9] In dogs, clinical signs such as disorientation and confusion may be difficult to appreciate. Although most dogs in a hypothyroid crisis have mental dullness, coma upon initial examination is uncommon.[1,2,4-6] The pathophysiology of altered mental status is multifactorial and may be a result of decreased blood flow to the brain, hyponatremia, or lack of a direct effect of thyroid hormone on the brain.[9]

The pathophysiology of altered thermoregulation resulting in hypothermia is likely also multifactorial. Inadequate thyroid hormone function in the hypothalamus may result in inability to regulate body temperature.[9] Additionally, a decrease in the calorigenic effect of thyroid hormones contributes to hypothermia.[9] The body temperature of some individuals with myxedema coma may appear to be normal because of a concurrent infection and a fever.[9]

Hypoventilation develops secondary to decreased respiratory system responsiveness to hypoxia and hypercapnia, and may be complicated by obese body condition, muscle weakness, pneumonia, pericardial or pleural effusion, and ascites.[11] In the heart, thyroid hormones increase the number of β-adrenergic receptors and their affinity to catecholamines, thereby increasing the inotropic and chronotropic effects of catecholamines.[10] Hypothyroid cardiomyopathy is also caused by an increase in α-myosin heavy chains (MHC), which have decreased adenosine triphosphatase (ATPase) activity, and a decrease in β-MHCs, which have more adenosine triphosphatase activity.[10] These changes result in hypothyroid cardiomyopathy typified by impaired left ventricular function or atrial fibrillation.[12,13] During a hypothyroid crisis, cardiovascular dysfunction is characterized by bradycardia, decreased cardiac contractility, cardiac enlargement, and hypotension, although diastolic hypertension has also been documented.[11]

Concurrent disease may prevent normal compensatory mechanisms from responding appropriately to a hypothyroid crisis, and may therefore be involved in the pathophysiology of myxedema coma.[9] Absence of concurrent disease in most cases of hypothyroidism may explain why myxedema coma remains rare.

When myxedema does occur, it is thought to develop secondary to accumulation of the glycosaminoglycan hyaluronic acid in the dermis.[6,14] Impaired renal perfusion secondary to decreased cardiovascular function results in inability to excrete water and contributes to development of edema.[11] Excessive secretion of antidiuretic hormone may also contribute to fluid retention and edema in some patients.[15]

73.4 RISK FACTORS

Rottweiler dogs are at increased risk for myxedema coma.[1] Most dogs with myxedema coma are of middle age (median 6 years, range 4 to 10 years).[1] The age of dogs with myxedema coma is not significantly different from the age of other hypothyroid dogs. Female dogs do not appear to be at increased risk compared with other hypothyroid dogs, although myxedema coma is more common in women than in men.[1,8,11] Dogs with untreated hypothyroidism are at increased risk.[1-6]

Most dogs with myxedema coma have a concurrent disorder, most commonly an infection.[1] In a recent report of seven dogs in a hypothyroid crisis, concurrent disease was diagnosed in five.[1] Infection was diagnosed in four of the seven dogs.[1] Three of the four dogs with infection had aspiration pneumonia. Additional infections included foreign body keratoconjunctivitis, pyometra, severe bilateral otitis, and pyoderma.[1] The most commonly observed concurrent infections in humans with myxedema coma are pneumonia, influenza virus, urinary tract infection, and sepsis.[8]

Glucocorticoids were administered to three dogs with myxedema coma within 1 month of a hypothyroid crisis.[1,5] Oral prednisone at a dosage of 0.55 mg/kg q12h lowers the concentration of thyroid hormones in dogs.[16] Nonsteroidal antiinflammatory medications (carprofen and flunixin meglumine) were used in conjunction with glucocorticoids in one dog in a hypothyroid crisis.[1] Nonsteroidal antiinflammatory drugs (NSAIDs) may cause suppression of thyroid stimulating hormone (TSH) secretion.[17] It is therefore possible that administration of glucocorticoids to dogs with untreated hypothyroidism may increase the risk of myxedema coma. An association between NSAIDs, or other thyroid hormone synthesis–altering drugs, and canine myxedema coma may become apparent in the future.

Surgery increases the risk of myxedema coma in human beings and has been reported in three dogs with myxedema coma.[1,6] It is possible that surgery compromises the ability of normal cardiovascular and pulmonary compensatory mechanisms to respond to a hypothyroid crisis, and therefore increases the risk for such a crisis.[8]

Other factors that increase the risk of myxedema coma in human beings include burns, carbon dioxide retention, gastrointestinal hemorrhage, hypoglycemia, infection, hypothermia (most cases are diagnosed during the winter), stroke, trauma, and various medications including anesthetics, barbiturates, β-blockers, diuretics, narcotics, phenothiazines, and tranquilizers.[8]

73.5 CLINICAL SIGNS AND PHYSICAL EXAMINATION FINDINGS

Clinical signs and physical examination findings may be attributed to chronic untreated hypothyroidism, an acute hypothyroid crisis, or concurrent disease. Clinical signs commonly observed in dogs with chronic untreated hypothyroidism include weight gain or obese body condition, lethargy, mental dullness, weakness, and dermatologic abnormalities such as hyperkeratosis, alopecia, or thin hair coat.[7] In a recent study of seven dogs in a hypothyroid crisis, physical abnormalities included overweight or obese body condition (noted in five of seven dogs), nonpitting facial, jaw, or other edema (four of seven), tachypnea (four of seven), alopecia (three of seven), dehydration (two of seven), dermatitis (two of seven), otitis (one of seven), elevated or decreased body temperature (one dog each), heart murmur (one of seven), bradycardia (one dog), or tachycardia (one dog).[1] Neurologic findings included mental dullness (observed in five of seven dogs) and stupor (two of seven). None of the dogs was comatose.[1] In a literature review of five previously published manuscripts describing seven other dogs with myxedema coma, one dog was in a coma on initial examination,[3] although ultimately four of seven dogs developed coma.[2,4-6] Stupor was noted in six of these dogs.[2,4-6]

Most dogs in a hypothyroid crisis do not have all of the classic physical hallmarks including myxedema, hypothermia, bradycardia, hypoventilation, hypotension, and coma.[1,5,6]

73.6 CLINICAL PATHOLOGY

The most common abnormalities noted on complete blood count and serum chemistry screen are a mild nonregenerative anemia, hypercholesterolemia, lipemia, and increased alkaline phosphatase activity.[1] However, not all dogs with severe unregulated hypothyroidism have all of these clinicopathologic abnormalities, and normal cholesterol concentration or hematocrit has been documented in dogs with myxedema coma.[1,5,6] Although hyponatremia and hypoglycemia are well recognized in humans with myxedema coma and have been noted anecdotally in dogs, they were not noted in any of seven dogs in a hypothyroid crisis.[1] Urinalysis and urine culture results are usually normal.[1]

Nonregenerative anemia is associated with hypothyroidism for several reasons. Thyroid hormones bind thyroid hormone receptors on erythroid progenitors and act directly to increase erythroid proliferation.[18] Thyroid hormones also increase expression of the erythropoietin gene, further contributing to red blood cell formation.[18]

The mechanisms by which decreased thyroid hormone function induces dyslipidemia are widely studied and not fully understood. Alterations in both synthesis and transport of lipids are involved in the pathogenesis of hypothyroid dyslipidemia.[19] Decreased messenger ribonucleic acid (mRNA) expression of hepatic low-density lipoprotein (LDL) receptors results in fewer LDL receptors, decreased clearance of LDL by the liver, and elevated plasma LDL concentration.[19] High-density lipoprotein (HDL) subfraction concentration is also altered, with an increase in the subfraction HDL_2, attributed mainly to decreased hepatic lipase activity.[19]

Many possible explanations for hyponatremia have been investigated. These include increased renal reabsorption of sodium, impaired water clearance, increased antidiuretic hormone concentration, low plasma renin activity, and a low aldosterone concentration.[15] Hypoglycemia can develop secondary to reduced insulin clearance or may be observed in patients with concurrent hypoadrenocorticism.[8,20] Sepsis should also be considered in these cases.

Systolic hypotension is reported commonly in humans with myxedema coma, and is thought to develop secondary to bradycardia, decreased cardiac output, and hypovolemia.[8,11] Blood pressure was not measured in most reports of canine myxedema coma.[4-6,14] Systolic hypotension was documented in four of five dogs in which the blood pressure was measured.[1,2] Diastolic hypertension is also recognized in humans with myxedema coma and is believed to develop because of peripheral vasoconstriction and central shunting of blood that occurs as a result of hypothermia and low oxygen consumption.[11]

Hypoxia and hypercarbia are reported in humans with myxedema coma. Venous blood gas analysis has been 312
reported in seven dogs in a hypothyroid crisis.[1,2] Hypercarbia was documented in one of these dogs,[2] and the 313
arterial partial pressure of carbon dioxide ($PaCO_2$)was at the high end of normal in two other dogs[1] and normal in the remaining four dogs.[1] Lactate concentration was increased in five of the six dogs in which it was measured.[1]

Thyroid axis testing is performed to confirm the diagnosis of hypothyroidism. However, results often are not available immediately, and treatment of a hypothyroid crisis must begin before confirmation of a diagnosis. Serum should be stored for future analysis before thyroid hormone supplementation is begun. Severe lipemia can interfere with hormone measurement, further complicating the diagnosis.[1] Hypothyroidism is confirmed based on low thyroxine and high TSH concentrations, although some hypothyroid dogs do not have elevated TSH concentrations. Endogenous TSH concentration was normal in 63% of measurements in dogs with spontaneous hypothyroidism.[21]

73.7 DIFFERENTIAL DIAGNOSIS

Many of the clinical and clinicopathologic abnormalities observed in dogs with myxedema coma are nonspecific. Differential diagnosis for obesity, lethargy, mental dullness, weakness, dermatologic abnormalities, and nonregenerative anemia are discussed elsewhere. Some nonspecific differentials might include chronic inflammatory disease, cardiac disease, metabolic disease (i.e., hypoadrenocorticism), intracranial disease, hypothermia, and sepsis.

Differential diagnoses for edema can be divided into those caused by increased hydrostatic pressure, decreased oncotic pressure, lymphatic obstruction, sodium retention, and vascular endothelial leak syndromes. Such differential diagnoses include heart failure, constrictive pericarditis, ascites, venous obstruction or compression, heat, hormonal imbalance, protein-losing nephropathy or enteropathy, liver disease, malnutrition, neoplasia, renal hypoperfusion, sepsis, and excess secretion of renin, angiotensin, or aldosterone.

Differential diagnoses for hypercholesterolemia includes hypothyroidism, diabetes mellitus, hyperadrenocorticism, protein-losing glomerulopathy, cholestatic disease, postprandial hyperlipidemia, primary hyperlipidemia (Miniature Schnauzers, Shetland Sheepdogs), lipoprotein lipase deficiency (cats), idiopathic causes (Doberman Pinschers, Rottweilers), and iatrogenic causes (glucocorticoids).

73.8 TREATMENT

Treatment is divided into supportive care, thyroid hormone supplementation, and treatment of concurrent conditions. Hypotension can be treated cautiously with fluids and vasopressors (see Chapter 176, Vasoactive Catecholamines).[11] Dogs must be observed carefully for signs of fluid overload, which may exacerbate underlying cardiac disease or dysfunction. Hypothermia is treated by wrapping the dog with blankets and keeping the room warm.[11] Heating pads are avoided because they can lead to vasodilation and worsening hypotension.[11] If respiratory depression is profound, mechanical ventilatory support is needed.[1,2] Hyponatremia can be corrected slowly (no more than 0.5 mEq/hr) with 0.9% saline solution.[11]

Ultimately, clinical signs resolve with thyroid hormone supplementation. Thyroid hormone is usually administered before results of thyroid axis testing are available, and before the diagnosis of a hypothyroid crisis is confirmed. IV levothyroxine has a higher bioavailability than does oral levothyroxine, resulting in a more rapid clinical response. IV levothyroxine at a dosage of 5 µg/kg administered q12h is safe and effective in dogs in a hypothyroid crisis.[1] Adverse side effects of IV thyroid hormone supplementation in humans may be reduced with thyroxine (T_4) rather than with intravenous triiodothyronine (T_3).[22,23] Such adverse side effects include cardiac arrhythmias, angina pectoris, and pneumonia.[23] Mortality of humans with myxedema coma is increased with high dosages of IV levothyroxine (>500 µg/24 hours, which is equivalent to about 7 µg/kg/24 hours).[24] Dogs should be monitored closely for these complications. Administration of IV levothyroxine may have led to the development of pneumonia in two dogs.[1] When the hypothyroid crisis is resolved, the oral route can be used (0.1 mg/5 to 7 kg PO q12h).[7]

Treatment of concurrent disease such as pneumonia, other infections, cardiac disease, concurrent endocrinopathy, or any other illness will facilitate recovery. Discontinuation of any medication that may have exacerbated the hypothyroid crisis is also recommended.

73.9 OUTCOME

Most dogs with myxedema coma respond well to therapy when given IV levothyroxine.[1,3] Seven of eight reported dogs that received IV levothyroxine were discharged from the hospital (87%).[1,3] Subjective improvement in mentation or ambulation occurs within 24 to 30 hours of administration of IV levothyroxine in most dogs.[1] Severity of concurrent disease, persistent hypothermia, advanced age, and degree of mental alteration (coma) is associated with a poor prognosis in humans.[25]

74 Chapter 74 Pheochromocytoma

Benjamin M. Brainard, VMD, DACVA, DACVECC

Deborah C. Mandell, VMD, DACVECC

74.1 KEY POINTS

- Pheochromocytoma is a tumor of the chromaffin cells of the adrenal medulla.
- Clinical signs may include hypertension and manifestations of hypertension, weakness, syncope, lethargy, vomiting, diarrhea, tachypnea, abdominal distention, tachyarrhythmias, and/or abdominal pain.
- Most pheochromocytomas in small animals are diagnosed either by abdominal imaging or during postmortem examination.
- Definitive treatment for a pheochromocytoma is surgical excision.
- Preoperative, perioperative, and postoperative treatment may be challenging.
- With complete surgical resection and an uneventful postoperative course, even dogs with vena caval thrombi may experience a significant survival time, reported from 18 months to 3 years.

74.2 INTRODUCTION

Pheochromocytoma is a tumor of the chromaffin cells of the adrenal medulla. These cells synthesize, store, and secrete catecholamines in response to sympathetic stimulation (Color Plates 74-1 and 74-2).[1] Chromaffin cells are also termed APUD cells, because they are responsible for amine precursor uptake and decarboxylation. Pheochromocytoma may occur alone, or as part of the multiple endocrine neoplasia syndrome. In humans this is a heritable constellation of two or more endocrine neoplasias (or hyperplasia), usually involving the parathyroid and thyroid glands in addition to the adrenal gland.[2] Extraadrenal pheochromocytomas (paragangliomas) occur rarely. Most (48% to 80%) of pheochromocytomas in small animals and 30% to 76% in humans are diagnosed on postmortem examination, or as incidental findings on abdominal ultrasonography, and the patient may be clinically asymptomatic.[1,3-5] It is thought that pheochromocytomas represent between 0.01% and 0.13% of all canine tumors; however, this number may be low, because the tumor may be benign or nonfunctional and thus not suspected.[6] These tumors may be both locally invasive and metastatic.[3,5] Most pheochromocytomas in humans secrete norepinephrine (NE) (versus epinephrine), but this has not been studied in dogs or cats.[2] It is thought that negative feedback of NE on tyrosine hydroxylase (which converts tyrosine to dopa, leading to synthesis of more NE) does not work normally in the tumor cells, or that the tumor metabolizes NE so quickly that the levels required for negative feedback are never reached.[2]

74.3 CLINICAL SIGNS

In dogs with a pheochromocytoma, approximately 30% to 50% have clinical signs attributable to the tumor. Dogs tend to be older (10 to 12 years),[1,5,8] and there is no gender predilection.[7,8] Clinical signs may include hypertension, manifestations of hypertension (e.g., blindness from retinal detachment), weakness, collapse, lethargy, vomiting, diarrhea, tachypnea, abdominal distention, syncope, tachyarrhythmias, and/or abdominal pain.[5,8] These signs may be sustained or paroxysmal. Because the pheochromocytoma is not innervated like a normal adrenal gland, it is unclear what stimuli cause secretion of catecholamines from the tumor. A Budd-Chiari–like syndrome resulting from tumor invasion and extension up the caudal vena cava has been reported in a dog.[9] Approximately 15% to 38% of dogs with a pheochromocytoma have neoplastic invasion of the caudal vena cava; however, clinical signs are not reliably associated with the extent or presence of vena caval invasion.[6,10]

Concurrent pheochromocytoma and hyperadrenocorticism have been reported in six dogs, and some clinical signs (e.g., panting) may overlap.[11] Rupture of pheochromocytomas may result in hemoperitoneum or hemoretroperitoneum.[12,13] Dogs may exhibit neurologic deficits or paraparesis secondary to metastatic tumor in the spinal canal, or secondary to aortic thromboembolic disease.[5,6,8] Cardiac arrhythmias may include third-degree atrioventricular block, supraventricular tachycardia, or ventricular ectopy.

Of the few cats in the literature with an antemortem diagnoses of a pheochromocytoma, clinical signs consisted of lethargy, vomiting, polyuria, polydipsia, or were associated with systemic hypertension (congestive heart failure and retinal detachment).[14-16]

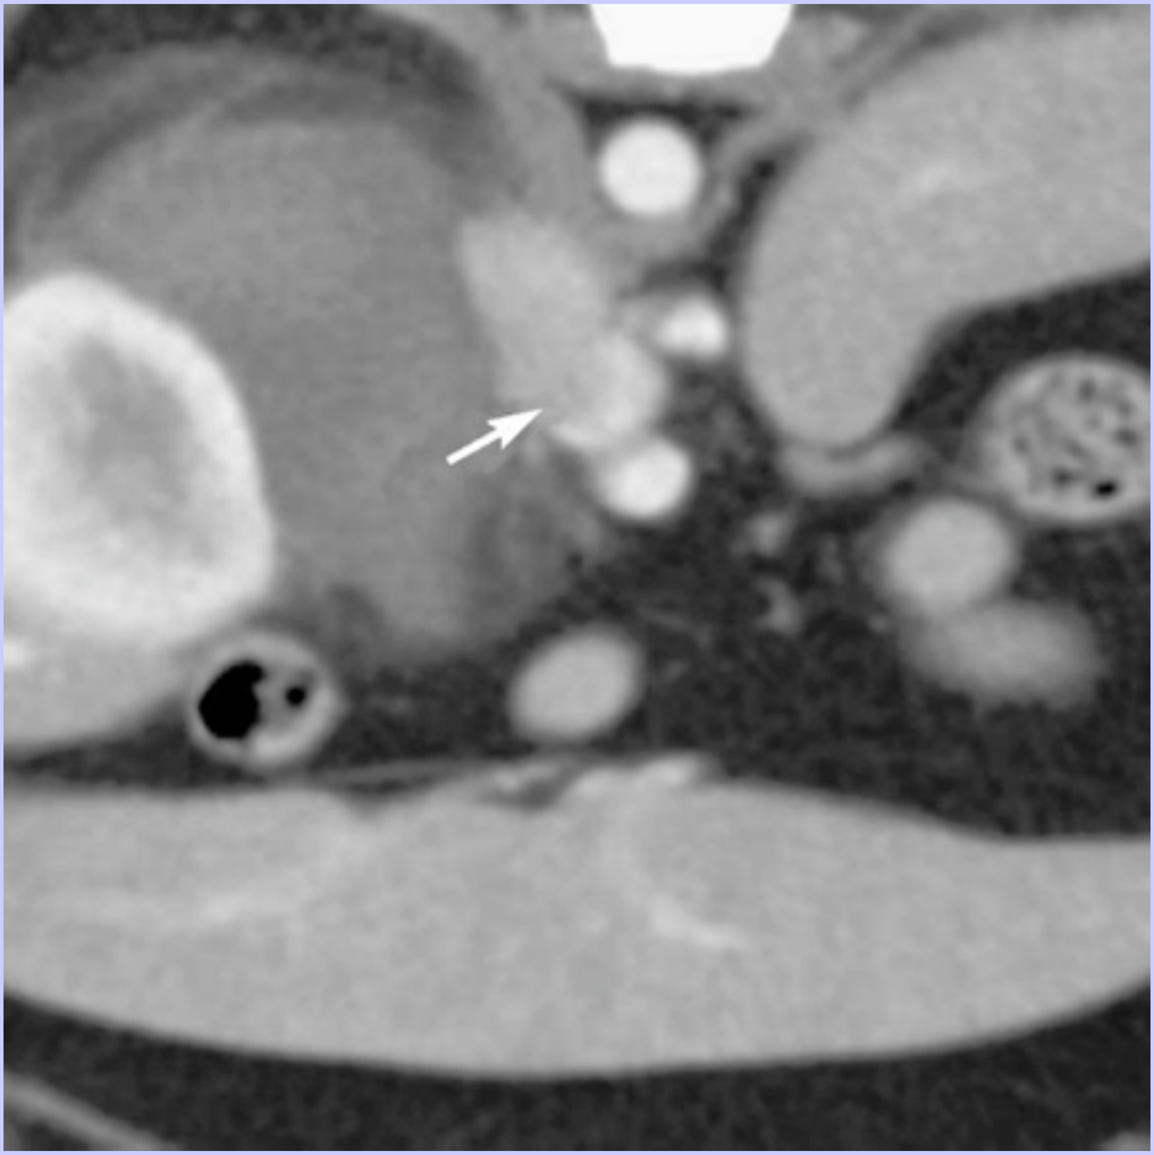
74.4 DIAGNOSIS

As in humans, most pheochromocytomas in small animals are incidental findings, diagnosed by abdominal imaging or postmortem examination. In some dogs, an abdominal mass may be palpated.[5,8]

Abdominal radiography may show mineralization in the area of the adrenal glands, or may demonstrate retroperitoneal effusion or an abdominal mass effect associated with the tumor (30% to 50% of cases).[5,18] Chest radiographs may show cardiomegaly and pulmonary venous congestion or pulmonary edema secondary to chronic hypertension or tachycardia.[1,5] These findings may be confirmed via echocardiography.[7] Rarely, metastatic disease may be seen on thoracic radiographs.[7,8]

Sixty-five to eighty-three percent of pheochromocytomas in dogs are detected via abdominal ultrasonography, making it a useful first-line imaging modality.[2] The origin and architecture of the mass, as well as blood flow within the mass and invasion into adjacent structures, may be determined. Pheochromocytomas seem to have a 314 higher likelihood for 315 vena caval invasion than do adrenocortical tumors,[16] but ultrasonographically they appear similar to adenocarcinomas.[17] It is difficult to determine the cellular origin of an adrenal mass based on ultrasonography, and some masses may be too small for detection by this means.[1,2] Invasive pheochromocytomas have been reported to invade not only the vena cava, but also the aorta, renal veins, and hepatic veins.[10] Ultrasound-guided biopsies may be obtained, if indicated, but caution should be exercised.

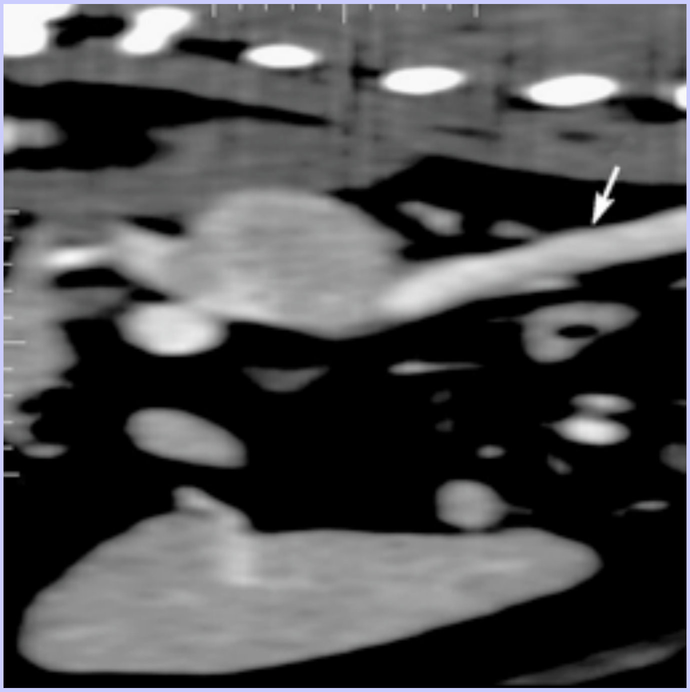
Figure 74-1 Transverse helical postcontrast computed tomography image at the level of the cranial pole of the right kidney. A right adrenal mass is seen, and a large filling defect is present in the caudal vena cava at that level *(arrow)*. This mass was determined to be a pheochromocytoma by histopathology.



Advanced imaging techniques such as computed tomography (CT) or magnetic resonance imaging (MRI) are very helpful for determining the size of the tumor and the extent of tumor invasion, although these require general anesthesia in the veterinary patient. Nonionic, low-osmolar contrast media is recommended for CT studies to minimize adverse reactions.[18] Gadolinium contrast for MRI studies is not contraindicated in patients with a suspected pheochromocytoma.[19] CT findings in dogs with pheochromocytoma show a lobulated, irregularly shaped mass associated with the adrenal gland. Areas of decreased intensity are interspersed with highly vascular areas with increased intensity (Figures 74-1 and 74-2).[18] MRI may be used to differentiate between histologic types of adrenal tumors.[2] Scintigraphy using ^{123}iodinemetaiodobenzylguanidine (an NE analog) or ^{99m}technetium-methylene diphosphonate has been used in the dog to identify a pheochromocytoma.[20,21] One group used p-[^{18}F]fluorobenzylguanidine to identify tumors in dogs using positron emission tomography.[22] These techniques are useful for identifying metastatic tumors.

Laboratory test results in animals with a pheochromocytoma are generally unremarkable. In dogs, a mild nonregenerative anemia may be present secondary to chronic disease, or an increased mean cell volume or packed cell volume may be seen secondary to catecholamine or erythropoetin-like stimulation of the bone marrow.[1] A regenerative anemia may reflect hemorrhage from the tumor.[3] Leukocytosis or a stress leukogram may be found secondary to catecholamine release or inflammatory changes associated with the tumor.[2,3] If there has been hemorrhage or intravascular coagulation from the tumor, a consumptive thrombocytopenia may occur. Evidence of hypercoagulability may be present, but this has not been investigated in veterinary medicine (see Chapter 117, Hypercoagulable States).

Figure 74-2 Sagittal reconstruction of the helical computed tomography scan in Figure 74-1 showing invasion of the caudal vena cava along the length (4 cm) of the mass. Irregular filling of the cava is present cranial and caudal to the mass, likely representing thrombus formation. The cranial aspect of the caudal vena cava is denoted with an *arrow*.



Serum chemistry profiles may be normal, or may show elevations in liver enzymes (unrelated to liver metastasis).[3,7] Dogs with multiple endocrine neoplasia syndrome may be hypercalcemic as a result of elevated parathyroid hormone or parathyroid hormone–related peptide (PTH or PTH-rp). Dogs may be hyperglycemic from catecholamine stimulation of hepatic glucose production and decreased insulin release from α-receptor stimulation.[1] Pheochromocytomas may also secrete hormones such as vasoactive intestinal peptide, which may contribute to clinical signs such as diarrhea. In two retrospective reports of dogs with pheochromocytoma, hypercholesterolemia was present in 25% of dogs, possibly secondary to increased fat mobilization from catecholamine secretion or due to concurrent hyperadrenocorticism.[7,8]

In 20 dogs with a pheochromocytoma, but without concurrent disease, 50% showed proteinuria, likely caused by a hypertensive glomerulopathy.[2] Measurement of urinary catecholamine concentrations (metanephrine, normetanephrine, vanillylmandelic acid) as a spot check referenced to urine creatinine, or over a 24-hour period, is performed in humans with suspected pheochromocytomas and has been investigated in dogs.[7] Secondary factors, such as excitement, exercise, vanilla-containing foods, and radiographic contrast agents may result in false-positive elevations.[2]

Because of the similarity in clinical signs and ultrasonographic appearance of pheochromocytomas and adrenocortical tumors, and reports of the coexistence of hyperadrenocorticism and pheochromocytoma, hyperadrenocorticism should be ruled out at the time of medical workup.[8]

Other tests reported in humans include the clonidine suppression test, which should decrease serum catecholamine levels in normal patients but not in patients with a functional pheochromocytoma (because catecholamine release
from the tumor is not neurally mediated). The administration of intravenous phentolamine, an α-adrenergic 315
antagonist, to hypertensive patients will cause a decrease in blood pressure if the hypertension is catecholamine 316
mediated (close monitoring is vital). These tests have varying sensitivity and specificity, especially in the context of paroxysmal hypertension, and have not been evaluated thoroughly in veterinary patients.[2]

Provocation tests using metoclopramide, histamine, tyramine, and glucagon, all of which cause increased secretion of catecholamines from the tumor, are not recommended because of the potential for inducing acute hypertensive crises.[2] For this reason, the use of metoclopramide as an antiemetic in patients with suspected pheochromocytoma may be contraindicated.

Because hypertension and tachycardia may be paroxysmal, blood pressure and electrocardiogram (ECG) monitoring should be performed, but results may be low yield. Holter or continuous ECG monitoring may be necessary for the diagnosis of intermittent tachyarrhythmias.

The results of a biopsy or fine-needle aspiration of adrenal tumor masses are not discussed at length in the literature. This may be partially due to the difficulty of safely obtaining samples, or because excisional biopsy is preferred. Gilson and others note a similarity in cytologic appearance between lymphosarcoma and pheochromocytoma when diagnosed from ascitic fluid in three dogs, so an adequate index of suspicion is necessary to prevent misdiagnosis.[7] Impression smears of a pheochromocytoma may also appear similar to a round cell tumor.[5] In addition, it is difficult to characterize relative malignancy on the basis of histopathologic evaluation, so it may be difficult to accurately predict tumor behavior on the basis of biopsy specimens.[7] Any tumor that demonstrates invasion of adjacent structures should be considered malignant.

74.5 TREATMENT

Definitive treatment for pheochromocytoma is surgical excision. Surgery is often complicated, and may necessitate vena caval venotomy or nephrectomy to fully remove or debulk the tumor. A recent study found an overall mortality rate of 22% after removal of adrenal tumors in dogs, which was not correlated with vena caval invasion or tumor type.[17] A thorough abdominal exploration is recommended during surgery to identify gross metastatic disease. In a study of 61 dogs, 15% showed metastasis and 39% had locally invasive tumors.[8] In this study, concurrent neoplasia of various cellular origins was identified in 54% of the dogs.

Noncompetitive α-adrenergic blockade with phenoxybenzamine (0.5 to 2.5 mg/kg PO q12h) should be instituted at least 1 week before anesthesia for surgical resection of the tumor. This may help to blunt hypertensive episodes during anesthesia, although high dosages may be necessary.[17] In humans, preoperative α-adrenergic blockade decreased perioperative mortality associated with resection of pheochromocytoma from 13% to 45% to 0 to 3%.[25] α-Methyl-para-tyrosine competitively inhibits tyrosine hydroxylase, interfering with catecholamine biosynthesis.[23] It may be a useful drug for patients with pheochromocytoma, although there are limited reports of its use in dogs or cats, none of which had a pheochromocytoma.

Chronic sympathetic stimulation and vasoconstriction may result in intravascular volume depletion, which should be assessed and corrected before the induction of anesthesia.

Anticholinergic drugs that cause tachycardia and barbiturate agents that may cause ventricular arrhythmias in the presence of excess catecholamines should be avoided for anesthetic premedication and induction. Long-lasting α-adrenergic antagonists such as acepromazine may complicate intraoperative or postoperative treatment and should be avoided, especially if the animal has been pretreated with phenoxybenzamine. A safe induction protocol includes an opioid, such as oxymorphone, hydromorphone, or fentanyl (minimal histamine release), combined with a benzodiazepine and propofol or etomidate to facilitate endotracheal intubation. Inhalant agents such as isoflurane or sevoflurane are preferred to halothane, which sensitizes the myocardium to catecholamine-induced arrhythmias. Desflurane can cause sympathetic stimulation and should be avoided. There are no contraindications to the use of nitrous oxide in humans undergoing surgery for pheochromocytoma.[23] Inhalant agents may be supplemented with balanced anesthetic techniques using potent opioids such as fentanyl, administered as a constant rate infusion (0.7 to 2 μg/kg/min).

Intraoperative monitoring must include ECG and arterial blood pressure (preferably direct), as well as central venous pressure to estimate intravascular volume. Pulmonary arterial catheterization will give information about cardiac output and systemic vascular resistance that may help to tailor fluid and drug therapy during and after surgery; however, placement of these catheters may be associated with increased morbidity (see Chapter 50, Pulmonary Artery Catheterization).[23]

During anesthesia, treatment with short-acting β-blocking drugs such as esmolol (0.1 to 0.5 mg/kg IV followed by 0.5 to 2 μg/kg/min IV), or vasodilators such as nitroprusside (0.2 to 10 μg/kg/min IV), may be necessary to maintain normal hemodynamics (see Chapters 178 and 191, Antihypertensives and β-Blockers, respectively). Some human reports advocate magnesium sulfate for vasodilation during surgery for pheochromocytoma.[24] Supraventricular tachycardia (SVT) is a common arrhythmia during surgery, although bradycardia with atrioventricular block and ventricular premature complexes have also been seen. Lidocaine may be used to treat ventricular arrhythmias (see Chapter 190, Antiarrhythmic Agents). Before surgery, blood type and crossmatch to multiple units of packed red blood cells or fresh whole blood should be performed in case of severe intraoperative hemorrhage. Blood pressure during anesthesia in the hypertensive animal should be maintained at levels close to its resting blood pressure to prevent renal hypoperfusion, and urine output should be measured intraoperatively. If a venotomy is anticipated for removal of a thrombus, external cooling of the patient may be of benefit to protect tissues during intraoperative interruption of blood flow and ischemia.[16] Surgical manipulation of the tumor may cause catecholamine release. Alternatively, removal of the tumor may result in cardiovascular collapse from lack of catecholamines, requiring supplementation with sympathomimetic drugs such as phenylephrine (0.5 to 10 μg/kg/min IV) or norepinephrine (0.1 to 3 μg/kg/min IV) (see Chapter 176, Vasoactive Catecholamines).

Postoperatively, hypertension may or may not resolve, even with full excision of the tumor.[7] If bilateral adrenalectomy has been performed, supplementation with glucocorticoids and mineralocorticoids will be necessary. Postoperative hypotension or cardiovascular collapse is possible, and a decreased sensitivity to catecholamines from chronic stimulation may require noncatecholamine pressors such as vasopressin to maintain adequate blood pressure.[25] Blood glucose should be monitored postoperatively, because the removal of sympathetic stimulation may cause hypoglycemia.

Functional adrenocortical tumors may be associated with pulmonary thromboembolic disease; however, the association in the context of pheochromocytoma is unclear. If an animal is suspected to be hypercoagulable, postoperative anticoagulation with heparin may be indicated.

In animals with symptomatic pheochromocytomas that are nonresectable or metastatic, in which surgical resection is not likely to be successful, medical treatment with phenoxybenzamine, oral β-blockers, or other antiarrhythmic agents is indicated to alleviate some clinical signs. β-Blockers should not be administered without concurrent α-blockade, because the loss of β_2-receptor–mediated vasodilation may exacerbate hypertension. Other therapy directed more specifically toward the clinical signs (e.g., diuretics to treat ascites) may also be indicated. Chemotherapeutic or radiotherapeutic treatment of pheochromocytoma in small animals has not been reported; however, it has been unrewarding in human medicine.[5]

74.6 PROGNOSIS

Extensive information on prognosis after surgical resection or medical treatment of pheochromocytoma is not available. According to the studies that have been published, larger tumors with invasion of neighboring structures may indicate a poorer prognosis. Gilson reported that factors such as neurologic deficits, weight loss, and abdominal distention may be associated with a poorer prognosis in dogs.[7] In humans, histopathologic analysis which shows multiploidy (e.g., aneuploidy or tetraploidy) in the nuclear DNA of the tumor cells has been associated with poorer prognosis.[26]

With complete resection and uneventful recovery from surgery, even dogs with vena caval thrombi may experience significant survival, reported from 18 months to 3 years.[2,8,16] Many dogs, however, experience significant complications during the first 24 to 72 hours postoperatively.[16] In one study, 51% (20 of 39) dogs experienced postoperative complications after resection of adrenal tumors. These included ventricular tachyarrhythmias, dyspnea, disseminated intravascular coagulopathy, abdominal incisional dehiscence, internal hemorrhage, and vomiting.[16] One dog in this group experienced refractory hypertension after removal of a pheochromocytoma. Tumor type (adrenocortical versus pheochromocytoma) or presence of caval thrombi was not related to complications. Seven of eleven dogs with pheochromocytoma experienced perioperative morbidity after resection of the tumor.[16]

In the limited studies available, recurrence of primary tumor or of metastatic disease is rare.[8] In the nine dogs that survived surgical resection of a pheochromocytoma in the study by Kyles and colleagues recurrence of clinical signs or tumor-related death was not reported, with a median follow-up time of 9 months (range from 1 to 36 months).[16]

75 Chapter 75 Relative Adrenal Insufficiency

Jamie M. Burkitt, DVM, DACVECC

75.1 KEY POINTS

- Cortisol is an important hormone involved in modulation of inflammation and regulation of vascular tone.
- Relative adrenal insufficiency (RAI) is common in humans with sepsis and other types of critical illness.
- Human patients with RAI have poor vascular responsiveness and worse survival than those with normal hypothalamic-pituitary-adrenal axis (HPA) function.
- The best method for diagnosing RAI is unknown.
- Low dosages of hydrocortisone improve pressor responsiveness and survival in humans with RAI and septic shock.
- RAI likely occurs in a subpopulation of critically ill dogs and cats.
- Appropriate methods for the diagnosis and management of RAI in dogs and cats are unknown.

75.2 INTRODUCTION

Cortisol is a hormone released by the adrenal glands in small amounts in a circadian rhythm, and in larger amounts during times of physiologic stress. It has many important homeostatic functions including regulation of carbohydrate, lipid, and protein metabolism; immune system modulation; ensuring proper production of catecholamines and function of adrenergic receptors; and stabilizing cell membranes. A classic example demonstrating the importance of cortisol function is the patient with glucocorticoid-only hypoadrenocorticism. Patients with minimal endogenous corticosteroid production show clinical signs of gastrointestinal disturbance, weight loss, and collapse, particularly in stressful situations. These patients can be treated successfully with glucocorticoid supplementation.

Serum cortisol concentration is determined by the hormonal cascade and negative feedback mechanisms of the hypothalamic-pituitary-adrenal (HPA) axis. The hypothalamus produces corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH). ACTH in circulation stimulates the zona fasciculata and zona reticularis of the adrenal gland to produce and release cortisol. Cortisol has negative feedback action on both the hypothalamic release of CRH and the pituitary release of ACTH. Thus, when circulating cortisol concentration is low, CRH and ACTH will increase, stimulating the adrenal glands to produce more cortisol. The increased serum cortisol concentration inhibits the release of more CRH and ACTH.

Research over the past decade has shown that abnormalities of HPA axis function are common in human patients with severe sepsis and septic shock, conditions that frequently carry a mortality rate of 50% or more in both human and veterinary medicine.[1-5] Many well-conceived and well-performed clinical studies have found RAI, also called *critical illness-related corticosteroid insufficiency (CIRCI),* in up to 77% of human patients with severe sepsis and septic shock.[1,6-9] Unlike patients with classic hypoadrenocorticism, those with critical illness-associated RAI usually have normal to elevated basal serum cortisol concentration, but a blunted cortisol response to an ACTH stimulation test. Therefore their adrenal dysfunction truly is relative—it is believed that although the adrenal glands can make and release cortisol, the quantity is inadequate for the degree of physiologic stress. Following recovery from sepsis, HPA axis dysfunction resolves.[10]

75.3 ASSOCIATED PRIMARY ILLNESSES

Patients with relative adrenal insufficiency (RAI) include humans with severe sepsis and septic shock,[1,6-9] severe hepatic disease,[11] acute myocardial infarction,[12] and hemorrhagic shock.[13] It is important to note that although many illnesses are associated with RAI, all humans who have RAI are critically ill; RAI has not been documented in patients with localized infections, mild to moderate hepatopathy, or stable heart disease.

75.4 SUSPECTED PATHOPHYSIOLOGY

The underlying mechanisms of RAI are unknown. Studies have suggested that the inflammatory cytokines interleukin-6[14,15] or tumor necrosis factor,[16,17] or corticostatin peptides produced by immune cells[18] may interfere with HPA axis function. Also, there have been reports of RAI associated with adrenal hemorrhage in critically ill humans.[19,20] Adrenal hypoperfusion and microvascular disease from disseminated intravascular coagulation may contribute. Even if glucocorticoids are produced in adequate amounts in critically ill patients, they may not be able to exert their effects. There is evidence that corticosteroid receptor numbers may be decreased in patients with hemorrhagic and septic shock.[21] Cytokines may cause corticosteroid receptor dysfunction.[22]

75.5 SPECIES AFFECTED

It is widely accepted that RAI occurs in critically ill humans but strong evidence of RAI does not yet exist in veterinary medicine. One study of 20 dogs sequentially admitted to a veterinary intensive care unit failed to find HPA axis abnormalities in any patients,[23] although another study in critically ill septic dogs found a 48% incidence of RAI.[24] A study in cats admitted to an intensive care unit did not demonstrate RAI in septic cats, but did find HPA axis abnormalities in cats with neoplasia.[25] Another study showed a decreased response to exogenous ACTH in septic cats compared with a group of normal cats.[26] Thus it appears that RAI probably occurs in some subpopulations of critically ill dogs and cats. Clinical evidence in other species is unavailable.

75.6 CLINICAL MANIFESTATIONS

The most common clinical abnormality associated with RAI in humans with septic shock is hypotension refractory to fluid loading. Studies have shown that RAI is associated with decreased pressor responsiveness in human patients that is reversed with glucocorticoid administration.[27] In vitro studies have shown that smooth muscle adrenergic receptor expression is modulated by glucocorticoids.[28,29] One human clinical study showed that myocardial adrenergic receptor down-regulation in shock could be reversed by glucocorticoids.[30] Another study investigating the phenylephrine–mean arterial pressure relationship in humans with septic shock showed that physiologic dosages of hydrocortisone normalized vasomotor response to the drug,[31] underscoring the clinical importance of glucocorticoids in smooth muscle response to catecholamines.

Human patients with RAI may be more likely to die than those with similar illness severity and an intact HPA axis.[32-34] Preliminary data from a study in septic dogs suggests that those with RAI may be more likely to die than those with normal HPA function.[24]

75.7 DIAGNOSIS

There is no consensus in the human medical community regarding the identification of patients with RAI. A variety of tests have been used, including basal cortisol concentration, ACTH-stimulated cortisol concentration, the difference in cortisol concentration when subtracting baseline from stimulated cortisol concentration (δ-cortisol), the relationship between endogenous ACTH concentration and basal cortisol concentration, and combinations of these methods. When stimulated or δ-cortisol concentration is used in the diagnosis, questions remain regarding the appropriate dosage of synthetic ACTH to be administered. Many human studies have used a single 250-μg injection,[1,7,9] but some authors suggest using a total dosage of 1 μg per adult human.[35] Studies have found differences in the incidence of RAI depending on whether they administer a 250-μg or a 1-μg dose of ACTH, thus further complicating the diagnosis.[6,8]

The best way to identify critically ill patients with HPA axis dysfunction is unclear. Indeed, it is unknown for any individual exactly how much cortisol is needed or optimal for a given severity of illness. Hence, the diagnosis of RAI from a population perspective may ultimately prove impossible.

75.7.1 Human Data

A study in humans with septic shock found that a baseline cortisol level less than or equal to 34 μg/dl combined with a δ-cortisol level of 9 μg/dl or more in response to 250 μg ACTH was associated with a relatively good prognosis (28-day mortality 26%), although baseline cortisol concentration over 34 μg/dl combined with a δ-cortisol level of less than 9 μg/dl was associated with a very poor prognosis (28-day mortality 82%).[34] Likely because this protocol successfully predicted outcome, the 250-μg ACTH stimulation test is commonly used to diagnose RAI in human medicine. Blood is collected for basal serum cortisol concentration, contents of a single 250-μg vial of synthetic ACTH is injected intravenously, and a poststimulation cortisol concentration is determined 1 hour later. The basal cortisol concentration is then subtracted from the stimulated value, which yields the δ-cortisol value. In humans, a δ-cortisol concentration of less than 250 nmol/L (<9 μg/dl) is generally considered diagnostic for RAI, although many studies have used different criteria.

75.7.2 Veterinary Data

No clinical veterinary studies have been performed to determine how best to diagnose RAI in dogs and cats. Although studies exist in the veterinary literature investigating the presence of RAI in these species, none of the investigations has surveyed critically ill patients to see if there is a specific HPA axis abnormality associated with increased mortality. We have performed a study to determine whether RAI occurs in dogs with sepsis using a standard 1-hour 250-μg ACTH stimulation test. As part of this study, we performed ACTH stimulation tests in a group of normal dogs, then arbitrarily used a δ-cortisol level one-half that of the lowest control dog (δ-cortisol 5.7 μg/dl) to define RAI. Using this definition, we found that a δ-cortisol concentration less than or equal to 2.8 μg/dl in septic dogs was associated with nonsurvival when compared with dogs with δ-cortisol values more than 2.8 μg/dl.[24] Therefore using the δ-cortisol cutoff value of 2.8 μg/dl may be an appropriate preliminary method for diagnosing RAI in septic dogs, because it appears to be associated with outcome. Note, however, that the cutoff of 2.8 μg/dl was arbitrary and likely does not represent the best value for diagnosis. Further study of larger populations of critically ill dogs is required to determine the best way to diagnose RAI in this population.

The studies performed in cats have used basal cortisol concentrations, stimulated cortisol concentrations, and δ-cortisol values. The ACTH stimulation test was performed using 125 μg synthetic ACTH injected intravenously with samples collected 1 hour later for determination of poststimulated cortisol concentration.[25,26] A cutoff value for RAI was not proposed in either study, but Costello and colleagues found that septic cats had a mean δ-cortisol value of 2.3 μg/dl (SD ± 2.5 μg/dl) whereas the mean δ-cortisol concentration in normal cats was 6.5 μg/dl (SD ± 4.6).[26] Note that although the mean δ-cortisol value in septic cats was significantly lower than that in normal cats, the ranges likely overlap. Thus, although RAI appears to occur in cats, appropriate diagnostic criteria are undetermined.

75.8 TREATMENT

75.8.1 Human Data

Human patients with documented RAI that are treated with supplemental doses of hydrocortisone are more likely to be weaned from pressors* and ultimately survive[1,9,11] than patients with RAI that do not receive steroid supplementation. Studies over the decades have repeatedly failed to show benefit when large dosages of steroids (i.e., 30 to 120 mg/kg methylprednisolone per day) are used in septic patients. These high dosages for septic human and veterinary patients are out of favor, because their use is not supported by clinical evidence.[38-40] The dosages of steroids used to manage RAI are significantly smaller, called *supplemental, physiologic, low-dosage,* or *replacement* in the literature. Most human studies have used a protocol of 200 to 300 mg q24h of hydrocortisone for a 70-kg human (2.9 to 4.3 mg/kg q24h). Hydrocortisone is one-fourth as potent as prednisone and one thirtieth as potent as dexamethasone. Therefore this supplemental steroid dosage is 0.7 to 1 mg/kg q24h of prednisone equivalent or 0.1 to 0.4 mg/kg q24h of dexamethasone equivalent. Thus one can see how much lower these steroid dosages are than those commonly used for treatment of endotoxemia and shock.[41] The higher dosages are not supported by clinical evidence and should not be used.

Human studies have used various protocols to administer the 200 to 300 mg hydrocortisone q24h. Some studies have divided the total daily hydrocortisone dosage into four equal bolus doses every 6 hours, and others have started with an initial dosage of 0.7 mg/kg hydrocortisone as a bolus followed by a constant rate infusion to attain total daily dosage from that point forward.

* References 1, 6, 9, 11, 36, 37.

75.8.2 Veterinary Data

There is no clinical evidence to determine whether dogs and cats with RAI would benefit from low-dosage steroid supplementation. In our hospital, dogs and cats with septic shock (hypotension despite adequate fluid loading determined by central venous pressure or pulmonary artery occlusion pressure measurements) are treated at the clinician's discretion with 2.9 to 4.3 mg/kg q24h of hydrocortisone after undergoing a standard 1-hour ACTH stimulation test. This total daily dosage is split into four equal intravenous doses given every 6 hours. It seems reasonable to continue steroid therapy only in patients who have either a low δ-cortisol concentration (≤2.8 μg/dl for dogs; unknown for cats) or in those that show significant improvement in cardiovascular status within 24 hours of starting the drug. We have no direct clinical evidence to support the use of steroids in veterinary patients.

75.9 PROGNOSIS

Human patients with RAI have a worse prognosis than those with normal HPA axis function. However, with supplemental hydrocortisone therapy, patients with RAI may have the same prognosis as those with normal HPA axis function and the same severity of illness.[1] If the patient survives the primary underlying illness, prognosis for return of normal HPA axis function is good.[10]

76 Chapter 76 Hypoadrenocorticism

Jamie M. Burkitt, DVM, DACVECC

76.1 KEY POINTS

- Hypoadrenocorticism is uncommon in the dog and rare in the cat.
- Primary hypoadrenocorticism is due to failure of the adrenal glands, whereas secondary hypoadrenocorticism is due to pituitary or hypothalamic malfunction.
- Young to middle-aged female dogs are predisposed.
- Certain breeds are overrepresented, but most dogs with Addison's disease are of mixed breeding.
- Diagnosis is challenging because signs and clinicopathologic findings of hypoadrenocorticism mimic many other disease processes.
- Definitive diagnosis is by adrenocorticotropic hormone (ACTH) stimulation test, ideally coupled with an endogenous ACTH concentration.
- Treatment of the animal in crisis consists of aggressive, appropriate fluid resuscitation followed by hormone replacement.
- Electrocardiographic (ECG) changes associated with hyperkalemia can be life threatening and must be treated promptly and appropriately.
- Cats may require 3 to 5 days for a good clinical response to therapy.
- Long-term prognosis is very good with lifelong hormone supplementation.

76.2 INTRODUCTION

The adrenal cortex is responsible for secreting many important hormones including cortisol and aldosterone. Cortisol is a glucocorticoid released in small amounts in a circadian rhythm, and in larger amounts during times of physiologic stress. It has many important homeostatic functions including regulation of carbohydrate, lipid, and protein metabolism; modulation of immune system function; ensuring proper production of catecholamines and function of adrenergic receptors; and stabilizing cell membranes. Serum cortisol concentration is determined by the hormonal cascade and negative feedback mechanisms of the hypothalamic-pituitary-adrenal axis. The hypothalamus produces corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH). ACTH in circulation stimulates the zona fasciculata and zona reticularis of the adrenal cortex to produce and release cortisol. Cortisol has negative feedback action on both the hypothalamic release of CRH and the pituitary release of ACTH. Thus, when circulating cortisol concentration is low, CRH and ACTH will increase, stimulating the adrenal glands to produce more cortisol. The increased serum cortisol concentration inhibits the release of more CRH and ACTH.

Aldosterone is a mineralocorticoid released from the zona glomerulosa of the adrenal cortex under the influence of a complex hormonal cascade that starts in the kidney. Its main purposes are to maintain normovolemia and enhance potassium excretion. When effective circulating volume is depleted, glomerular filtration decreases. The macula densa, a group of specialized cells in the distal portion of the thick ascending loop of Henle, senses decreased filtrate (specifically chloride) delivery. The macula densa then induces renin release from the nearby juxtaglomerular cells of the afferent arteriole serving that nephron. Renin cleaves the circulating hormone angiotensinogen into angiotensin I. Angiotensin I is then converted to angiotensin II by angiotensin-converting enzyme located in the lung, on endothelial cells throughout the body, and in many other organs. Angiotensin II stimulates the zona glomerulosa to release aldosterone, which stimulates cells of the renal collecting duct to reabsorb sodium and excrete potassium. Sodium reabsorption leads to water retention and thus augmentation of effective circulating volume. The adrenal cortex also releases a significant amount of aldosterone in response to hyperkalemia and a minimal amount in response to ACTH.

Hypoadrenocorticism, also called *Addison's disease,* is an uncommon disease in dogs and is rare in cats. Primary hypoadrenocorticism is caused by adrenal gland dysfunction, whereas secondary hypoadrenocorticism occurs when hypothalamic or pituitary malfunction prevents the release of CRH or ACTH, respectively. In most cases, patients with primary hypoadrenocorticism will have both glucocorticoid and mineralocorticoid insufficiency. However, there are many reports of dogs with atypical primary hypoadrenocorticism who have only glucocorticoid insufficiency.[1-4] Dogs with atypical primary hypoadrenocorticism may progress to mineralocorticoid deficiency within months of initial diagnosis.[1,2,4] Because aldosterone release is mediated primarily by the renin-angiotensin cascade and serum potassium concentration, patients with secondary hypoadrenocorticism do not usually have the classic electrolyte abnormalities seen in patients with typical primary hypoadrenocorticism (see Clinicopathologic Findings).

76.3 WHO IS AFFECTED?

Hypoadrenocorticism usually occurs in young to middle-aged dogs, and females are more commonly affected than males.[2,4-7] Although the average age of onset is approximately 4 years,[4-7] naturally occurring hypoadrenocorticism has been documented in dogs as young as 4 months,[5,8] as well as in geriatric dogs. The most commonly affected pure breeds vary somewhat by report and include the Portuguese Water Dog, Great Dane, West Highland White Terrier, Standard Poodle, Wheaton Terrier, and Rottweiler.[5] It is important to note that mixed breed dogs are more commonly affected than any individual breed.[4,5] Primary hypoadrenocorticism has been reported in fewer than 40 cats. There appears to be no sex predilection in this species, and most are domestic shorthaired or longhaired cats.[4,9-13] Most cats are young to middle aged, with ages ranging from 1.5 to 14 years.[11]

76.4 ETIOLOGY

The cause of naturally occurring primary hypoadrenocorticism in dogs and cats is unknown, but the most widely accepted theory is one of immune-mediated destruction of the adrenal cortices.[4,6] In support of this theory, young to middle-aged female dogs are most commonly affected by both Addison's disease and established immune-mediated diseases, and naturally occurring primary hypoadrenocorticism in humans is caused by immune-mediated destruction of the adrenal cortices. On necropsy, adrenal glands of affected animals are atrophied and fibrosed, consistent with prior immune-mediated destruction.[4,6,9,11] Other documented causes of primary hypoadrenocorticism in dogs and cats include adrenal neoplastic infiltration,[14,15] trauma,[16] suspected hemorrhage or hypoperfusion,[17] and iatrogenic destruction due to mitotane[18] or trilostane[19] therapy for hyperadrenocorticism. Adrenal infiltration with infectious organisms has also been implicated.[4]

Secondary hypoadrenocorticism is due to hypothalamic or pituitary malfunction; decreased CRH or ACTH secretion causes decreased adrenal cortisol production. The most common cause of secondary hypoadrenocorticism is steroid withdrawal after long-term glucocorticoid therapy.[4,20] Long-term steroid administration causes negative feedback on the hypothalamus and pituitary, significantly decreasing ACTH production, which leads to adrenal cortical atrophy. Other documented causes of secondary hypoadrenocorticism in dogs and cats include hypothalamic or pituitary neoplasia,[21] trauma,[22] and iatrogenesis (surgical).

76.5 CLINICAL PRESENTATION

The most important thing to remember about hypoadrenocorticism is that the clinical picture is vague and mimics other disease processes, most of which are significantly more common than Addison's disease. The classic signs and basic diagnostic test results in the hypoadrenal patient are generally nonspecific, and the vast majority of Addisonian patients will not have all the classic signs. Therefore the clinician must always remember to place hypoadrenocorticism on the rule-out list for the patient that has any of these clinical signs.

76.5.1 History

The history for patients with Addison's disease is often vague and nonspecific, and usually includes decreased appetite, lethargy, gastrointestinal (GI) disturbance, and weight loss. GI bleeding manifested by hematemesis, hematochezia, or melena may be present.[1,3,4,7,23] Other historical findings may include polyuria, polydipsia, weakness, shaking, pain, muscle cramps, and other nonspecific problems.[1,4-6,24] Because the clinical signs are often vague, patients may be brought for treatment in acute crisis without specific prior clinical signs. Thus the absence of such signs does not exclude hypoadrenocorticism as a diagnosis.

76.5.2 Physical Examination

Physical examination findings can vary significantly, depending on whether the hypoadrenocorticism involves hypoaldosteronism and on the severity and duration of illness. The most common physical examination findings include lethargy, weakness, poor body or coat condition, and dehydration. Collapse, hypovolemic shock, GI bleeding, abdominal pain, bradycardia, and hypothermia are common (particularly in emergency and critical care practice), although not all these abnormalities should be expected concurrently in any individual.[1,4-7,11] Patients with secondary hypoadrenocorticism or atypical primary hypoadrenocorticism may be less likely to arrive in crisis, because these patients have adequate aldosterone to maintain intravascular volume and normal electrolyte concentrations.[1,3,4]

76.5.3 Clinicopathologic Findings

The most common clinicopathologic findings are a decrease in the sodium-to-potassium ratio, azotemia with an inappropriately low urine specific gravity, anemia, and a leukogram inconsistent with the patient's degree of illness. The normal sodium-to-potassium ratio is 27:1 to 40:1. Patients with typical primary hypoadrenocorticism (i.e., with aldosterone insufficiency) usually have a pretreatment sodium-to-potassium ratio of less than 27:1. Note that these patients need not have both hyponatremia and hyperkalemia[2]; rather, some have only one of these abnormalities, and the ratio of these cations can still be less than 27:1. Patients with only glucocorticoid insufficiency are unlikely to have these electrolyte changes.[1-4] Many other diseases and conditions occasionally have been associated with low sodium-to-potassium ratios, including renal failure or postrenal obstruction,[25,26] severe GI disease,[4,26,27] parasitic infestation,[25,27,28] pregnancy,[29] body cavity effusions,[26] and others.[4,26] Note that although a low sodium-to-potassium ratio is the classic electrolyte abnormality of Addison's disease, not all patients with hypoadrenocorticism will have this change, which may be present with other conditions.

Most Addisonian patients are azotemic and hyperphosphatemic on arrival.[4-7,11] These changes are generally attributed to hypovolemia and are therefore prerenal in origin. However, most dogs and cats with hypoadrenocorticism have inappropriately low urine specific gravity (i.e., <1.030). Inability to appropriately concentrate urine has been attributed to lack of sodium retention and resultant renal medullary washout.[4,30] Renal concentrating ability resolves with mineralocorticoid supplementation.

The complete blood count (CBC) usually reveals a mild to moderate nonregenerative anemia due to lack of cortisol tropism at the level of the bone marrow. Patients with significant concomitant GI bleeding can have severe anemia that may be nonregenerative.[23] The degree of anemia may be masked initially by dehydration and resultant hemoconcentration. The CBC may reveal a “reverse stress leukogram,” with relative or absolute neutropenia, lymphocytosis, and eosinophilia; however, the Addisonian patient can also have the neutrophilia and lymphopenia commonly seen with severe illness. Addisonian patients frequently have very normal-appearing CBC findings. It is very important to interpret the CBC values in light of the severity of disease; a normal CBC result or the “reverse stress leukogram” in an ill patient should always raise the clinician's suspicion for hypoadrenocorticism.

Other blood work may reveal hypoglycemia, hypercalcemia, metabolic acidosis, hypoalbuminemia, and hypocholesterolemia. Hypoglycemia has been reported in up to 38% of dogs with hypoadrenocorticism.[1,4-7] Cortisol promotes glycogenolysis and gluconeogenesis, and lack of these processes may cause the hypoglycemia seen in some Addisonian patients. Seizures have been reported as a result of severe hypoglycemia in hypoadrenocorticism.[31,32] It is important to note that hyperglycemia has also been reported in dogs with hypoadrenocorticism,[4-7] so its presence does not exclude the diagnosis. Hypercalcemia has been reported in dogs and cats with hypoadrenocorticism[1,4-7,11,20,33]; its mechanism is unclear. Metabolic acidosis is seen commonly in dogs with hypoadrenocorticism. The acidosis is attributed to hypovolemia, with its resultant lactic acidosis, and decreased renal tubular hydrogen ion excretion, which is enhanced by aldosterone. Hypoalbuminemia has been reported in dogs with hypoadrenocorticism; the mechanism is unclear, but it may be related to GI bleeding, protein-losing enteropathy, or decreased hepatic synthesis.[4,34] Lastly, hypocholesterolemia has been reported in association with hypoadrenocorticism.[1,4,5,7] Elevated cholesterol concentration has also been reported in these patients; thus its importance in the diagnosis is equivocal. The most important feature of the basic clinicopathologic data in the hypoadrenal patient is its highly variable nature. One should not expect to find all the classic clinicopathologic changes in one animal.

76.5.4 Electrocardiographic Findings

An electrocardiogram (ECG) should be performed in all patients with clinical signs of hypovolemia or established hyperkalemia. Hypoadrenal patients may have bradycardia, which can be seen with or without hyperkalemia.[1,4,7] Those with hyperkalemia may have bradycardia, diminished or absent P waves, “tented” T waves, wide or bizarre QRS complexes, ventricular fibrillation, or asystole. Ventricular fibrillation and asystole require immediate cardiopulmonary resuscitation (see Chapter 4, Cardiopulmonary Resuscitation). All hyperkalemia-related ECG changes are of immediate life-threatening importance and should be treated promptly and appropriately (see Chapter 55, Potassium Disorders). Before using insulin to treat hyperkalemic ECG abnormalities, make sure the patient is not already hypoglycemic and that glucose supplementation is adequate.

76.5.5 Diagnostic Imaging

Radiographic findings in patients with hypoadrenocorticism may include microcardia, decreased size of pulmonary vasculature, small caudal vena cava, and microhepatica.[5,7,11,35] Although one study found that approximately 80% of dogs in Addisonian crisis had at least one of these radiographic abnormalities,[35] it is important to remember that many hypoadrenal patients will have normal radiographic findings. Abdominal ultrasonographic findings may reveal small adrenal glands bilaterally.[36] Because of the difficulty in locating normal adrenal glands in many animals, size interpretations should be made only by people highly trained and experienced in veterinary abdominal ultrasonography.

76.6 DIAGNOSIS

Although the above clinical picture with its accompanying biochemical and CBC changes should increase the clinician's suspicion of hypoadrenocorticism, a definitive diagnosis is made by the ACTH stimulation test. A standard ACTH stimulation test is performed using 250 μg cosyntropin per dog or 125 μg cosyntropin per cat; the drug can be given intramuscularly or intravenously. Blood is collected for serum cortisol measurement prior to ACTH administration, and after 60 minutes in the dog, and after both 30 and 60 minutes in the cat.[4] If cosyntropin is not available, ACTH gel can be used. The protocol is 2.2 IU/kg ACTH gel IM in dogs and cats. Cortisol measurements are made before and 2 hours after ACTH administration in dogs and before and 1 and 2 hours after administration in cats.[4] Contact a veterinary reference laboratory for appropriate sample handling techniques, which can significantly alter the results.

Endogenous ACTH concentration is useful in differentiating primary from secondary hypoadrenocorticism. The distinction is particularly important in Addisonian patients with normal electrolyte values: if they have low endogenous ACTH concentration, they have secondary hypoadrenocorticism (hypothalamic or pituitary malfunction) and are unlikely to develop mineralocorticoid deficiency. However, the hypoadrenal patient with normal electrolyte values and an elevated endogenous ACTH concentration (atypical primary hypoadrenocorticism) may develop mineralocorticoid deficiency over time and therefore requires close monitoring. The sample for endogenous ACTH concentration should be taken along with the sample for baseline cortisol, before exogenous ACTH administration. Contact a veterinary reference laboratory for appropriate sample handling techniques, which can alter the results significantly.

Most exogenously administered glucocorticoids will interfere with adrenal function testing, affecting baseline cortisol, stimulated cortisol, and endogenous ACTH concentrations. Therefore, if the patient has a history of recent steroid administration, the tests should be delayed while glucocorticoids are withheld and the patient is treated symptomatically. The patient in crisis requires fluid resuscitation first and foremost; it is appropriate to collect an endogenous ACTH sample and complete the ACTH stimulation test before administration of supplemental steroids.

76.7 TREATMENT
